Most of the world production of CTO ($\approx 1.5 \times 10^6$ t/a) is utilized as raw material in continuous distillation processes, producing high-quality tall oil fatty acid fractions and tall oil rosins as primary products. If the CTO is "low grade" (e.g., the content of valuable components is too low), the product (or the corresponding soap) is used as liquid (or solid) fuel. Since CTO, irrespective of quality, can always be used as a fuel oil, its minimum price is more or less related to actual "fuel oil" prices on the market, including taxes and other associated costs.

Tall Oil Fractions. The TOFA and TOR fractions are used widely for further processing into a variety of chemical products, replacing other raw materials such as gum and wood rosin, hydrocarbon resins, and vegetable oils. Improved distillation techniques have led to upgraded fractions of TOFA and TOR that are attractive raw materials for special chemicals. The chemical structure of some fatty and rosin acids makes the primary tall oil fractions suitable as raw material for making intermediate chemicals. Examples are the production of dimeric fatty and rosin acids, polymerized rosin, and maleic and fumaric anhydride (acids)–rosin adducts including their salts and esters. The dimeric acids are utilized as raw materials to make products used in adhesives, coatings, inks and epoxy resins. Most of the intermediate chemicals are processed in the presence of certain catalysts. An overview of the applications of tall oil fractions is given in Table 4.

TALUS. The mass of coarse rock fragments which accumulate at the foot of a cliff as a result of the processes of weathering and gravity. In Great Britain, the term scree is used for such material.

TABLE 4. APPLICATIONS OF TALL OIL FRACTIONS

Composition, uses	Pitch	Rosin	Distilled tall oil	Fatty acids	Heads
Principal composition	Esters, sitosterol, estolides, rosin dimer, free fatty and rosin acids	Rosin acids (isomeric diterpene acids, complex mixture), free fatty acids, neutrals, unsaps 3–10 %, esters	Fatty and rosin acids, neutrals, unsaps, esters < 10%	Fatty acids (oleic, linoleic types > 90%), rosin acids (neutrals < 10%)	Fatty acids (saturated)
As intermediates in miscellaneous processes	Mixtures for chemical modification	Fortification, Diels–Alder reaction, dimerization (catalytic process), isomerization, esterification, disproportionation	Alkyd formation, esterification, saponification, epoxidation	Dimerization, isomerization, esterification, alkyd formation, saponification, separation, ethoxylation, decarboxylation, C_{21} diacids	Mixtures, crystallization (palmitic acid)
Final uses	Fuel, binders, coatings, rubber modifier, asphalt, sizing, printing inks, hardboard impregnation	Paper size, protective coating, adhesive, ink, rubber, hot melt	Soap, coating,flotation, board impregnation	Protective coating, soap, ink	Fuel, flotation, asphalt emulsifier

TAMARACK. See **Larch Trees**.

TAMM LEVELS. Surface states; the extra electron energy levels found at crystal surfaces.

TANAGER *(Aves, Passeriformes).* An American bird of brilliant coloration, related to the finches. The tanagers are chiefly birds of the Central and South American tropics, where over 200 species are found. Of the few species that enter the United States, only the scarlet tanager, *Piranga erythromelas*, is widely known. The brilliant red of its body, contrasting with the black wings and tail, makes it one of our most striking species. The dull olive plumage of the female exemplifies a common contrast between the sexes in the entire group.

TANDEM (Cascade). Two-terminal pair networks are in tandem when the output terminals of one network are directly connected to the input terminals of the other network.

TANGENT (Geometry). Take a point P on a curve, a neighboring point P', also on the curve, and draw the secant line PP'. As P' approaches P, the secant approaches a limiting position which is the tangent to the curve at P. The slope of the tangent at P is frequently called the slope of the curve at that point. See Fig 1.

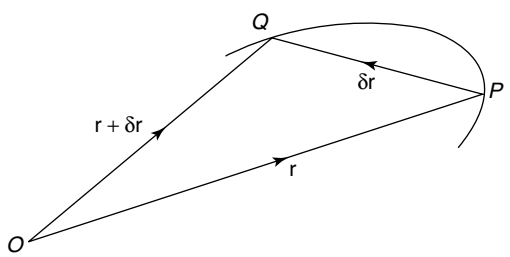

Fig. 1. Tangent to a curve at a point P. Let $\mathbf{r}$ and $\mathbf{r}+\delta\mathbf{r}$ be the vectors drawn from an origin O to the point P and a neighboring point Q on the curve. Let δs be the distance measured along the curve from P to Q. Denote the limit $\lim_{\delta s\to 0}\delta\mathbf{r}/\delta s$, if it exists, by $\mathbf{t}$. Then $\mathbf{t}$ is the unit tangent to the curve at P. A line through P in the direction of $\mathbf{t}$ is called the tangent to the curve at P.

The equation of a plane curve may be given, in rectangular coordinates, in either one of the equivalent forms: (a) $y = f(x)$; (b) $x = f_1(t)$, $y = f_2(t)$, where t is a parameter; (c) $F(x, y) = 0$. If ϕ is the angle between the tangent to the curve and the X-axis, then tan ϕ for the three cases is given by: (a) y'; (b) f_2'/f_1'; (c) $-F_x/F_y$. The tangent to the curve is

$y \csc \phi$. Additional quantities of interest are: the subtangent, $y \cot \phi = y/y'$; the normal, $y \sec \phi = y\sqrt{1 + y'^2}$; the subnormal, $y \tan \phi = yy'$. The intercept of the tangent on the X-axis is $x - y/y'$ and on the Y-axis, $y - xy'$. Corresponding quantities for the normal are $x + yy'$ and $y + x/y'$, respectively.

Equations of the tangent at (x_0, y_0) for the three forms of the curve are: (a) $y - y_0 = f'(x_0)(x - x_0)$; (b) $(y - y_0)f_1'(t) = (xx_0)f_2'(t)$; (c) $(x - x_0)F_x + (y - y_0)F_y = 0$, where the derivatives are to be evaluated at (x_0, y_0). The corresponding equations for the normal are:

$$\text{(a)} \quad f'(x_0)(y - y_0) + (x - x_0) = 0$$

$$\text{(b)} \quad (y - y_0)f_2'(t) + (x - x_0)f_1'(t) = 0$$

$$\text{(c)} \quad (x - x_0)F_y - (y - y_0)F_x = 0$$

All tangents to a surface at a given point lie in a tangent plane to the surface. If the surface is given by $z = f(x, y)$, the equation of the tangent plane is $(x - x_0)F_x + (y - y_0)F_y = (z - z_0)$, where the partial derivatives are to be evaluated at the given point.

See also **Circle (Geometry)**; and **Circular Curves**.

TANGENTIAL ACCELERATION. 1. In meteorology, the component of the acceleration directed along the velocity vector (streamline), with magnitude equal to the rate of change of speed of the parcel dV/dt, where V is the speed. See also **Atmosphere (Earth)**.

2. In horizontal, frictionless atmospheric flow, the tangential acceleration is balanced by the tangential pressure force

$$\frac{dV}{dt} = -\alpha \frac{\partial p}{\partial s}$$

where α is the specific volume, p the pressure, and s a coordinate along the streamline. Thus, flow without tangential acceleration is along the isobars, and the wind is the gradient wind.

TANGERINE. See **Citrus Trees**.

TANK CIRCUIT. In a signal transmission system, a circuit consisting of inductance and capacitance, capable of storing electric energy over a band of frequencies continuously distributed about a single frequency at which the circuit is said to be resonant (tuned). The selectivity of the circuit is proportional to the ratio of the energy stored in the circuit to the energy dissipated. This ratio is sometimes termed the Q of the circuit.

TANNIN. [CAS: 1401-55-4]. Substances found in many plants; generally related to one of the phenols, pyrogallol or catechol. By their action on animal skins, they cause changes that make the skins resistant to decomposition and at the same time leave them flexible and very strong, greatly improved in wearing qualities. Skins so treated are said to be tanned, and are called leather. Tanning is a very old art, having been practiced in China since long before the Christian era. It was also known to the American Indians before the arrival of the Europeans.

Tannins are found in various parts of the plant, appearing frequently in leaves, and in the cortical tissues of stems. Tannins may be found in the walls of cells or in the vacuoles; often their presence causes the cell to appear dark-colored. Many fruits, such as the persimmon, contain large amounts of tannin, especially before they are ripe. Wound tissues, and especially the hypertrophied tissues known as galls, which result from the bits of certain insects, are particularly rich in tannins. Tannins appear to be by-products of the metabolism of the plant. When present in the epidermal cells, tannins are seen as a deterrent to snails, which might injure the leaf by feeding on it, to parasitic fungi, which might otherwise enter the leaf tissue, and as a protection against desiccation, since they form substances impervious to water.

An important source of tannin is the bark of various trees, especially that of the hemlock and several species of oaks. The bark is removed from the tree in sheets approximately 4 feet long. Stripping from the tree is usually done in the spring, when the cambial cells are most active and the bark separates easily. To remove the bark, two rings are cut completely through the bark and around the tree. A longitudinal slit is made through the bark from one ring to the other. With the use of a blunt, long-handled implement, the bark is then pried loose from the tree and allowed to dry. By felling the tree, the entire trunk may be stripped of its bark in this way. The dried bark is shipped to mills, where the tannin is extracted. Tannins from these barks are used to tan leather for shoe-soles and other heavy leathers. The wood of the chestnut tree yields a tannin similarly used.

Trees of the genus *Schinopsis*, native to the southern part of South America, including southern Brazil, Bolivia and other southern countries are very important source of tannin. These trees are known by the name "quebracho," which means "ax-breaker," because of their very hard, dense, heavy, dark-red wood, which is cut with difficulty. The heartwood of the tree contains 20–27% tannin, which is obtained by cutting the wood into small chips and extracting with water. This tannin is often used in combination with tannins from other plants.

The bark of many other trees yields large amounts of tannins. Among these are the mangrove, and several species of Acacia, known as wattles, natives of Australia. Fruits also may be a source of tannin. The fruits of *Terminalia chebula*, called *myrobalans*, are an important tannin source. The tree is a native of tropical Asia. Another fruit rich in tannin is *divi-divi*, the pods of a legume, *Caesalpinia coriaria*, which is native in tropical America and the West Indies. Sumac leaves, especially those of *Rhus coriaria*, a shrub or small tree native in Mediterranean Europe, are rich in tannins. To obtain the tannin, the plants are cut down and spread out to dry. The leaves are then removed from the stems and packed into bags, which are shipped to the mills. There the leaves are first cleaned and then ground up. The tannins from this source are used in manufacturing fine leathers, like glove leathers. Leaves of other species of sumac, including the various American sumacs, also contain tannins which, however, are not so valuable and are little used.

Tannins are solids, soluble in water or alcohol [CAS: 67-63-0], usually extracted by hot water, insoluble in ether, chloroform [CAS: 67-66-3], carbon disulfide [CAS: 75-15-0], benzene [CAS: 71-43-2], soluble in alcohol-ether mixture, and in ethyl acetate [CAS: 141-78-6], possessing a bitter astringent taste. Tannins (1) yield precipitates with gelatin, proteins (connected with the property of making leather from hides), alkaline salt solutions of many heavy metals, e.g., lead acetate [CAS: 301-04-2], copper acetate [CAS: 4180-12-5] (precipitate brown), antimonyl tartrate, concentrated dichromate solution, also by chromic acid (1% CrO_3); (2) yield dark blue or green coloration with ferric salt solutions; (3) in alkaline solution, absorb oxygen and yield dark colored solution; (4) with iodine in potassium iodide plus small proportion of ammonium hydroxide, yield red color (5) with dilute solution potassium hexacyanoferrate(II) in ammonium hydroxide, yield a red to brown coloration (care not to use excess reagent).

While tannins probably vary in composition, the type generally termed tannic acid is a pentadigalloylglucose for hydrolysis yields diagallic acid and glucose.

TANTALITE. This black mineral, $(Fe, Mn)(Ta, Nb)_2O_6$, is isomorphous with columbite and dimorphous with tapiolite. Tantalite occurs in pegmatites and is a principal ore of tantalum.

TANTALUM. [CAS: 7440-25-7]. Chemical element symbol Ta, at. no. 73, at. wt. 180.948, periodic table group 5, mp 2,996 °C (5,425 °F), bp 5,427 °C (9,801 °F), density 16.65 g/cm^3 (solid at 20 °C (68 °C)), 17.1

(single crystal). Elemental tantalum has a body-centered cubic crystal structure. Because of high mp, it is considered a refractory metal.

Tantalum is a slightly bluish metal; ductile, malleable, and when polished resembles platinum; burns upon being heated in air; insoluble in HCl or HNO_3, but soluble in hydrofluoric acid or a mixture of hydrofluoric and HNO_3. The tough, impermeable oxide film formed on the metal when exposed to air makes tantalum the most resistant of all metals to atmospheric corrosion. Tantalum was first identified by Ekeberg as a new element in yttrium minerals in 1802 and was first obtained in pure form by Berzelius in 1820 by heating potassium tantalofluoride with potassium. There is one, naturally occurring stable isotope ^{181}Ta. ^{180}Ta also occurs naturally (isotopic abundance 0.012%), with a half-life of something greater than 10^7 years. At least nine other radioactive isotopes have been identified ^{176}Ta through ^{179}Ta and ^{182}Ta through ^{186}Ta. With exception of ^{179}Ta (half-life of about 600 days), the remaining half-lives are expressed in minutes, hours, or days. ^{182}Ta has been used as a source of gamma rays. See also **Radioactivity**. In terms of abundance, tantalum does not appear on the list of the first 36 elements that occur in the earth's crust and hence is relatively scarce. Also, tantalum does not appear on the list of the first 65 elements that are found in seawater. First ionization potential, 7.7 eV. Oxidation potential $2Ta + 5H_2O \leftarrow Ta_2O_5 + 10H^+ + 10e^-$, 0.71V. Other important physical properties of tantalum are given under **Chemical Elements**.

Tantalum is found in a number of oxide minerals, which almost invariably also contain niobium [CAS: 7440-03-1] (columbium). The most important tantalum-bearing minerals are tantalite and columbite, which are variations of the same natural compound $(Fe, Mn)(Ta, Nb)_2O_6$. Much of the tantalum concentrates has been obtained as a byproduct from tin mining; in recent years, tin slags, which are a byproduct of the smelting of cassiterite ores, such as those found in the Republic of Congo. Nigeria, Portugal, Malaya, and Thailand have been an important raw material source for tantalum.

The first successful industrial process used to extract tantalum and niobium from the tantalite-columbite-containing minerals employed alkali fusion to decompose the ore, acid treatment to remove most of the impurities, and the historic Marignac fractional-crystallization method to separate the tantalum from the niobium and to purify the resulting K_2TaF_7. Most tantalum production now employs recovery of the tantalum and niobium values by dissolution of the ore or ore concentrate in hydrofluoric acid. Then the dissolved tantalum and niobium values are selectively stripped from the appropriately acidified aqueous solution and separated from each other in a liquid-liquid extraction process using methyl isobutyl ketone (MIBK) or other suitable organic solvent. The resulting purified tantalum-bearing solution is generally treated with potassium fluoride or hydroxide to recover the tantalum in the form of potassium tantalum fluoride, K_2TaF_7, or with ammonium hydroxide to precipitate tantalum hydroxide, which is subsequently calcined to obtain tantalum pentoxide, Ta_2O_5. Tantalum metal is generally obtained by sodium reduction of K_2TaF_7, although electrolysis of K_2TaF_7 and carbon reduction of Ta_2O_5 in an electric furnace have also been used. Tantalum metal can absorb large volumes of hydrogen during heating in a hydrogen-bearing atmosphere at an intermediate temperature range (450–700 °C (842-1,292 °F)). The hydrogen is readily removed by heating in vacuum at higher temperatures.

Uses. The first commercial use of tantalum was as filaments in incandescent lamps but it was soon displaced by tungsten. Tantalum is used in chemical industry equipment for reaction vessels and heat exchangers in corrosive environments. It is usually the metal of choice for heating elements and shields in high temperature vacuum sintering furnaces.

Capacitor-Grade Powder. Since 1984 about 72 percent of the tantalum metal produced annually has gone into the manufacturing of solid tantalum capacitors (STC). Solid tantalum capacitors have a high volumetric capacitance which makes them attractive for use in miniaturized electronic systems like cellular telephones, hand-held video cameras, and personal computers. The insensitivity of their capacitance to temperature and their ability to operate at temperature extremes explains why these devices are used in such harsh environments as automobile engine compartments. Solid tantalum capacitors are extremely reliable and, therefore, are often the capacitor of choice in critical applications like spacecraft electronics, pacemakers, and safety equipment.

Wire. Tantalum wire is used primarily as the anode lead wire in solid tantalum capacitors. Since the 1970s, the average weight of tantalum in a solid tantalum capacitor has dropped from several hundred milligrams to less than 50 mg; but the consumption of tantalum powder for capacitors has remained relatively constant because of the dramatic increase in the number of capacitors manufactured. The weight of wire per capacitor has remained relatively constant and thus wire consumption has increased steadily.

Fabricated Parts. The starting point for manufacturing tantalum fabricated parts is mainly high grade tantalum scrap that is converted to ingots by a combination of electron beam and arc melting. The ingots are transformed into flat stock and rod by pressing and rolling. The fabrication of functional parts uses many standard metal working techniques including turning on a lathe, cutting, bending to shape, and welding under a helium atmosphere.

Typical equipment made from tantalum includes heat exchangers, reaction vessels liners, thermowells, and heating elements or heat shields for high temperature vacuum sintering furnaces. Tantalum fabricated parts are found in the manufacturing of pharmaceuticals, explosives, insecticides, dyes, acidic baskets for silver cyanide barrel platers, and in hydrochloric and hydrobromic acid condensers.

Other applications occur in the defense industry where tantalum has been used in ballistics as an explosively formed projectile. The requirements for this application are rigid as to purity and metallurgical texture. Tantalum shapes (plate, heavy-walled cylinders) are also used as sputtering targets for the deposition of thin tantalum films. These films are used in a variety of applications, for example, providing corrosion and wear resistance to ink jet printer heads, acting as a diffusion barrier in micro-circuitry, and serving as a substrate layer to form TaN resistors in situ.

Biomedical Devices. The biocompatibility of a metal is related to its corrosion resistance and toxicity of the metal ion. The very low corrosion rate and inertness of tantalum make it attractive for many biomedical applications. Surgeons have used the metal as sutures bone screws, and plates since the 1940s. Other uses include cartilage wire, nets to hold bone grafts in place, braided suture wire for skin closures and tendon repair, clips for ligature of vessels and bile ducts, mesh for abdominal wall reconstruction after hernias, plates for cranioplasty, and dental implants. The biocompatibility of tantalum coupled with the metal's high density has lead to widespread use in radiology; as powder it is used mainly for tracheography and bronchography of the respiratory tract. Tantalum for use in implants is sterilized by steam or γ-radiation.

Alloys. Tantalum is added to nickel [CAS: 7440-02-0] and nickel-cobalt superalloys for gas-turbine and jet-engine parts. Several surgical applications for tantalum have developed because of the inertness of the metal to body fluids and the tolerance of the body for the metal. Tantalum-base alloys are used for aerospace structures and space power systems, principally because of the high-temperature stability and strength of these alloys. They operate satisfactorily at temperatures in excess of 1,600 °C (2,912 °F). Tantalum alloys are used in heat exchangers. See Fig. 1. Small additions of zirconium to tantalum increases its tensile strength at normal temperatures and up to approximately 1,200 °C (2,192 °F). Also, when added in amounts of about 5%, hafnium [CAS: 7440-58-6] molybdenum [CAS: 7439-98-7], rhenium [CAS: 7440-15-5], tungsten [CAS: 7440-33-7], and vanadium [CAS: 7440-62-2] also increase the strength of tantalum. The tensile strength of ternary alloys of tantalum (Ta with 30% Nb and 5% Zr of V) at room temperature is about 3X that of tantalum alone. A tantalum-tungsten alloy is used for fabricating springs for high temperature and high vacuum applications.

The trend in the chemical industry is to use increasingly high processing temperatures and pressures, requiring stronger materials with better corrosion resistance. With these objectives in mind, researchers have been studying the influence of the alloying elements tungsten, molybdenum, niobium (columbium), hafnium, zirconium [CAS: 7440-67-7], and rhenium on both the mechanical properties and corrosion behavior of pure tantalum. They have found that additions of only 1% to 3% molybdenum to tantalum, for example, has a marked effect in decreasing the susceptibility

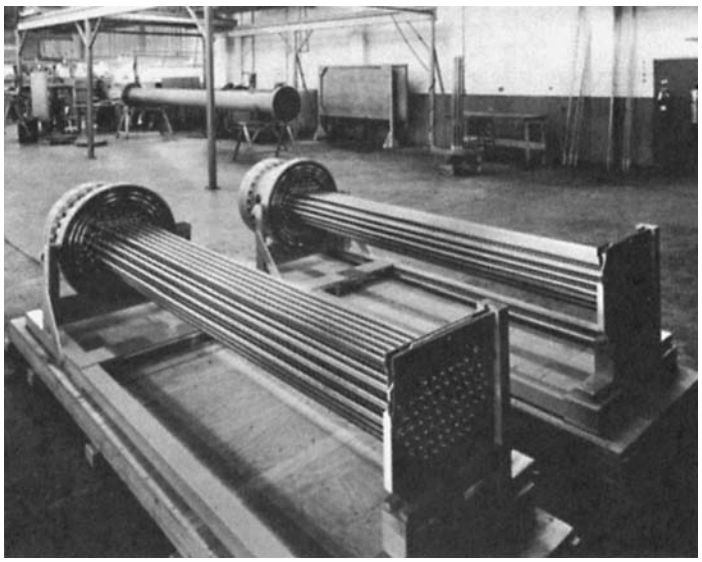

Fig. 1. High-heat-transfer bayonet-style exchangers employing tantalum alloy tubes. Each exchanger uses 104 tubes. (*Fansteel.*)

of pure tantalum to hydrogen embrittlement in severely corrosive conditions. Not only is the corrosion rate of tantalum decreased, but mechanical properties, such as strength and room temperature workability, are also improved.

Tantalum-tungsten alloys have been successfully developed, which exhibit at least four key advantages: (1) tungsten causes a considerable solid solution hardening (SSH) effect in tantalum; (2) tungsten shows almost no evaporation during electron beam melting; (3) tungsten is less costly than tantalum; and (4) the corrosion rate of tantalum is but slightly influenced by the addition of tungsten up to about 10% (wt).

Tantalum-hafnium and tantalum-zirconium alloys are less suitable for aggressive acid environments. Compared with tantalum-tungsten alloys, tantalum rhenium alloys are superior in corrosion resistance and to hydrogen embrittlement, but the major disadvantage is the high cost of rhenium.

Some of the properties of tantalum and its alloys are given in Table 1.

Chemistry and Compounds. As might be expected from its 5d 36s 2 electron configuration, tantalum forms pentavalent compounds. In fact, they constitute the great majority of tantalum compounds, although the valences 2, 3, and 4 are known. However, the existence of the Ta^{5+} ion is very brief, since it readily coordinates with H_2O, OH^-, and other anions or molecules. Tantalum is extremely resistant to chemical action, not being attacked by acids other than hydrofluoric acid, and by alkalies only upon fusion. Even fluorine and oxygen react only on heating.

Potassium heptafluorotantalate [CAS: 16924-00-8], K_2TaF_7, crystallizes in colorless, rhombic needles. It hydrolyzes in boiling water containing no excess of hydrofluoric acid. The solubility of potassium heptafluorotantalate in hydrofluoric acid decreases from 60 g/100 mL at 100 °C to 0.5 g/100 mL at room temperature. The different solubility characteristics of K_2TaF_7 and K_2NbOF_5 are the fundamental basis of the Marignac process.

Tantalum pentoxide [CAS: 1314-61-0], Ta_2O_5, (mp = 1880 °C, density = 8.73 g/cm^3) is a white powder existing in two thermodynamically stable modifications. The orthorombic b-phase changes at 1,360 °C (2,480 °F) into the tetragonal a-modification. The existence of an e-modification has also been reported. Tantalum pentoxide reacts slowly with hot hydrofluoric acid but is insoluble in water and in most solutions of acids and alkalies. For analytical purposes, it can be dissolved by fusion with alkali hydroxides, alkali carbonates, and potassium pyrosulfate.

Tantalum(II) oxide [CAS: 12035-90-4], TaO, is the only other oxide the existence of which has been confirmed. It can be prepared from Ta_2O_5 by reduction with carbon at 1,900 °C (3,452 °F) or with H_2 at 1,100 °C (2,012 °F).

Tantalum pentafluoride [CAS: 7783-71-3], TaF_5, (mp = 96.8 °C, bp = 229.5 °C) is used in petrochemistry as an isomerization and alkyalation catalyst. In addition, the fluoride can be utilized as a fluorination catalyst for the production of fluorinated hydrocarbons. The pentafluoride is produced by the direct fluorination of tantalum metal or by reacting anhydrous hydrogen fluoride with the corresponding pentoxide or oxychloride in the presence of a suitable dehydrating agent. The ability of TaF_5 to act as a fluoride ion acceptor in anhydrous HF has been used in the preparation of salts of the AsH_4, H_3S, and PH_4 ions. The oxyfluorides $TaOF_3$ [CAS: 20263-47-2] and TaO_2F [CAS: 13597-27-8] do not find any industrial application.

Tantalum pentachloride [CAS: 7721-01-9], $TaCl_5$, (mp = 216 °C, bp = 242 °C 242 °C) forms strongly hydroscopic, needle-shaped white crystals. It is produced on an industrial scale in large tonnage by the chlorination of tantalum scrap or ferrotantalum with $NaFeCl_4$ or by the reductive chlorination of natural ores or synthetic raw materials. High purity $TaCl_5$ is hydrolyzed with steam and thus converted to Ta_2O_5 of the highest purity. The reduction of $TaCl_5$ with Mg or Al was repeatedly attempted but this thermite-type process never attained any industrial application. $TaCl_5$ is soluble in absolute alcohol, forming the corresponding alkoxides. The alkoxides as well as the chlorides are suitable products for the deposition of tantalum or tantalum pentoxide layers.

$TaBr_5$ [CAS: 13451-11-1] and TaI_5 [CAS: 14693-81-3] are well known but do not find industrial application.

Tantalum monocarbide [CAS: 12070-06-3], TaC, is a gold-colored powder produced industrially by direct reaction of carbon with either tantalum scrap or tantalum pentoxide at temperatures up to 1,900 °C (3,452 °F). It is added in small amounts (0.2–2 wt %) in the form of TaC or mixed carbides like TaNbC and WTiTaC to tungsten carbide–cobalt-based cutting tools in order to reduce grain growth. Adding 2–15 wt % TaC to cemented carbides considerably increases their thermal shock resistance and their resistance to cratering and oxidation. The tantalum–carbon phase diagram shows the existence of several subcarbides.

Tantalum nitride [CAS: 12033-62-4], TaN, is produced by direct synthesis of the elements at 1,100 °C (2,012 °F). Very pure TaN has been

(*After Advanced Materials & Processes*)

produced by spontaneous reaction of lithium amide, $LiNH_2$, and $TaCl_5$. The compound is often added to cermets in 3–18 wt %. Ta_3N_5 [CAS: 12033-94-2] is used as a red pigment in plastics and paints.

Tantalic acid [CAS: 75397-94-3], $Ta_2O_5 \cdot nH_2O$, is the name of the white insoluble precipitate formed by hydrolysis of alkali hydroxide or alkali carbonate fusions containing tantalum, or by adding ammonia to an acidic solution containing tantalum ions. Tantalic acid is characterized by a high surface acidity, affording it potential use as a catalyst.

Lithium tantalate [CAS: 12031-66-2], $LiTaO_3$, is the most important tantalate. The crystal structure is related to that of perovskite. $LiTaO_3$ exhibits high spontaneous polarization and a high Curie temperature. For several applications in electronic devices such as surface acoustic wave (SAW) filters, second harmonic generators (SHG), and wave guides, crystals are grown by the conventional Czochralski technique from melts made of Li_2CO_3 and Ta_2O_5. Similarly, other tantalates like $Ba_3MgTa_2O_9$ [CAS: 12231-81-1] and $Ba_3ZnTa_2O_9$ [CAS: 12231-88-8] also have the perovskite structure and are used in high frequency resonators in satellite communication systems.

Health and Safety. The corrosion resistance imparted to tantalum by the passivating surface thermal oxide layer makes the metal inert to most hazards associated with metals. Tantalum is noncorrosive in biological systems and consequently has a no chronic health hazard MSDS rating.

Above 300 °C (572 °F) in air, fine tantalum powder can ignite because of the rapid oxygen diffusion through the oxide layer into the substrate. Once burning starts, a dramatic temperature rise usually occurs and the oxidation reaction can accelerate rapidly. Tantalum powder can be ignited by the localized heating associated with a static electrical discharge or contact with a hot surface.

Tantalum metal powder does not explode in the normal sense of the word, because there is no release of gas when tantalum burns. The burning of suspended tantalum powder in a confined gaseous environment containing an oxidizing agent, for example air, only produces a pressure rise associated with the heating of the gas. The potentiality of a disastrous explosion occurring exists if hot tantalum comes in contact with an oxidizing agent that reacts with the metal to produce a combustible gas. For example in the presence of water, hot tantalum reacts to produce hydrogen gas, which will then likely detonate, with tragic consequences.

A tantalum fire cannot be extinguished with the usual firefighting chemicals. The only effective way to control a tantalum fire is to smother it with a nonoxidizing chemical like sodium chloride or argon. Fire extinguishers containing sodium chloride under pressure are available for this purpose but a container of salt and a noncombustible scoop will work. Under no circumstances should burning tantalum be allowed to come in contact with water. If tantalum powder is routinely handled in a closed environment, it is prudent to design the system so that it can be flooded with argon.

Good housekeeping practices to prevent the accumulation of tantalum dust and a proper passivation procedure will prevent most tantalum fires. All equipment used to handle the powder should be properly grounded and contact with hot surfaces or flames should be avoided.

Exposure to tantalum metal dust may cause eye injury and mucous-membrane irritation. The threshold limit value (TLV) in air is 5 mg/m^3, LD_{50} is and the Occupational Safety and Health Administration (OSHA) time weighted average (TWA) exposure limit is 5 mg/m^3. The immediate dangerous to life or health (IDLH) concentration is 2500 mg/m^3. Whereas some skin injuries from tantalum have been reported, systemic industrial poisoning is apparently unknown.

A major portion of this article was furnished by M. Schussler, Fansteel, North Chicago, Illinois.

TANTOCHRONE. A curve in a vertical plane such that a particle sliding frictionless along it under the sole influence of gravity will vibrate with the same period for all amplitudes. This curve is a cycloid. The period of vibration is

$$T = 4\pi\sqrt{\frac{r}{g}}$$

Such a pendulum is also known as Huygen's pendulum.

TAPEWORM. Tapeworms (cestodes) are parasitic flat worms, segmented in form, and having a head portion (scolex) which can continually give rise to new segments. As long as this head remains in the human intestine the worm has not been destroyed, for from this an entire new body can grow. These worms do not possess a digestive canal and are usually hermaphrodites. Nourishment is absorbed from the host through the surface of the worm's body. Fertilization is accomplished between segments of different worms or between different segments of the same worm.

Certain tapeworms apparently do not greatly harm the host while others may produce marked symptoms such as severe anemia. Larval forms of the worm may invade the various human tissues in certain forms of cestode infestation and cause serious trouble.

The kinds of tapeworms commonly found in humans are as follows: (1) The fish tapeworm (*Diphyllobothrium latum*) is found throughout the world and infests humans when infected fish, which has not been thoroughly cooked, is eaten. The growing popularity of raw fish dishes has increased the risk of infestation. Serious symptoms may not develop for years, but often a condition resembling pernicious anemia develops. Recovery follows the expulsion of the worm. (2) The dwarf tapeworm (*Hymenolopsis nana*) is also found throughout the world and is the most common of tapeworms occurring in the United States. It is of small size, being only a few centimeters long, but when present in large numbers the worms cause diarrhea, loss of weight and appetite, and nervous manifestations. The symptoms disappear when the parasites are expelled. (3) The pork tapeworm (*Taenia solium*) is large, measuring 9 to 12 feet (2.7 to 3.6 meters) in length. Most of the symptoms and dangers of this worm are due to the invasion of the tissue by its larval forms. This form is rare in the United States. (4) The beef tapeworm (*Taenia saginata*) is common in the world wherever beef is eaten. Cold storage will kill the parasite. The adult forms are extremely large worms; some measure 30 to 50 feet (9 to 15 meters) in length. Colic and pain may be present in patients infected with this worm. Spontaneous discharge of a long piece of worm may inform the patient of his guest.

The diagnosis of worm infestation is made by finding either segments of worms or eggs in the feces. The white blood count often reveals an eosinophilia.

Treatment with various antihelminths is usually successful if correctly employed. The drugs most frequently used are niclosamide or praziquantel.

R. C. V.

TAPHONOMY. The study of fossils in their geological contexts with a view to sorting out the factors intervening between death and definitive burial that bias the fossil record in certain ways and render paleoecological reconstruction difficult. This topic of science was proposed by the Russian paleontologist I.A. Efremov as a branch of paleontology in 1940. Activity in the field has not been extensive. In 1976, the Wenner-Gren Foundation for Anthropological Research sponsored a symposium, "Taphonomy and Paleoecology, with Special Reference to Sub-Saharan Africa." The papers were published in a book entitled "Vertebrate Taphonomy and Paleoecology," K. Behrensmeyer and A.P. Hill, editors, Univ. Chicago Press, Chicago, Illinois, 1988.

TAPIOCA. See **Euphorbiaceae**.

TAPIR *(Mammalia, Perissodactyla; Tapirus)*. Moderately large animals found in the neighborhood of water in the forests of Central and South America and the Malayan region. See Fig. 1. They reach a length of 8 feet (2.4 meters) and a height of a little over 3 feet (0.9 meter) and are stoutly built. Their most conspicuous characteristic is the short trunk into which the snout is prolonged. Only one of the five species occurs in the Old World.

Fig. 1. American tapir. (*A.M. Winchester*.)

The natives of the American tropics hunt tapirs for their flesh and hides, although the value of the latter for leather is limited.

TAR ACID. Any mixture of phenols present in tars or tar distillates and extractable by caustic soda solutions. Usually refers to tar acids from coal tar and includes phenol, cresols, and xylenols. When applied to the products from other tars it should be qualified by the appropriate prefix, e.g., wood tar acid, lignite tar acid, etc. See also **Coal Tar and Derivatives**.

TAR AND PITCH. Most organic substances, other than those of simple structure and low boiling point, when pyrolyzed, ie, heated in the absence of air, yield dark-colored, generally viscous liquids termed tar or pitch. The differentiation between these terms is not precise. When the by-product is a liquid of fairly low viscosity at ordinary temperature, it is regarded as a tar; if of very viscous, semisolid, or solid consistency, it is designated as a pitch. Thus, in preparative organic chemistry, a tar or pitch is frequently the distillation residue. Some thermal decomposition always accompanies the distillation of vegetable and animal fats and oils, resulting in the production of small amounts of vegetable-oil pitch, wool-grease pitch, stearin pitch, and so on. Such products, of poorly defined composition and properties, have little industrial importance and are mainly burned as fuel.

Large amounts of tar or pitch by-products are produced by industrial processes. The distillation of crude petroleum yields a pitch-like residue termed bitumen or asphalt. In the United States, these terms are interchangeable, but in Europe the term asphalt is generally restricted to naturally occurring rock or lake asphalt, whereas the residual product of crude-oil distillation is termed bitumen. Although these are important industrial materials produced in millions of metric tons annually, they are not included herein. See also **Asphalt (or Asphaltum)**; and **Petroleum Refining**.

With regard to coal-derived tar and pitch, the following definitions are appropriate to distinguish them from ostensibly similar materials from other sources and from crude oil in particular.

Coal tar is the condensation product obtained by cooling to approximately ambient temperature, the gas evolved in the destructive distillation of coal. It is a black viscous liquid denser than water and composed primarily of a complex mixture of condensed ring aromatic hydrocarbons. It may contain phenolic compounds, aromatic nitrogen bases and their alkyl derivatives, and paraffinic and olefinic hydrocarbons. Coal-tar pitch is the residue from the distillation of coal tar. It is a black solid having a softening point of 30–180 °C (86–359 °F). See also **Coal Tar and Derivatives**.

In the processing of crude oil eventually bitumen or vacuum residues arise, ie, asphalt, obtained as a nonvolatile residue from the distillation of crude oil and contains a high proportion of hydrocarbons having carbon numbers predominantly greater than C_{25} and high carbon-to-hydrogen ratios; and residues petroleum vacuum, a complex residue from the vacuum distillation of the residuum from atmospheric distillation of crude oil, consisting of hydrocarbons having carbon numbers predominantly greater than C_{34} and boiling point of approximately 495 °C (923 °F). However, to complicate matters, Ashland (United States) also markets a material known as petroleum pitch, although technically it should be called bitumen. See also **Bitumen**.

Wood Tar

The pyrolysis or carbonization of hardwoods, eg, beech, birch, or ash, in the manufacture of charcoal yields, in addition to gaseous and lighter liquid products, a by-product tar in ca 10 wt % yield. Dry distillation of softwoods, eg, pine species, for the production of the so-called DD (destructively distilled) turpentine yields pine tar as a by-product in about the same amount. Pine tar, also called Stockholm tar or Archangel tar, was at one time imported from the Baltic by European maritime countries for the treatment of cordage and ship hulls; it was an important article of commerce from the seventeenth to the nineteenth century. The small amount produced in the late twentieth century is burned as a crude fuel. Charcoal production from hardwoods, on the other hand, has increased.

Composition, Processing, and Uses. There are no statistics available for the amount of wood tar processed, but almost all of it is burned. The commercial by-products from wood carbonization are limited to methanol, denatured methanol, methyl acetate, and acetic acid. These products are derived from the aqueous phase of the condensed products, the so-called pyroligneous acid. On distillation, pyroligneous acid yields wood spirit, acetic acid having small amounts of propionic and butyric acids, and soluble tar. The wood spirit, on refining, yields methanol as well as methyl acetate and acetone. The aqueous acid fraction is neutralized with milk of lime to give gray acetate of lime, 82–84% $(CH_3COO)_2Ca$, which is neutralized to give acetic acid or pyrolyzed to give acetone. The soluble tars are mainly condensation products of aldehydes and phenols; they are burned as fuel.

Small amounts of the sedimentation tar, ie, the separated organic layer from the condensed wood-carbonization vapors, are distilled, first at atmospheric pressure to give wood spirit, crude acetic acid, and light wood oils. The first two of these fractions are added to similar fractions from the pyroligneous acid for further processing. The light wood oil is treated with permanganate and sulfuric acid and used as a solvent or for giving a wood smoke or tar note to perfumes, soaps, and shampoos. Further distillation under reduced pressure yields wood creosote, which is used for the preservation of cordage, timber, and Hessian sacks, and as a disinfectant, component of wood stains, and froth-flotation agent.

Chemically, wood tar is a complex mixture that contains at least 200 individual compounds, among which the following have been isolated: 2-methoxyphenol [CAS: 90-05-1], 2-methoxy-4-ethylphenol, 5-methyl-2-methoxyphenol, 2,6-xylenol [CAS: 576-26-1], butyric acid [CAS: 107-92-6], crotonic acid [CAS: 3724-65-0], 1-hydroxy-2-propanone [CAS: 116-09-6], butyrolactone [CAS: 96-48-0], 2-methyl-3-hydroxy-4*H*-pyran-4-one, 2-methyl-2-propenal [CAS: 78-85-3], methyl ethyl ketone [CAS: 78-93-3], methyl isopropyl ketone [CAS: 563-80-4], methyl furyl ketone, and 2-hydroxy-3-methyl-2-cyclopenten-1-one [CAS: 80-71-7].

Coal Tar

By far the largest source of tar and pitch is the pyrolysis or carbonization of coal. Generally, the terms tar and pitch are synonymous with coal tar and the residue obtained by its distillation. The importance of coal tar as an industrial raw material dates back to the first half of the eighteenth century, when the carbonization of coal and the by-product production of tar were expanding rapidly in the United Kingdom. Initially, the crude tar was subjected to a simple flash distillation in pot stills to yield a solvent naphtha, creosote for timber preservation, and a residue of pitch that found an outlet as a binder for coal briquettes. Later, coal tar was the main source of aromatic hydrocarbons, phenols, and pyridine bases needed by the rapidly expanding dyestuffs, pharmaceuticals, and explosives industries. The development of by-product coke ovens and crude-benzene recovery at both coke ovens and gasworks greatly increased the supplies of crude tar and tar distillates for the recovery of tar chemicals, ie, benzene [CAS: 71-43-2], toluene [CAS: 108-88-3], xylenes [CAS: 1330-20-7], phenol [CAS: 108-95-2], cresols [CAS: 1319-77-3] and cresylic acids, pyridine [CAS: 110-86-1] and methylpyridines, and naphthalene [CAS: 91-20-3] and anthracene [CAS: 120-12-7], in addition to the so-called bulk products, eg, creosote, tar paints, road tars, and pitch binders.

Until the end of World War II, coal tar was the main source of these aromatic chemicals. However, the enormously increased demands by the rapidly expanding plastics and synthetic-fiber industries have greatly outstripped the potential supply from coal carbonization. This situation was exacerbated by the cessation of the manufacture in Europe of town gas from coal in the early 1970s, a process carried out preponderantly in the continuous vertical retorts (CVRs), which has led to production from petroleum. Over 90% of the world production of aromatic chemicals is derived from the petrochemical industry, whereas coal tar is chiefly a source of anticorrosion coatings, wood preservatives, feedstocks for carbon-black manufacture, and binders for road surfacings and electrodes.

Apart from the presence of a few percent (usually below 5%) of aqueous liquor containing inorganic salts and a percent or so of coal-char-coke dust arising from carryover of particles in the carbonization process, coal-tar consists essentially of two parts. The first, which at atmospheric pressure distills up to about 400 °C, is primarily a complex mixture of mono- and polycyclic aromatic hydrocarbons, a proportion of which are substituted with alkyl, hydroxyl as well as amine and/or hydro sulfide groups, and to a lesser extent their sulfur-, nitrogen-, and oxygen-containing analogues and, for those tars produced at the lower coal carbonization temperatures, they contain in addition hydroaromatics, alkanes, and alkenes. The second part is the residue from the distillation, amounting to at least 50% of the coal-tar products by high temperature carbonization and consisting of a continuation of the sequence of polynuclear aromatic, aromatic, and heterocyclic compounds, but reaching molecules containing 20 to 30 rings. See also **Coal**; and **Coal Conversion (Clean Coal) Processes**.

TARANTULA. 1. *Arachnida, Araneida*. A name applied indiscriminately to many of the large hairy spiders of the warmer parts of the Americas, perhaps most commonly to the forms so often imported into temperate latitudes in bunches of bananas. The name comes from the generic name *Tarantula*, which has been applied to an entirely different group of spiders. 2. *Arachnida, Pedipalpi*. A genus of whip scorpions. The application of this name is dependent upon rules of nomenclature, which have apparently received no authoritative interpretation. It will undoubtedly remain in popular usage as a name for many large spiders, whatever its scientific disposition. See Fig. 1.

Fig. 1. Tarantula. (*A.M. Winchester*.)

TARNISH. A reaction that occurs readily at room temperature between metallic silver and sulfur in any form. The well-known black film that appears on the silverware results from reaction between atmospheric sulfur dioxide and metallic silver, forming silver sulfide. It is easily removable with a cleaning compound and is not a true form of corrosion. Plating with a mixture of silver and indium will increase tarnish resistance. Gold will also tarnish in the presence of a high concentration of sulfur in the environment.

TARO. Several perennial herbaceous plants of the genus *Colocasia* of the *Arum* family are commonly referred to as *taro* and, in some parts of the world, by the name *cocco* or *cocoyam*. These large and leafy plants are cultivated for their fleshy roots, which comprise a main foodstuff in parts of Polynesia and in southeast Asian countries. In some areas, the roots are called *eddoes*. The tubers contain a high percentage of starch, but considerably more protein than another common starchy vegetable, the potato. The leaves of taro plants are large and heart-shaped, resulting in one variety being called the *elephant's ear*. The plant is characterized by greenish flowers that resemble a calla, without petals, a floral envelope, stamens, or pistils. The fruit of the plant is a berry. Many varieties and forms of taro are known to the natives of the Pacific islands.

Colocasia esculenta is the principal and most commonly known form of taro. This is the main form of taro, cultivated in Hawaii, for example, and is the basis of *poi*. This pastelike material is prepared by steaming or boiling the tubers, after which they are peeled and pounded to form a mash. This mash is then permitted to ferment for several days. The taro is also eaten much as the potato, usually parboiled, after which it is baked. The tender, unopen leaves of the taro plant, sometimes termed *luau*, are used as greens.

The dasheen is a variety of taro grown in the southern United States. It is a long-season crop, adapted for culture only in southern regions, where there is normally a very warm frostless season of at least 7 months. Dasheen requires a rich loamy soil, an abundance of moisture with good drainage, and a fairly moist atmosphere. The plant was originally brought to the United States in about 1905 from Trinidad and Puerto Rico.

Small tubers from 2 to 5 ounces (57 to 142 grams) in weight are used for planting in much the same way as potatoes. Planting may be done 2

or 3 weeks before frosts are over, and the season may be lengthened by starting the plants indoors and setting them out after the last frost. The plants usually are set in 3.5- to 4-foot (about 1 to 1.3 meters) rows, about 2 feet (0.6 meter) apart in the rows. Dasheen tubers may be dug and dried on the ground in much the same way as sweet potatoes, and stored at 50 °F (10 °C) with ventilation.

Colocasia antiquorum, a plant of great antiquity, still is grown in Egypt in limited quantities. The plant is inferior to most other forms of taro, but is edible. This plant is sometimes called the Egyptian or Indian taro and in Egypt is known as *golgas*.

Cyrtosperma chamissonis, actually the *mwang* plant, is called taro in Micronesia. This particular plant is very much larger than the taro, having a rootstock weighing up to 50 pounds (22.7 kilograms) as compared with the ordinary taro rootstock weighing usually less than 5 pounds (2.3 kilograms).

Xanthosma sagittifolium, also known as *yautia*, is grown in the West Indies. This plant resembles, and is sometimes called, taro, but the plant is much larger. The root is high in starch and has a greater caloric value per unit of weight than the potato.

See also **Aroids**.

TARPAN. See **Horses, Asses, and Zebras**.

TARPON *(Osteichthyes)*. Of the order *Isospondyli*, family *Elopidae*, the tarpon is probably the most primitive of the suborder of clupeids. It is a large marine fish of silvery color, found in the waters of the West Indies, along the Gulf Coast, and northward to a limited extent along the Atlantic coast. It reaches a length of about 6 feet (1.8 meters) and is known for its very large scales, which may measure 3 inches (7.5 centimeters) across. Also known as the silver fish, silver king, savanilla, and sabalo. The tarpon is among the great game fishes, but is not commonly regarded as desirable for food. *Megalops atlanticus* (the Atlantic tarpon) has been recorded at 200 pounds (90.9 kilograms), length of 8 feet (2.4 meters) on several catches; the largest recorded has an 8-foot (2.4-meter), 340 pounder (154 kilograms). The *Megalops cyprinoides* (Pacific tarpon) is smaller, rarely exceeding 40 inches (1 meter) in length.

TARRAGON. See **Artemisia**; and **Flavorings**.

TAR SANDS. In addition to conventional petroleum and heavy crude oil, there remains another subclass of petroleum, one that offers to provide some relief to potential shortfalls in the future supply of liquid fuels and other products. This subclass is the bitumen found in tar sand deposits. Also called *bituminous sands* and *oil sands*, these sand deposits are impregnated with dense, viscous petroleum. Tar sands are found throughout the world, often in the same geographical areas as conventional petroleum.

Petroleum, and the equivalent term crude oil, covers a vast assortment of materials consisting of gaseous, liquid, and solid hydrocarbon-type chemical compounds that occur in sedimentary deposits throughout the world. When petroleum occurs in a reservoir that allows the crude material to be recovered by pumping operations as a free-flowing dark- to light-colored liquid, it is often referred to as conventional petroleum.

Heavy oil is another type of petroleum, different from conventional petroleum insofar as the flow properties are reduced. The heavy oil is much more difficult to recover from the subsurface reservoir. These materials have a high viscosity and low API gravity relative to the viscosity and API gravity of conventional petroleum (Fig. 1) and recovery of heavy oil usually requires thermal stimulation of the reservoir.

The definition of heavy oil is usually based on API gravity or viscosity, but the definition is quite arbitrary. Although there have been attempts to rationalize the definition based on viscosity, API gravity, and density, such definitions, based on physical properties, are inadequate, and a more precise definition would involve some reference to the recovery method.

In a general sense, however, the term heavy oil is often applied to a petroleum that has a gravity. The term heavy oil has also been arbitrarily

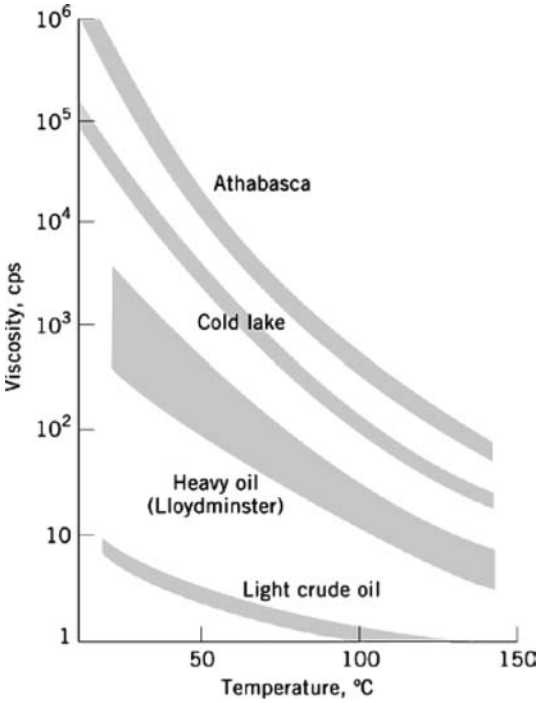

Fig. 1. Relative viscosity data for conventional petroleum, heavy oil, and bitumen.

used to describe both the heavy oil that requires thermal stimulation for recovery from the reservoir and the bitumen in bituminous sand (also known as tar sand or oil sand) formations, from which the heavy bituminous material is recovered by a mining operation. Extra heavy oil is the subcategory of petroleum that occurs in the near-solid state and is incapable of free flow under ambient conditions. The bitumen from tar sand deposits is often classified as an extra heavy oil.

Tar sand, also variously called oil sand (in Canada) or bituminous sand, is the term commonly used to describe a sandstone reservoir that is impregnated with a heavy, viscous black extra heavy crude oil, referred to as bitumen (or, incorrectly, as native asphalt). Tar sand is a mixture of sand, water, and bitumen, but many of the tar sand deposits in the United States lack the water layer that is believed to cover the Athabasca sand in Alberta, Canada, thereby facilitating the hot-water recovery process from the latter deposit. The heavy asphaltic organic material has a high viscosity under reservoir conditions and cannot be retrieved through a well by conventional production techniques.

It is incorrect to refer to bitumen as tar or pitch. Although the word tar is somewhat descriptive of the black bituminous material, it is best to avoid its use in referring to natural materials. More correctly, the name tar is usually applied to the heavy product remaining after the destructive distillation of coal or other organic matter. Pitch is the distillation residue of the various types of tar. See also **Tar and Pitch**.

The heavy, viscous petroleum substances impregnating the tar sands are called *asphaltic oils*. Other names used to describe these oils include *maltha*, *brea*, and *chapapote*. Asphaltic petroleums are most commonly confused with, but are *not* related to *asphaltites* (gilsonite, glance pitch, and grahamite); the *asphaltic pyrobitumens* (elaterite, wurtzilite, albertite, and impsonite); the native *mineral wax* (ozokerite); and the *pyrogenous distillates* of bituminous substances (tar and pitch).

Properties

Tar sand has been defined as sand saturated with a highly viscous crude hydrocarbon material not recoverable in its natural state through a well by ordinary production methods. Technically the material should perhaps be called bituminous sand rather than tar sand because the hydrocarbon is bitumen, ie, a carbon disulfide-soluble oil.

TABLE 1. BULK PROPERTIES OF TAR SANDS

Property	Alberta	Asphalt Ridge[a]	P.R. Springs[a]	Sunnyside[a]	Tar Sand Triangle[a]	Texas	Alabama
Bulk density, g/cm^3	1.75–2.19		1.83–2.50				
Porosity, vol %	27–56	16–27	6–33	16–28	9–32	32	6–25
Permeability, $m^2 \times 10^{-16}$[b]	99–5,900	4,905–5,950	553–14,902	5,265–7,402	2,043–7,777	3158	9.9–6,316
Specific heat, J/(g · °C)[c]	1.46–2.09						
Thermal conductivity, J/(s · °C)[c]	0.0071–0.0015						

[a] Deposit in Utah.
[b] To convert m^2 to millidarcies, multiply by 1.013×10^{12}.
[c] To convert J to cal, divide by 4.184.

The data available are generally for the Athabasca materials, although workers at the University of Utah (Salt Lake City) have carried out an intensive program to determine the processibility of Utah bitumen and considerable data have become available. Bulk properties of samples from several locations (Table 1) show that there is a wide range of properties. Substantial differences exist between the tar sands in Canada and those in the United States; a difference often cited is that the former is water-wet and the latter, oil-wet,

Canada	United States
sand is water-wet, thus disengagement of bitumen is efficient using hot-water process (caustic = sodium hydroxide; bitumen recovery >98%)	sand is oil-wet, thus efficient dis-engagement of bitumen requires high shear rates (caustic = sodium carbonate; bitumen recovery ~95%)
formations usually unconsolidated	formations usually consolidated to semiconsolidated by mineral cementation
few deposits have been identified (Alberta contains ca 0.4 m^3 bitumen)	numerous deposits identified (33 major deposits = 12 m^3 bitumen; 20 minor deposits − 12 m^3 bitu-men); total resource − 6.5 m^3 bitumen (2.6 m^3 measured and 3.8 m^3 billion speculative)
problems exist in settling and removal of clay from tar sand deposits and process streams	little is known about the nature and effect on processing of clays
bitumen properties fairly uniform (sulfur = 4.5–5.5 wt%, nitrogen = 0.1–0.5 wt %; H/C ratio ~1.5; API gravity from 6 to 12°)	bitumen properties diverse (sul-fur = 0.5–10 wt%, nitrogen 0.1–1.3 wt %; H/C ratio = 1.3–1.6; API gravity from −2 to 14°)
bitumen deposits large with uniform quality; recovery and upgrading plants on-stream since 1970s	bitumen deposits small and not of uniform quality; recovery and upgrading methods need to be site-specific

The sand component is predominantly quartz in the form of rounded or angular particles, each of which is wet with a film of water. Surrounding the wetted sand grains and somewhat filling the void among them is a film of bitumen. The balance of the void volume in the Canadian sands is filled with connate water plus, sometimes, a small volume of gas. Usually the gas is air but methane has been reported from some test borings in the Athabasca deposit. Some commercial gas deposits were developed in the late 1980s. The sand grains are packed to a void volume of ca 35%, corresponding to a mixture of ca 83 wt % sand; the remainder is bitumen and water which constitute ca 17 wt % of the tar sands.

Bitumen. There are wide variations both in the bitumen saturation of tar sand (0–18 wt % bitumen), even within a particular deposit, and the viscosity. Of particular note is the variation of density of Athabasca bitumen with temperature, and the maximum density difference between bitumen and water (70–80 °C (160–175 °F)); hence the choice of the operating temperature of the hot-water bitumen-extraction process.

The API gravity of tar sand bitumen varies from 5 to ca 10° API, depending on the deposit, and the viscosity is very high. This offers a formidable obstacle to bitumen recovery and, as a result of the high viscosity, bitumen is relatively nonvolatile under conditions of standard distillation.

Minerals. Usually >99% of the tar sand mineral is composed of quartz sand and clays. In the remaining 1%, more than 30 minerals have been identified, mostly calciferous or iron-based. Particle sizes range from large grains (99.9% finer than 1000 μm) to 44 μm (325 mesh), the smallest size that can be determined by dry screening.

Clays are aluminosilicate minerals, some of which have definite chemical compositions. In regard to tar sands, however, clay is only a size classification and is usually determined by a sedimentation method. See also **Clays**.

Tar Sand Resources

The presence of tar sands in North America was noted by American Indians several centuries ago. Pitch recovered from surface deposits was used for waterproofing canoes. It is reported that Columbus observed asphalt from Pitch Lake in Trinidad and used the material for repairing his ships on his third voyage to the West Indies in 1498. The same bitumen deposit was reported by Sir Walter Raleigh in 1595. For several centuries the material was used for repairing vessels.

In 1962, reports were received of tar sands in the Bjorne Formation of Triassic age on Melville Island in the Canadian Arctic Archipelago near the southern margin of the Sverdrup sedimentary basin. Subsequent investigations of these deposits by officers of the Geological Survey of Canada revealed them to be a seepage derived from the oxidation and polymerization of 19–31° API gravity oil, with a total in-place reserves of only 30 million barrels. The largest find of tar sands in Canada (and possibly in the world) was located in the subsurface of northern Alberta in the valley of the lower Athabasca River, along a distance of 160 kilometers (100 miles). This is now known as the Athabasca deposit. As indicated by Mossop (1980), McMurray Formation deposition began in the Athabasca region in Early Cretaceous time. The surface on which the initial sediments were laid down was an exposed landscape of Devonian limestone. It is envisioned that, during the McMurray period, the region underwent

gradual subsidence, with the Boreal Sea[1] slowly transgressing across it from the north. The McMurray sand deposition stopped when the sea eventually transgressed the entire area, giving subsequent rise to deposition of Clearwater Formation marine shales. Not all geologists are agreed upon the details of the formation and possible later biodegradation of tar sand deposits. Geographically close to the Athabasca deposit are the Cold Lake, Wabasca, and Peace River deposits. Underlying these Cretaceous tar sands are Devonian carbonate rocks (limestone and dolomite) impregnated with bitumen of essentially the same composition as the bitumen in the Cretaceous sands. See Fig. 2.

Along with other alternative sources of energy during the energy crisis of the 1970s, considerable attention was devoted to the exploitation of tar sands. Once, it was predicted that deposits in Canada could yield a light synthetic crude oil to the extent of a million barrels per day, or about one-third of Canada's petroleum requirements. Later, when serious environmental concern over fossil fuels was indicated, research turned essentially elsewhere. It was estimated in the late 1970s that tar sands reserves in the United States, mainly in Utah, would have the petroleum equivalent of 90 billion barrels. The remoteness of the U.S. tar sands is often cited as a deterrent to development but topography of the site, overburden-to-ore body ratio, and richness of the ore body are also important. In the 1990s context of mining tar sand deposits in the United States, the Utah deposits (Tar Sand Triangle, P.R. Springs, Sunnyside, and Hill Creek) generally have an overburden-to-net pay zone ratio above the 0.4–1.0 range, with a lean oil content.

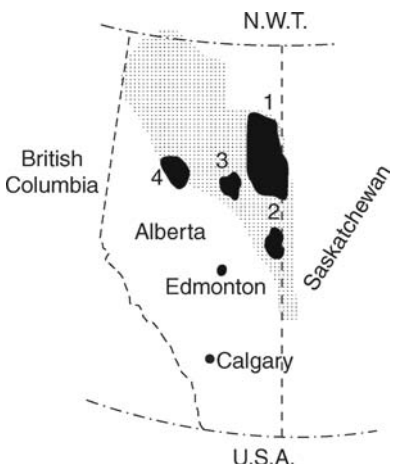

Fig. 2. Location of major tar (oil) sand deposits in Alberta, Canada: (1) Atha basca, (2) Cold Lake, (3) Wabasca, and (4) Peace River, N.W.T. (Northwest Territories).

It is interesting to note that tar sands worldwide contain the largest accumulations of liquid hydrocarbons in the earth's crust.

The seriousness of the Canadian tar sands effort is demonstrated by a view of a plant in Alberta. See Fig. 3.

The government of the Canadian Province of Alberta has announced a standard royalty formula for the oil sands industry and embraced the principles and, to a large degree, put into practice the recommendations of the National Task Force on Oil Sands Strategies. The Canadian government plans to extend the mining tax regulation to include *in situ* operations. Over $3,400,000,000 (Canadian $) in new projects and expansions have been set aside to allow the industry to move forward with projects in the initial stages of development (Table 2) which should encourage further development of Canadian tar sand resources.

[1] Boreal is a term that pertains to the north, or to things located in northern regions. The Boreal region is characterized by tundra and taiga — a climatic zone having a definite winter that experiences snow and a short summer that is generally hot, characterized by a large annual range of temperature. This region includes parts of North America, central Europe, and Asia, generally between latitudes 60°N and 40°N.

Fig. 3. General view of upgrading plant for processing bitumen mined from Athabasca deposit. In the foreground is the sulfur stockpile; in the background is a tailings pond. Right background shows the extraction plant; left is the coke pile. (*Alberta Government Photographic Service*).

TARSIOIDS *(Mammalia, Primates)*. Comprised of small creatures known as Tarsiers, this is the smallest of the divisions of the *Primates*. The tarsier is a peculiar animal found on some islands of the Oriental Region, notably in Borneo, Celebes, Java, Sumatra, and the Philippines. Tarsiers are forest dwellers and they are about as large as a medium-size rat, with very short muzzles and large eyes, circular, close together, and directed forward. The hind legs, particularly the ankles, are long, and the tips of the digits are expanded into fleshy disks. The tarsier moves about on its hind legs by spring leaps. They are of considerable scientific interest because they appear to be a leftover from some ancient line of animals. It is reasoned that the ancient ancestry may trace to the *Tupaioids* (tree-shrews). However, some authorities identify the Tarsier more with the *Lorisoids*. Tarsiers also are of interest because they are insectivorous, feeding at night, and literally catching their prey with their hands and conveying it to their mouths for eating. They are covered with short, thick, soft, and wooly fur, with a long furry tail at the base, but with essentially a naked terminal. With exception of their extra-long legs, due to elongated ankle bones, they have somewhat the appearance of a squirrel with very large eyes.

TARSUS. 1. The terminal division of the leg of an insect. It consists of five segments in the typical form, the terminal segment bearing a pair of claws. Tarsi are modified in various species by the fusion or loss of segments, and in one genus, *Bittacus*, the terminal joint folds back on the next to form a grasping organ. 2. The shank of the leg of a bird (*Aves*). 3. The proximal portion of the foot of vertebrates, containing several tarsal bones. 4. The framework of connective tissue which gives shape to the eyelid.

TABLE 2. PROJECTS FOR BITUMEN AND HEAVY OIL RECOVERY/CONVERSION

Project	Investment, $\$\times 10^6$	Timing	Description[a]	Production, m^3/d (bbl/d)[b]
Amoco				
Primrose	500	Immediate	SAGD heavy oil production	6,000 (50,0000) heavy oil
Alberta Energy Co., Ltd.				
Cold Lake	13	Immediate	SAGD heavy oil pilot plant	120 (1,000) heavy oil
Foster Creek	200	1997–1998	commercial heavy oil	3,600 (30,000) heavy oil
Elan Energy, Ltd.				
Lindbergh	60	Immediate	SAGD heavy oil plant	Increased 1,680–2,640 (14,000–22,000)
Elk Point				
Gibson Petroleum, Ltd.,	7	1996–1997	SAGD bitumen project	Increased 240–540 (2,000–4,500)
Utf				
Gulf Canada Resources, Ltd.				
Surmont	30	1996	Phase 1 SAGD heavy oil	360 (3,000)
		1998–1999	phase 2	Increased 2,400 (20,000)
Imperial Oil Limited				
Cold Lake	250	Immediate	Phases 9–10 *in situ* bitumen production	Increased 14,400; 3,000 (120,000; ~25,000+)
Cold Lake (proposed)	250	1997	Phases 11–12 *in situ* bitumen production following completion of phases 9–10	add 2,400 (~20,000)
Imperial				
Cold Lake	40	Immediate	Heavy oil development below current Cold Lake lease	1,128 (9,400) Heavy oil
Koch Oil Co., Ltd.				
Cold Lake		1997–1998	*in situ* bitumen project	6,000 (50,000)
Reita Lake				
Shell Canada Ltd.				
Peace River	3	Immediate	SAGD heavy oil project	Increased
Solvex				
Bitumount	170	1997	Bitumen mine/extraction complex, minerals extraction plant	168 (14,000) bitumen, 100,000 t alumina, 200,000 t synthetic silica (tailings)
Suncor Inc.				
Primrose	17	1996–1997	Phase 1, SAGD pilot plant	300 (2,500) heavy oil
Burnt Lake	122	1998–1999	Phase 2, commercial plant	Increased 1,500 (12,500) heavy oil
Suncor Inc., Osg				
Steepbank Mine	300	2001	New bitumen mine	Increased production 10,800 (90,000+) light sweet crude, custom blends
Fort McMurray	300	1998–2001	Upgrader improvements, plant modifications	Increased 9,600 (80,000) light sweet crude, custom blends
Fort McMurray	190	Immediate	Environmental measures	reduced SO_2 emissions
Syncrude Canada, Ltd.				
North Mine Mildred Lake	500	1998	New bitumen mine, debottlenecking plant	Increased
Syncrude Canada, Ltd.				
Aurora Mine	500	2001	New bitumen, remote plant, debottleneck	First train, 2001; increased 11.3 (94×10^6 bbl/yr)
Total	*3,452* $\$ \times 10^9$			

[a] SAGD = steam − assisted gravity draining.
[b] To convert m^3/d to bbl/d, multiply by 6.29.

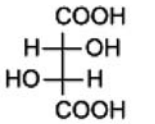
TARTARIC ACID. [CAS: 526-83-0]. Tartaric acid (2,3-dihydroxy butanedioic acid, or 2,3-dihydroxysuccinic acid) $(CHOHCO_2H)_2$, formula weight 150.09, is a white crystalline organic acid. It occurs naturally in many plants, particularly grapes and tamarinds, and is one of the main acids found in wine. It is added to other foods to give a sour taste, and is used as an antioxidant.

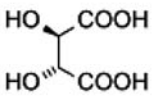
Tartaric acid was first isolated from potassium tartrate, known to the ancients as tartar, circa 800 CE[1] by the alchemist Jabir ibn Hayyan, who was also responsible for numerous other basic chemical processes still in use today. The modern process was developed in 1769 by the Swedish chemist Carl Wilhelm Scheele. The chirality of tartaric acid was discovered in 1832 by Jean Baptiste Biot, who observed its ability to rotate polarized light. Louis Pasteur continued this research in 1847 by investigating the shapes of tartaric acid crystals, which he found to be asymmetric. Pasteur was the first to produce a pure sample of levotartaric acid.

Naturally-occurring tartaric acid is chiral, meaning that it has molecules that are non-superimposable on their mirror-images. It is a useful raw material in organic chemistry for the synthesis of other chiral molecules. The naturally occurring form of the acid is L-(+)-tartaric acid or dextrotartaric acid (**1**) [CAS: 87-69-4]. The mirror-image (enantiomeric) form, levotartaric acid or D-(−)-tartaric acid (**2**) [CAS: 147-71-7] (both with the same mp 168-170 °C (334-338 °F), sp gr 1.760), and the achiral form, mesotartaric acid (**3**) [CAS: 147-73-9] (mp 159-160 °C (318-320 °F), sp gr 1.737), can be made artificially. Note, that the *dextro* and *levo* prefixes are not related to the D/L configuration (which is derived from the reference

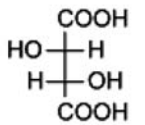
[1] The Common Era (CE), also known as the Christian Era and sometimes the Current Era, is the period of measured time beginning with the year 1 until the present.

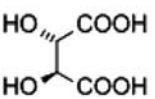
D- or L-glyceraldehyde), but to the orientation of the optical rotation, (+) = dextrorotatory, (−) = levorotatory. Sometimes, instead of capital letters, small italic *d*, *l* are used. They are abbreviations of *dextro-* and *levo-*, and nowadays should not be used. Levotartaric and dextrotartaric acid are enantiomers, mesotartaric acid is a diastereomer of both of them.



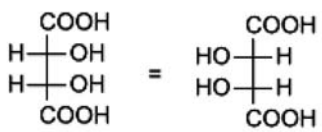


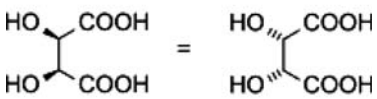
(1)





(2)





(3)

A rarely occurring optically inactive form of tartaric acid, DL-tartaric acid is a 1:1 mixture of the *levo* and *dextro* forms. It is distinct from mesotartaric acid and was called racemic acid [CAS: 133-37-9] (from Latin *racemus* - "a bunch of grapes"). The word *racemic* later changed its meaning, becoming a general term for 1:1 enantiomeric mixtures - racemates.

Tartrates (like citrates) in solution change silver of ammonio-silver nitrate into metallic silver. Potassium hydrogen tartrate and calcium tartrate, on account of their solubility characteristics, are of importance in the separation and recovery of tartaric acid. The former salt is readily converted into the latter, and the resulting calcium tartrate plus dilute sulfuric acid yields tartaric acid plus calcium sulfate, and the latter may be separated by filtration. Tartaric acid may be obtained by evaporation of the filtrate. Ester: Diethyl tartrate $COOC_2H_5(CHOH)_2COOC_2H_5$, melting point 17 °C (63 °F), boiling point 280 °C (536 °F). Tartaric acid may be obtained (1) from some natural products, e.g., in the juice of grapes and acid fruits, often in conjunction with citric or malic acid; potassium hydrogen tartrate, "argol," in the residue of wine vats, (2) by synthesis.

Tartaric acid is used: (1) in baking powders as potassium hydrogen tartrate ("cream of tartar") with sodium bicarbonate; (2) in medicine, e.g., potassium antimonyl tartrate ("Tartar emetic"); (3) in effervescent medicinal salts; (4) in blue printing as ferric tartrate; and (5) in silvering mirrors — ammonio-silver nitrate yielding a smooth deposit of silver. Sodium potassium tartrate ("Rochelle salt," $NaKC_4H_4O_6 \cdot 4H_2O$) is used in medicine, and in the preparation of Fehling's solution, which is an alkaline cupric solution made by mixing copper sulfate solution, sodium potassium tartrate solution and sodium hydroxide solution, and is used as an oxidizing reagent in the case of many organic compounds, such as glucose and reducing sugars, and aldehydes, with which cuprous oxide, red to yellow precipitate, is formed.

Tartaric Acid in Wine

Tartaric acid may be most immediately recognizable to wine drinkers as the source of "wine diamonds," the small potassium bitartrate crystals that sometimes form spontaneously on the cork. These "tartrates" are harmless, despite sometimes being mistaken for broken glass, and are prevented in many wines through cold stabilization. The tartrates that remain on the inside of aging barrels were at one time a major industrial source of potassium bitartrate.

However, tartaric acid plays an important role chemically, lowering the pH of fermenting "must" to a level where many undesireable spoilage bacteria cannot live, and acting as a preservative after fermentation. In the mouth, tartaric acid provides some of the tartness that is currently out of fashion in the wine world, although citric and malic acids also play a role. The modern practice of extended hang time, where grapes are allowed to sit on the vine nearly until they become raisins, can dramatically reduce the taste of tartaric acid in a wine, leaving it smoother but also potentially less compatible with food.

TASMANIAN GUM TREE. See **Eucalyptus Trees**.

TASTE BUD. A sensory organ of the vertebrates, sensitive to contact with substances in solution and those in a liquid state. A taste bud consists of a spindle-shaped group of cells in the epithelium of the vertebrate tongue and in some species in the lining of the mouth and pharynx. Taste buds have been reported in the skin of some aquatic animals. The bud includes supporting cells of thick spindle shape and slender taste cells ending with a short taste hair which projects into a minute pit at the free end of the bud. The interpretation of these two types of cells is a subject of disagreement; it is possible that they represent stages in the development of a single form of cell.

The action of taste buds results in four fundamental taste sensations: sweet, sour or acid, salty, and bitter. Perception of these chemical properties is localized in the tissues containing organs of taste, but differentiation of the organs accompanying this localization has not been demonstrated.

More detail on taste and odor receptors is given in the entry on **Flavorings**.

TATLER. See **Waders, Shorebirds, and Gulls**.

TAUBE, HENRY (1915–). A Canadian-born chemist who won the Nobel Prize for Chemistry in 1983 for his pioneering work in inorganic chemistry and the study of electron-transfer reactions, particularly of metal complexes. Known as an outstanding teacher, he is admired and respected by students and colleagues for his work at Stanford University.

TAU PARTICLE. Discovered in 1975, the tau particle is a lepton with a mass of 1.8 GeV, almost twice that of the proton. Like other leptons, the tau particle is considered as pointlike. See also **Particles (Subatomic)**.

TAURUS (the bull). A constellation of great antiquity; the second sign of the zodiac. Two of the open clusters of Taurus, the Pleiades and the Hyades, are frequently referred to in the Bible, and Aldebaran, its brightest star, is mentioned by both Homer and Hesiod. See also **Aldebaran**.

The two asterisms, the Pleiades and the Hyades, are both open clusters, i.e., groups of stars moving together through space. The Pleiades group is also noteworthy in that it is filled with diffuse nebulous material.

There are a number of double stars within Taurus available for observers with small telescopes. With a wide-field instrument, such as an opera glass, the two doubles, Sigma and Theta, can both be seen at once and, with the surrounding stars, make a very interesting spectable.

See map accompanying the entry on **Constellations**.

TAUTOMERISM. See **Isomerism**.

TAXODIACEAE. See **Cypress Trees**; **Giant Sequoia**; and **Redwood (Coast)**.

TAXONOMY. The science of classification. In dealing with the many details involved in classifying the half-million known species of animals, it has been found necessary to adopt rules of procedure in order to secure approximate uniformity and stability of results.

For many years, zoologists and botanists tried to classify animals and plants into a system that represented a survey of the abundance of forms in fauna and flora. Scientists found early in their work toward a perfect classification that new knowledge constantly required alterations in the system and, of course, to a degree this continues today. Classification always has been difficult, too, because of fundamental differences of opinion among the persons who were constructing the system. Often these differences are insignificant — yet they can cause difficulty for persons who attempt to locate information in the literature.

The animal kingdom, for example, has been split into several subkingdoms and these have been divided into further sections, subsections, etc. The scale of the most important systematic categories follows in a descending rank order, as shown below:

Kingdom
Subkingdom
Phylum
Subphylum
Class
Subclass
Superorder
Infraorder
Family
Subfamily
Tribe
Genus
Subgenus
Species
Subspecies

The scientific names of animals and their spelling are determined by the international rules for the zoological nomenclature as agreed by the XV International Congress for Zoology and are obligatory for zoological publications. The name of the genus, which is a Latin or Latinized noun, is singular and capitalized or otherwise typeset (such as italics) to distinguish it from the remainder of words in a sentence or listing. The names of species and subspecies may be nouns or adjectives and they are spelled in the lower case, preferably italicized. The name of a subgenus, which is formed in the same manner as a genus, may be added in brackets following the name of the genus. The names of the tribes, subfamilies, families, and superfamilies are usually plural nouns, sometimes fully capitalized or with an initial capital. They are formed from the name of a given genus by adding to the principal word the endings -ini for the tribe, -inae for the subfamily, -idae for the family, and -oidea for the superfamily. The names of the authors who were the first to describe and to name a species, subspecies, or group of animals can be cited with the year of this naming. In a description involving several mentions of a species, subspecies, etc., the author acknowledgment need be made only once — when the term is first mentioned in a text.

The principal objectives of taxonomy are: (1) to discriminate among organisms and to provide means for the subsequent recognition (identification) of the discriminated entities (taxa); (2) to develop a suitable procedure (nomenclature) for designating taxa for reference purposes; and (3) to devise and perfect a scheme of classification in which the named taxa can be arranged. The functions of the classification are: (1) to provide a means for the communication and retrieval of information concerning each of the approximately 1.5 million different kinds of organisms; (2) to facilitate the gathering of new information by permitting the prediction of characters in unfamiliar organisms; and (3) to demonstrate at once the unit and diversity of organic life by expressing past adaptive patterns of the various taxa.

TAXONOMY (The History). Taxonomy is the theory and practice of making classifications and detecting relationships. The formal classification of organisms in Western science begins around 1753, but societies worldwide have always assigned organisms to named groups.

Introduction

The history of classification is coextensive with human history. All societies have often quite complex classifications of plants and animals, and there are cross-cultural commonalities in the major groups named. Furthermore, the correspondence between species recognized in groups that are particularly salient to the local people and those recognized by Western-trained taxonomists can be very close. In classical Greece Aristotle and Theophrastus recorded a wealth of observations on natural history and plant culture, while copies of manuscripts such as that of Dioscorides, including much information on the medicinal properties of plants, remained in use for almost two millennia. In the Renaissance, works like those of Gesner, Brunfels and Bock include a mix of more or less careful working of classical sources, original observation, and original illustrations of high quality. See also **Gesner, Conrad (Konrad) (1516–1565)**.

Problems arose when botanists from Western Europe who were interested in medicine tried to equate their plants with those mentioned in classical sources, while more fanciful accounts of animals in particular flourished in the rich emblematic culture. European voyages yielded what soon became a flood of new animals and plants which made their entry piecemeal into the literature. Ideas of spontaneous generation and heterogenesis died slowly, although order was brought into part of the insect world by Jan Swammerdam's demonstration of the metamorphosis of caterpillars into butterflies. However, comparing names in different accounts became progressively more difficult. See also **Plant Sciences (The History)**.

Linnaeus and the Development of Classification Systems

The goal of Linnaeus and his friend Petrus Artedi was to solve this problem by classifying and naming all animals, plants and minerals — as Linnaeus said, this was the foundation of natural history. Despite Artedi's premature death, Linnaeus classified all organisms in successive editions of the *Systema naturae* (Linnaeus's main interest was botany). By 1753 Linnaeus was consistently using binomials, e.g. *Homo sapiens*, *Taraxacum officinale*, initially only as an *aide-mémoire* to the polynomial, the real name encapsulating the essence of the organism. But binomials soon became the names for organisms, with the diagnosis taking second place. Linnaeus also provided guidelines for classification and nomenclature, lists of botanical terms, etc. In addition, his cortex–medulla theory, the idea that all organisms are made up of external cortex, which largely provides form, and internal medulla, allowed him to explain many of the phenomena of life. See also **Linnaeus, Carl (Linné) (1707–1778)**.

Linnaeus did not pretend to recognize natural groups above the level of genus, and Antoine-Laurent de Jussieu, Michel Adanson and Lamarck addressed this omission in the late eighteenth century. In Jussieu's widely used *Genera plantarum* plants were arranged following the natural system. He emphasized the importance of looking at all characters, although not all were equally valuable in classification; in plants in particular useful characters were overwhelmingly those of external form. He proposed that the natural system should be built up by synthesis, adding species to species. Lamarck provided guidelines for writing keys (identification aids) and outlined a numerical method for analyzing relationships, while Adanson suggested that all characters should be treated as being equally important. Lamarck and Jussieu in particular believed that relationships formed some sort of continuum of form, the limits of groups being more or less arbitrary. See also **Adanson, Michel (1727–1806)**; **de Jussieu, Antoine-Laurent (1748–1836)**; and **Lamarck, Jean-Baptiste Pierre Antoine de Monet de (1744–1829)**.

George-Louis Leclerc, Comte de Buffon, rejected many of Linnaeus's ideas on nomenclature and classification, yet his great *Histoire naturelle* helped shape systematics almost as surely as Linnaeus's *Systema naturae*. Buffon defined natural history as description, nomenclature and the study of the habits and behavior of organisms, and in part because the *Histoire naturelle* focused on animals, natural history was often considered to be the study of animals alone. Buffon's collaborator, Louis-Jean-Marie Daubenton, tried to integrate comparative gross anatomy — his interest was in the viscera and skeleton — into natural history, hitherto largely the study of external form. Daubenton also distinguished his work from the detailed anatomical studies that emphasized the human body and medicine. See also **Buffon, Georges Louis (1707–1788)**.

Daubenton wanted to relate anatomy to how organs worked, and his general approach was developed by Georges Cuvier. Cuvier's extensive and detailed anatomical work included analyses of the blood system, nerves and muscles, as well as paleontological studies. Cuvier completed the transformation of zoology, not natural history; contemporary commentators noting that zoology had been taken over by comparative anatomy. He claimed that there were four major groupings of animals entirely separate one from another, and saw parallels between the taxonomic hierarchy and the physiological-functional-ecological hierarchy. Across the Atlantic Louis Agassiz developed this tradition, emphasizing parallels between classification, development, paleontology and the mind of God. See also **Agassiz, Jean Louis Rodolphe (1807–1873)**; **Cuvier, Georges Leopold Chretien Frederic Dagobert Baron de (1769–1832)**: and **Paleontology (The History)**.

Darwin's *On the Origin of Species* drew many of its examples from systematists' work. It suggested no changes in their practice, although some, like George Bentham, emphasized that there could now be no essences. However, there were changes in how systematists interpreted their work. Darwin focused on genealogies, ancestor–descendant series, and these were often drawn as trees (although the first known tree dates from 1804). Such trees were doomed to remain "hypothetical" since the needed fossils were rarely known, although Ernst Haeckel in particular thought development would reveal genealogies. Drawing evolutionary trees became popular, but they remained tentative constructions, becoming if anything more so in the twentieth century. See also **Darwin, Charles Robert (1809–1882)**; and **Haeckel, Ernst Heinrich Philipp August (1834–1919)**.

Phenetics and Cladistics

Taxonomy as a whole remained a largely atheoretical discipline, instinct commonly being used to explain how taxonomic conclusions were drawn. Neo-Adansonian, phenetic or numerical taxonomy developed in the late 1950s in part to correct the often unarticulated and apparently circular methodology of evolutionary systematics; in short, it claimed to make systematics a science. The goal of the computer-assisted analyses of data that soon became popular was to produce objective classifications of maximum utility based on the analysis of as many characters as possible. This general goal had been promoted from the 1930s onwards by the botanist J. S. L. Gilmour; in turn he drew on sources such as W. S. Jevons and George Bentham. See also **Systematics: Historical Overview**.

However, many systematists remained interested in phylogenies, and starting in zoology in the 1960s explicitly phylogenetically-oriented analyses began to predominate. The entomologist Willi Hennig became the patron saint of what was soon called *cladistics*. Again, emphasis was placed on making systematics scientific — justification of *cladistics* was often by appeal to the philosopher Karl Popper — even as its goals became thoroughly historical. Debate between cladists, evolutionary systematists and pheneticists was especially bitter in the 1970s. In the 1990s the advent of massive amounts of molecular data, new analytical algorithms, and more powerful computers greatly facilitated the production of hypotheses of phylogeny. However, evolutionary systematists and cladists differed in how to derive classifications from phylogenies, a situation complicated by proposals for a new nonhierarchical nomenclature. Furthermore, some systematists attempted to exclude evolutionary considerations from data analysis, almost phenetics in a phylogenetic context, while others integrated them into their analytical algorithms.

Linnaeus classified all of life, but most of his successors studied either animals or plants, and by the middle of the nineteenth century yet smaller groups; separate botanical and zoological codes of nomenclature developed. But towards the middle of the twentieth century botanists and zoologists recognized they had common problems, and with the rise of phenetics and cladistics systematic theory became more or less unified. Some kinds of systematic studies became collaborative, partly because of the exigencies of molecular work and partly pushed by grant-awarding agencies. Massive data-basing projects also suggested the desirability of unification across kingdoms, and proposals for a single code of nomenclature reflect similar forces.

Species

John Ray's definition of species — that species reproduced by seed, their features remaining largely constant — has remained substantially unchanged for over 300 years. Animals more obviously sought their mates, but in both cases, members of species were united by common descent. However, even within species, ancestor — descendant series could be followed for only a few generations, and so had to be inferred from morphology. For many taxonomists the definition of species has effectively been "what a competent taxonomist says it is". In botany a group of taxonomists including Bentham, Joseph Hooker and Asa Gray promoted broadly delimited "Linnaean" species. This in part reflected the need to provide usable enumerations where usable emphasized not academics or local naturalists but metropolitan botanists of the vegetable products of empire. Controversies in which local and global knowledge were pitted against each other also occurred among those who studied birds and mammals, and similar controversies continue. See also **Gray, Asa (1810–1888)**; **Hooker, Joseph Dalton (1817–1911)**; and **Ray, John (1627–1705)**.

With the likes of Spencer Baird, some entomologists and ornithologists in particular started paying attention to individual variation. The American Ornithological Union's adoption of the rank of subspecies, and hence trinomials, in 1886 was a response to the problem of naming incompletely separated but geographically distinct forms; Ernst Hartert and Lionel Walter Rothschild promoted their use. "The New Systematics" of the 1940s signaled the developing evolutionary synthesis, in which zoology played an important role. Zoologists such as Léon Dufour, Thomas Henry Huxley and Karl Jordan had long emphasized the importance of breeding barriers between species, and this was formalized in Ernst Mayr's biological species concept of 1942. This remained popular for much of the century, and one of its beneficial effects was seen as reducing the number of species. Debate over species concepts was renewed in the 1970s. Characteristically, systematists' work was largely unaffected, although in ornithology the biological species concept was replaced and species numbers increased. Such species work remains largely the provenance of individual experts who develop intimate knowledge of "their" group — knowledge that is mostly lost on their death. See also **Huxley, Julian Sorrell (1887–1975)**; and **Mayr, Ernst Walter (1904–2005)**.

Collections

Taxonomy remains based on collections. The often rather miscellaneous collections of the natural history cabinet gave way in the eighteenth century to specialist collections, although for groups like birds these could develop only when appropriate preservatives were discovered. Large state collections became common by the middle of the nineteenth century, many expanding in step with the expansion of empire. By the twentieth century large private collections, except groups like mosses and insects, had disappeared, being too expensive for individuals to maintain. Professionalization occurred with the development of the collections and with the teaching of botany and zoology in universities, although there tended to be conflict between systematics as practiced in universities and that practiced elsewhere.

The Status of Taxonomy

Classificatory studies have long been dismissed by some scientists. Even by the late eighteenth century, botanists were seen as overly focused on names and little interested in the anatomical studies that were transforming zoology. "Botanique proprement dite" or simply "botany" encompassed largely classificatory studies based on herbarium material. Proponents of biology — the term was coined around 1800 — focused on the phenomena

of life and the nature of life itself, often explicitly dismissing classificatory studies. However, the anatomical and functional aspects of zoology drew it close to biology; "philosophical botany" or "botanique physique," usually excluded from botany proper, included physiological and anatomical studies and tended to be more biological.

Botany in particular was an important part of popular culture. It was variously the naming of plants (for a long time following the Linnaean system) collected during rambles in the countryside, whether by artisans or parsons; the language of flowers, wildly popular on both sides of the Atlantic in the early nineteenth century; or part of the education of women. Botanical societies, often including women, flourished, and popular botany — and by extension botany as a whole — became in part associated with women and hence trivialized. Natural history, on the other hand, often comprised field studies of vertebrates alone, and its proponents were men and boys with guns. Naturalists might also have more general interests, or be involved in classificatory studies, although the study of behavior, song and the like, was usually no part of such work. By the end of the nineteenth century natural history also had in part become associated with children especially. Stereotypes of botany and natural history were used to reduce the prominence of classificatory studies — especially those of "higher" plants — in the New Botany. Some wished to exclude most of botany from biology, others, classificatory studies from zoology, especially when the latter was synonymized with biology. See also **Plant Sciences (The History)**.

Through much of the twentieth century taxonomy remained in low repute. Mayr championed the cause of the naturalists — systematists with field experience and interested in evolution — against the closet taxonomists, and the journal *Evolution* was founded in 1947 in part to help showcase the evolutionary results of taxonomic work. New ways of hypothesizing relationships at the end of the century made understanding phylogeny essential for many comparative questions in evolutionary biology, even as much as descriptive taxonomy remained unchanged and often little appreciated.

TAYLOR, BROOK (1685–1731). Taylor was a British mathematician most remembered for his work that helped in the development of calculus. He grew up to be an accomplished musician and painter besides mathematician. In 1708 even before graduating from St. John's College Cambridge, Taylor had written his first important paper producing a solution to the problem of the center of oscillation. It was not published until 1714 and resulted in a priority dispute with the work of Johann Bernoulli.

Also in the year 1714, Taylor was elected Secretary to the Royal Society and during his years there (until 1718) he produced most his mathematics. His "Direct and Indirect Methods of Incrementation" added a new branch to mathematics called the calculus of finite differences. He also invented integration by parts, and discovered the celebrated series known as Taylor's expansion. His work *Methodus* contains the famous formula known as Taylor's theorem. Not until 1772, however, was its importance really understood and proclaimed by the French mathematician, Lagrange, as the basic principle of differential calculus.

A gifted artist, Taylor devised the basic principles of perspective in *Linear Perspective*. His work gives the first general treatment of vanishing points.

TAYLOR SERIES. A convergent power series is generally useful as a representation of a function. Let us assume that $f(x)$ can be so given as an infinite series in powers of $(x-a)$, expecting the series to be valid for values of x near a. Then,

$$f(x) = b_0 + b_1(x-a) + b_2(x-a)^2 + \cdots + b_k(x-a)^k + \cdots$$

and the coefficients can be obtained by successive differentiations to give

$$b_0 = f(a); b_1 < f'(a); \quad b_2 = f''(a)/2!; \cdots$$

The result, which is known as Taylor's series (Brook Taylor, 1685–1731, was an English mathematician), is

$$f(x) = f(a) + f'(a)(x-a) + f''(a)\frac{(x-a)^2}{2!} + \cdots + f^{(k)}(a)\frac{(x-a)^k}{k!} + \cdots$$

The procedure, so far, has been purely formal for it has only been assumed that such an expansion is possible. One can, however, apply the extended mean value theorem of differential calculus which shows that the Taylor series expansion and the extended mean value theorem are identical, if $x = b$ and $a < z < x$, provided we stop after n terms. Let the first n terms in the Taylor series (the nth term involves $f^{(n-1)}$ or $(n-1) = k$) be called S_n and the last term in the extended mean value theorem be called the remainder.

$$R = f^{(n)}(z)(x-a)^n/n!$$

so that $f(x) - S_n = R$. Now if $x = x_0$ and R approaches a limit, $\lim_{n\to\infty} S_n = f(x_0)$ so that the Taylor series does indeed converge to give $f(x_0)$ at $x = x_0$.

Another useful form of the Taylor series is obtained if we let $h = (x-a)$ and replace a by x_0. Finally dropping the subscript on x_0, the result is

$$f(x+h) = f(x) + f'(x)h + f''(x)\frac{h^2}{2!} + \cdots + f^{(k)}(x)\frac{h^k}{k!} + \cdots$$

The remainder after n terms can be given in several equivalent forms. Some of them are

$$R_n(x) = \frac{(x-a)^n f^{(n)}}{n!}\{a + \phi(x-a)\}.\ 0 < \phi < 1$$

$$R_n(x) = \frac{1}{(n-1)!}\int_0^{x-a} f^{(n)}(x-t)t^{n-1}dt$$

In the second form of the series

$$R_n(x) = \frac{h^n f^{(n)}}{n!}(x + \phi h)$$

$$R_n(x) = \frac{1}{(n-1)!}\int_0^h f^{(n)}(x + h - t)t^{n-1}dt$$

Use of the Taylor series requires that the function and its derivatives of all orders must exist at $x = a$. The binomial series is a special case of it. See also **Maclaurin Series**.

The Taylor series may be extensively generalized. Thus, in several variables

$$f(x + h, y + k, \ldots) = f(x, y, \ldots) + df(x, y, \ldots) + \frac{1}{2!}d^2 f(x, y, \ldots) + \cdots + \frac{1}{k!}d^k f(x, y, \ldots) + \cdots + R_n$$

It can also be used for the complex variable. In that case the boundary of the region of the complex plane in which a Taylor series converges is called the circle of convergence. For a given function, the radius of this circle depends on the point (center of the circle) about which the series is developed. On the boundary the power series diverges because there are one or more singular points of the function. Frequently it may be found outside of the circle of convergence by analytic continuation.

In starting the numerical solution of a differential equation, suppose $y' = f(x, y)$ is given with initial values (x_0, y_0). Then the solution in a Taylor series is

$$y = y_0 + (x - x_0)y_0' + \frac{(x - x_0)^2}{2!}y_0'' + \cdots + \frac{(x - x_0)^k}{k!}y_0^{(k)} + \cdots$$

If the derivatives can be evaluated readily, the solution can be computed numerically. Other methods (see also **Differential Equation, Numerical Solution of)** are preferred for continuing the solution. See also **Algebraic Equations**.

TAYRA. See **Mustelines**.

TCA CYCLE. (tricarboxylic acid cycle; Krebs cycle or citric acid cycle). A series of enzymatic reactions occurring in living cells of aerobic organisms, the net result of which is the conversion of pyruvic acid [CAS: 127-17-3], formed by anaerobic metabolism of carbohydrates, into carbon dioxide [CAS: 124-38-9] and water [CAS: 7732-18-5]. The metabolic intermediates are degraded by combination of decarboxylation and dehydrogenation. It is the major terminal pathway of oxidation in animal, bacterial, and plant cells. Recent research indicates that the TCA cycle may have predated life on earth and may have provided the pathway for formation of amino acids.

TCP (TRANSMISSION CONTROL PROTOCOL). See **Transmission Control Protocol (TCP) / Internet Protocol (IP) Suite**.

***t* DISTRIBUTION.** If $\overline{x}$ is the mean of n independent observations, from a normal population with mean zero, and if s^2 is an estimate of the population variance based on the sample variance with $n - 1$ degrees of freedom, the quantity $t = \overline{x}/s$ has the distribution

$$\frac{\Gamma\left(\frac{1}{2}n\right)}{(n\pi)^{1/2}\Gamma\left(\frac{1}{2}n - 1\right)}\left(1 + \frac{t^2}{n}\right)^{-1/2(n+1)}, -\infty < t < \infty$$

The t distribution is the basis for significance tests and confidence of fiducial statements referring to means, regression coefficients, and so on. It does not depend on the variances of the normal population.

***T* DISTRIBUTION.** A generalization, due to H. Hotelling, of the t-distribution to multivariate statistics. Given n values of the p variables $x_1, x_2, \ldots, x_p$ let D_{jk} be the inverse of the dispersion matrix. Define

$$T^2 = n\sum_{j,k=1}^{p} D_{jk}\overline{x}_j\overline{x}_k$$

Then T^2 has, in samples from a multivariate normal distribution, the distribution

$$dF = \frac{1}{B\left\{\frac{1}{2}(n-p), \frac{1}{2}p\right\}}\frac{\{T^2/(n-1)\}^{\frac{1}{2}(p-2)}}{\{1 + T^2/(n-1)\}^{\frac{1}{2}(p-2)}}d\{T^2/(n-1)\}$$

TEA *(Camellia sinensis; Ternstroemiaceae)*. The tea plant is an evergreen shrub probably indigenous to China, where it has been cultivated since early times. The plant possesses alternate elliptical leaves which when mature are tough, and vary in length from 2 to 5 inches (5 to 12.5 centimeters). The flowers are axillary and appear singly or in small groups. They are white, slightly fragrant, and about an inch in diameter. Each flower has numerous stamens and a single pistil composed of three carpels. The fruit is a woody capsule containing three large seeds.

For successful growth, tea must be planted in regions having abundant rainfall. In China, most of the tea plants are grown on small farms. The plants are grown from seed or from nursery stock and begin to yield crops when 3 or 4 years old, continuing to do so thereafter for 50 years. The young shoots appear in flushes, growing rapidly for a time. From these flushes are picked the young leaves used for tea. Several flushes occur each year.

TEAK TREE *(Tectona grandis; Verbenaceae)*. The teak tree is tall, with very rough-surfaced oblong leaves from 10–20 inches (25–51 centimeters) long and 8–15 inches (20–38 centimeters) broad, and small white or blue-tinted flowers borne in large panicles. The tree is native in the tropics of Asia and is frequently grown in plantations in India, Java, and other Asian countries for its hard wood. This wood is very durable and much used in shipbuilding and in the making of fine furniture. The wood is very heavy and dries slowly. Drying is hastened somewhat by girdling the tree at the base and leaving it standing for a year or more. During this time it dies and dries out, after which it is felled and floated to the shipping port.

An adult teak tree may attain a height of from 75 to 100 feet (23 to 30.5 meters). The tree grows quite slowly. The wood is similar in coloration to the black walnut, being yellowish-golden brown. The durability of the wood is dependent largely upon the locale of the tree. The weight per cubic foot is approximately 40 pounds (641 kilograms per cubic meter). While the wood is similar to walnut in many respects, the tree per se resembles an oak. African teak is a term used for the wood from the *Chlorophora excelsa*, also called *iroko*, which grows well in parts of western Africa. Surinam teak is from *Hymenea courbaril*, a tree found in the West Indies and northern coast of South America. Australian teak is from the *Flindersia australis*, which grows in New South Wales. Most of the wood from the southeastern Asian countries is from *Dipterocarpus tuberculatus*.

TEAL. See **Waterfowl**.

TEARDROP BALLOON. A sounding balloon which, when operationally inflated, resembles an inverted teardrop. This shape was determined primarily by aerodynamic considerations of the problem obtaining maximum stable rates of balloon ascension.

TEARS. Tears are the salty fluid that lubricates and helps protect the cornea, the membrane that covers the front of the eye. Tears flow into the eye through ducts from tiny glands located under the upper eyelids and are spread over the eye each time a person blinks, which is about every six seconds. Tears keep the eye moist and free of dust and other eye irritants.

Tears drain into tiny openings on the edge of the upper and lower eyelids that lead to the nasolacrimal tear ducts near the bridge of the nose. From there, they are channeled into the nasal cavity where they are either swallowed or drain through the nostrils. That is why the nose runs when one cry. When eyes are irritated, they produce additional tears called reflex or irritant tears. Emotional tears are produced when a person is are either happy or sad. Excess tears often overflow the lower lid and run down the cheeks.

Tears provide five functions.

1. Keeping the epithelium moist, thereby protecting the outer covering of the eye from damage because of dryness.
2. Creating a smooth optical surface on the front of the cornea.
3. Acting as the main supplier of oxygen and other nutrients to the cornea.
4. Carrying waste products away from the cornea.
5. Providing enzymes that destroy bacteria that can harm the eye.

Normal tears that cover the corneal surface comprise three layers:

The *lipid*, or oil layer, which is the outer layer of the tear film and helps prevent the lacrimal layer beneath it from evaporating or overflowing the lower eyelid.

The *lacrimal*, or watery layer, which is the middle layer and contains salts, proteins, and an enzyme called lysozyme that actually protect and nourish the eye.

The *mucoid*, or mucus layer, which is the bottom layer of tears. It contains cells called goblet cells that cause the tears to adhere to the eye.

All three layers of tears are necessary for proper lubrication.

When an eye produces too few tears or tears of faulty composition, a condition called dry eye results. Ironically, one of the symptoms of dry eye can be excessive watering of the eyes. The watering is a natural reflex caused by irritation to the eye because the composition of the tears is wrong. In addition, if one has dry eye, the eye can feel scratchy, dry, irritated, or generally uncomfortable.

An eye doctor diagnoses dry eye by measuring production, thickness, and chemical makeup of the tear film. To treat dry eye, use a tear substitute, also called artificial tears. Administered several times a day, artificial tears bring relief in most cases. If left untreated, dry eye can damage eye tissue and possibly scar the cornea.

When artificial tears do not sufficiently lubricate your eye, an eye care professional may insert a small plug in the corner of the eye to slow drainage and loss of tears. In rare cases, the eye doctor may recommend surgery.

Vision Rx, Inc., Elmsford, NY

TECHNETIUM. [CAS: 7440-26-8]. Pronounced tek-nee-s(h)ee-um, chemical element symbol Tc, at. no. 43, at. wt. 98.906, periodic table group 7, mp 2172 °C (3942 °F), bp 4877 °C (8811 °F), does not occur in nature. The chemical properties of this silvery grey, radioactive, crystalline transition metal are intermediate between rhenium and manganese. This element is unusual among the lighter elements because it has no stable isotopes and is therefore extremely rare on Earth. Its short-lived isotope Tc-99m is used in nuclear medicine for a wide variety of diagnostic tests. Tc-99 is used as a gamma ray-free source of beta particles, and its pertechnetate ion (TcO_4^-) could find use as an anodic corrosion inhibitor for steel.

Technetium has been detected in certain stars and this discovery must be resolved with current theories of stellar evolution and element synthesis. In 1952 astronomer Paul W. Merrill in California detected the spectral signature of technetium (in particular, light at 403.1 nm, 423.8 nm, 426.8 nm, and 429.7 nm) in light from S-type red giants. These massive stars near the end of their lives were rich in this short-lived element, meaning nuclear reactions within the stars must be producing it. This evidence was used to bolster the then unproven theory that stars are where heavier elements are produced. More recently, it provided evidence that elements were being formed by neutron capture in the s-process.

The claims of discovery of this element are extensive. For a number of years there was a gap in the periodic table between molybdenum (element 42) and ruthenium (element 44). Many early researchers were eager to be the first to discover and name the missing element; its location in the table suggested that it should be easier to find than other undiscovered elements. It was first thought to have been found in platinum ores in 1828and was named polinium but it was actually impure iridium. In 1846 the element ilmenium was claimed to have been discovered but was determined to be impure niobium. This mistake was repeated in 1847 with the 'discovery' of pelopium. Dmitri Mendeleev predicted that this missing element would be chemically similar to manganese and gave it the name ekamanganese.

In 1877 Russian chemist Serge Kern reported discovery of the missing element in platinum ore. Kern named what he thought was the new element davyum, after the noted English chemist Sir Humphry Davy, but it was determined to be a mixture of iridium, rhodium and iron. Another candidate, lucium, followed in 1896 but it was determined to be yttrium. Then in 1908 the Japanese chemist Masataka Ogawa found evidence in the mineral thorianite for what he thought indicated the presence of element 43. Ogawa named the element nipponium, after Japan (which is *Nippon* in Japanese). Later analysis indicated the presence of rhenium (element 75), not element 43.

German chemists Walter Noddack, Otto Berg and Ida Tacke (later Mrs. Noddack) reported the discovery of element 43 in 1925 and named it masurium (after Masuria in eastern Prussia). The group bombarded columbite with a beam of electrons and deduced element 43 was present by examining X-ray diffraction spectrograms. The wavelength of the X-rays produced is related to the atomic number by a formula derived by Henry Moseley in 1913. The team claimed to detect a faint X-ray signal at a wavelength produced by element 43. Contemporary experimenters could not replicate the discovery, and in fact it was dismissed as an error for many years. It was not until 1998 that this dismissal began to be questioned. John T. Armstrong of the National Institute of Standards and Technology ran computer simulations of the experiments and obtained results very close to those reported by the 1925 team; the claim was further supported by work published by David Curtis of the Los Alamos National Laboratory measuring the (tiny) natural occurrence of technetium. Debate still exists as to whether the 1925 team actually did discover element 43.

Discovery of element 43 has traditionally been assigned to a 1937 experiment in Sicily conducted by Carlo Perrier and Emilio Segrè. The University of Palermo researchers found the technetium isotope ^{97}Tc in a sample of molybdenum given to Segrè by Ernest Lawrence the year before (Segrè visited Berkeley in the summer of 1936). The sample had previously been bombarded by deuterium nuclei in the University of California, Berkeley cyclotron for several months. University of Palermo officials tried unsuccessfully to force them to name their discovery panormium, after the Latin name for Palermo, *Panormus*. The researchers instead named element 43 after the Greek word *technétos*, meaning "artificial", since it was the first element to be artificially produced. The reaction was ^{96}Mo$(d, n)^{97}$Tc. The isotope with the longest half-life, ^{99}Tc (half-life $= 2.12 \times 10^5$ years), is found in relatively large amounts among the fission products of uranium. It is also produced by neutron irradiation of ^{98}Mo, by the reaction

$$^{98}\mathrm{Mo}(n, \gamma)^{99}\mathrm{Mo}(\beta - \mathrm{decay})^{99m}\mathrm{Tc}(\mathrm{isomeric\ transition})^{99}\mathrm{Tc}$$

Significant quantities have been isolated and considerably larger quantities could be made available if applications for it were developed. A U.S. government-owned invention available for licensing concerns a method for recovering technetium from nuclear fuel reprocessing waste solutions. ^{99}Tc has found some application in diagnostic medicine. Ingested soluble technetium compounds tend to concentrate in the liver and are valuable in labeling and in radiological examination of that organ, and this was the basis of the early medical uses. However, the ideal nuclear properties of ^{99m}Tc have led to expanded usage in medical diagnostics. By technetium labeling of suitable compounds (or blood serum components), diseases involving the circulatory system and organs other than the liver can be diagnosed.

In all, sixteen isotopes of technetium have been reported of mass numbers 92–105, 107, and 108.

Superconductivity has been observed in technetium metal and in alloys based on technetium with additions of Pd, Os, Rh, Ru, Sn, V, Ti, Re, W, or C.

A study of the chemistry of technetium shows it to have, as expected, properties intermediate between those of its homologues manganese and

rhenium, the resemblance to the latter being perhaps greater than to the former. Like rhenium, technetium apparently exists in (IV), (VI), and (VII) oxidation states. Pure technetium metal has been prepared by passing hydrogen gas at 1,000 °C over the sulfide obtained by precipitation with H_2S from HCl solution. The metal has been shown to have the same crystal structure as rhenium and the adjacent elements osmium and ruthenium. Among its compounds are the ditechnetium heptasulfide, Te_2S_7, readily precipitated by H_2S from oxidized solutions, the corresponding oxide, Tc_2O_7 produced directly from the elements at higher temperatures, which reacts with NH_3 to form ammonium pertechnate, NH_4TcO_4, and the hexachloro complex ion, $TcCl_6^{2-}$, which like the corresponding rhenium ion, has a magnetic moment corresponding to three unpaired electron spins.

Tc-99m ("m" indicates that this is a metastable nuclear isomer) is used in radioactive isotope medical tests, for example as a radioactive tracer that medical equipment can detect in the body. It is well suited to the role because it emits readily detectable 140 keV gamma rays, and it has a short half-life of 6.01 hours (meaning it has almost completely decayed to Tc-99 in 24 hours). In the book *Technetium* by Klaus Schwochau, 31 different radiopharmaceuticals based on Tc-99m are listed for imaging and functional studies of the brain, myocardium, thyroid, lungs, liver, gallbladder, kidneys, skeleton, blood and tumors.

Immunoscintigraphy incorporates Tc-99m into a monoclonal antibody, an immune system protein capable of binding to cancer cells. A few hours after injection, medical equipment is used to detect the gamma rays emitted by the Tc-99m; higher concentrations indicate where the tumor is. This technique is particularly useful for detecting hard to find cancers, such as those affecting the intestine. These modified antibodies are sold by the German company Hoechst under the name Scintium.

When Tc-99m is combined with a tin compound it binds to red blood cells and can therefore be used to map circulatory system disorders. A pyrophosphate ion with Tc-99m adheres to calcium deposits in damaged heart muscle, making it useful to gauge damage after a heart attack. The sulfur colloid of Tc-99m is scavenged by the spleen, making it possible to image the structure of that organ.

Radiation exposure due to diagnostic treatment involving Tc-99m can be kept low. While Tc-99m is quite radioactive (allowing small amounts to be easily detected) it has a short half life, after which it decays into the less radioactive Tc-99. In the form administered in these medical tests (usually pertechnetate) both isotopes are quickly eliminated from the body (generally within a few days).

Health and Safety

All isotopes of technetium are radioactive but the element and its compounds do not occur in nature. Technetium plays no natural biological role and is not normally found in the human body.

Technetium is produced in quantity by nuclear fission, and spreads more readily than many radionuclides. In spite of the importance of understanding its toxicity in animals and humans, experimental evidence is scant. It appears to have low chemical toxicity, and even lower radiological toxicity.

When one is working in a laboratory context, all isotopes of technetium must be handled carefully. The most common isotope, technetium-99, is a weak beta emitter; such radiation is stopped by the walls of laboratory glassware. Soft X-rays are emitted when the beta particles are stopped, but as long as the body is kept more than 30 cm away these should pose no problem. The primary hazard when working with technetium is inhalation of dust; such radioactive contamination in the lungs can pose a significant cancer risk. For most work, careful handling in a fume hood is sufficient; a glove box is not needed.

TEHUANTEPECER. See **Winds and Air Movement**.

TEJU *(Reptilia, Sauria; Tupinambis)*. A large lizard of the West Indies and South America. Lives in the forests near water but is not aquatic. It reaches a length of a yard, with long slender tail and heavy forequarters. It is chiefly olive and black.

TEKTITE. Tektites (from Greek *tektos*, molten) are a small (usually walnut-size), rounded, pitted, jet-black to olive-greenish or yellowish body of silicate glass of nonvolcanic origin, found usually in groups in several widely separated areas of the earth's surface and apparently bearing no relation to the associated geologic formations. Their chemical compositions are similar to both granite and impure sandstone (greywacke) or soils of these compositions, being high in silica (68–82%) with 10–14% alumina and lesser iron, magnesium, calcium, potassium and titanium. Their composition is unlike that of obsidian and more like that of shale.

Tektites do not contain any water. They can be mistaken for obsidian or pitchstone (black volcanic glasses), but these will emit some water on strong heating. With a hardness of 6-7 on Moh's scale, tektites will easily scratch window glass. They have a density range of 2.2 (Libyan glass) to 2.8 (Moldavites), but are usually 2.4 to 2.5 grams per cubic centimetre. This is a little lighter than quartz beach sand. Human built objects can be mistaken for tektites, particularly molten bottle glass, glass marbles, and black buttons. Many of these will not have the correctly-shaped rims, symmetrical structures or colours of real tektites, while others will be too heavy or too light.

The streamlined shapes of many tektites suggest a rapid movement through the atmosphere under low gravity conditions, with melting early in their formation. About 30 distinctly different shapes have been described. They start as a molten blob projected through our atmosphere, then 'freeze' into a shape as they solidify. The shape depends on whether the initial molten blob was rotating, and the speed of rotation. The spherical and button types (common in Australites) had no or very little rotation with a fairly steady flight path direction. Their rear surfaces were more protected from heat, but the front surface, facing the flight direction, melted and was pushed towards the rear, piling up to form ridges and a rim or flange. These 'flanged button' shapes have been copied artificially at the Corning Glass Company in America, where molten glass spheres were placed in the jetstream of a wind tunnel. The tear-drop shapes formed from stretching and breaking apart of rapidly rotating, elongated dumb-bells. Flat disks, ovals and boomerang shapes have all been found.

Tektites are geologically young, with a range of about 300,000 years to 35 million years. Many Australites are 610,000 to 750,000 years old. The North American tektites have been dated at 34.5 million years, and the Libyan Desert glass at 28 million years. The Bohemian and Moravian sites are dated at 14.7 million years, Aouelloul Crater at 3 million years and Ivory Coast tektites at about 1 million years.

Tektites are named geographically, i.e. Australites (Australia), Indochinites (Thailand & Cambodia), Thailandites (Thailand), Philippinites and Rizalites (Philippines), Javaites (Java), Billitonites (Billiton Island, Indonesia), Moldavites (Vltavins) from the Czech Republic and Slovakia, Bediasites (Texas, U.S.A.), Georgiaites (Georgia, U.S.A.), and Irgizites (Irgiz, C.I.S.).

Over 600,000 tektites have been found in south-east Asia (heaviest 15 kg (33 lbs) and about 100,000 in Australasia (heaviest 0.4 kg (0.88 lb). About 2,000 (heaviest 91 g (3.2 ounce) have been found in the Caribbean-North American strewn field; 55,000 (heaviest 0.5 kg (1.1 lb) from Bohemia and

Moravia and 200 (heaviest 79 g 2.8 ounce) from the Ivory Coast, West Africa.

Some authorities believe that tektites are of extraterrestrial origin, or alternatively the product of large hypervelocity meteorite impacts on terrestrial rocks. The term was proposed by Suess in 1900 who believed they were meteorites which at one time had undergone melting.

TELECENTRIC SYSTEM. A telescopic system having the aperture stop at one of the foci of the objective lens. If the aperture stop is placed at the focus on the side of the image, the system is "telecentric" on the side of the image. If the aperture stop is placed on the side of the object, the system is "telecentric" on the side of the object. This is useful in measuring telescopes, since a slight change from exact focus will not greatly change the apparent size of the object.

With a telecentric system, either the entrance or the exit pupil is at infinity. See also **Telescope (Astronomical-Optical)**.

TELEOPERATION. As defined by Bejczy, "Mechanical activities performed by mechanical devices at a remote site under remote control." A rather comprehensive review of the history and current state of the art is given in Bejczy's article in *Science*, **208**, 1327–1334 (1980).

TELEOSTEICA. Suborder of the *Osteichthyes* (bony fishes). Includes all species with exception of *Chondrosteica* (sturgeons and lobedfinned fishes); *Holosteica* (alligator gars and bowfins); and *Choanichthyes* (coelacanths and lungfishes).

TELEPHONY (Telecommunications). Telephony is the technology of communicating speech and other sounds between telephones or other terminals, using analog or digital signals transmitted via electrical, wireless, or lightwave circuits. When the circuits also carry data, facsimile, or video signals, the combination is known as *telecommunications*. See also the **Satellites (Communication and Navigation)** entry and numerous other articles in this encyclopedia which relate to communications.

Early History of Telephony

As early as 1667, Robert Hooke (England) transmitted sounds mechanically over a distance of several meters by way of an extended wire. Charles Bourseul (France), in 1854, introduced the concept of a diaphragm for making and breaking electrical contacts when the diaphragm was vibrated by sound waves, but was unsuccessful in converting the electrical pulses back into sound. However, his work introduced the concept of a microphone, one of the key components of a telephone. Johann Philipp Reis (Germany), working on the basis of Bourseul's concept a few years later, developed a collodion membrane which, when vibrated by sound waves, interrupted a battery circuit. Because he lacked financial backing, and since Germany at that time lacked a credible patent protection system, Reis was frustrated in his efforts to achieve a marketable device that replicated the human voice.

It was not until the research of Alexander Graham Bell during the 1870s that a practical system capable of conducting the human voice over a distance with reasonable quality and timbre was achieved. Bell was granted a United States patent[1] in 1876 and the first commercial telephone exchange was installed in New Haven, Connecticut. See Figs. 1, 2, 3, and 4. It is of interest to note that the initial purpose of Bell's experiments was to develop a 'Harmonic Telegraph, "with which six or eight Morse messages could be sent on a single wire at the same time without interference. The machines did not work as well as Bell had hoped, but further experiments by the team of Bell and Thomas Watson accidentally discovered how to make a current of electricity vary in intensity to match the variations of sounds in air.

Bell's first telephone was called a "*gallows*" because of its resemblance to that structure. The commercial version was the "*iron box*" (possibly the

[1] It is interesting to note that later on the same day in 1876 (February 14), the U.S. Patent Office also received an application for patent from Elisha Gray, who in 1867 had received his first patent on a self-adjusting telegraph relay. This is an example of that rare human phenomenon, simultaneous invention. This is well-detailed by Hounshell (1981).

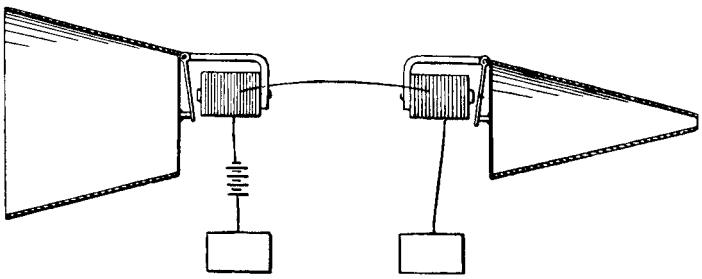

Fig. 1. Illustration from U.S. Patent 174,465, issued to Alexander Graham Bell on March 7, 1876. The transmitter, a receiver, and a connection between them illustrates the basic principle of the "Electric-Speaking Telephone." (*AT&T.*)

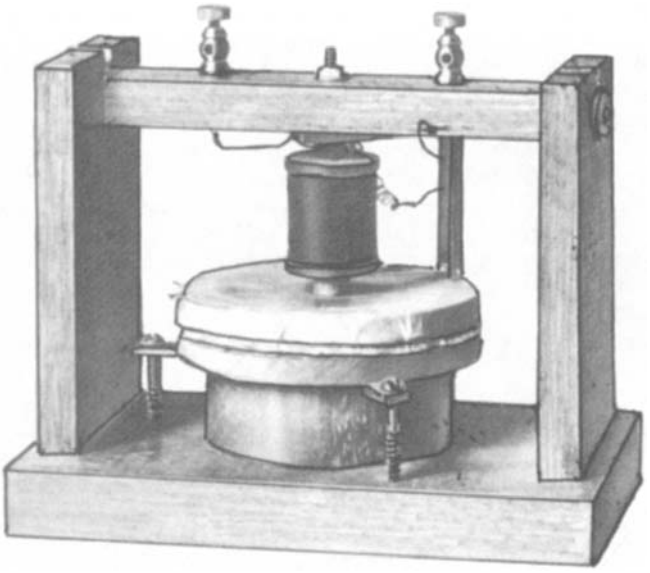

Fig. 2. First attempted telephone transmitter with its parchment diaphragm attached to the magnetized metallic reed. This instrument, sometimes called a "gallows telephone" because of its resemblance to that device, was used to transmit the first speech sounds electrically. While Bell was experimenting with vibrating reeds, he was shaping the concept that a current might be given the form of a sound wave (analog). When one of his transmitting reeds by accident generated an undulating current — a sound-shaped current — instead of an intermittent current, and he heard the corresponding sound as he listened to the receiving reed, he realized that he was on the track. This experiment was conducted on June 2, 1875. (*AT&T.*)

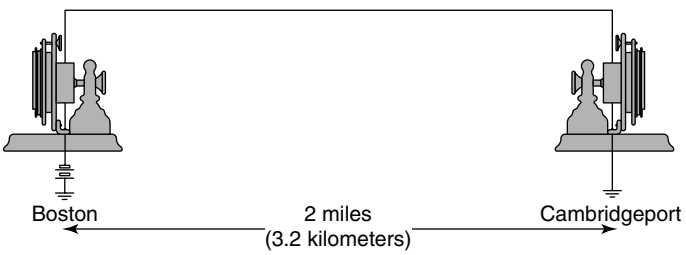

Fig. 3. The circuit and instruments used by Bell on October 9, 1876 in a trial of two-way telephoning over a private telegraph wire between an office in Boston and a factory in Cambridgeport, Massachusetts. This was the first time that satisfactory and sustained conversation was carried on by electrical means between persons a considerable distance apart. (*AT&T.*)

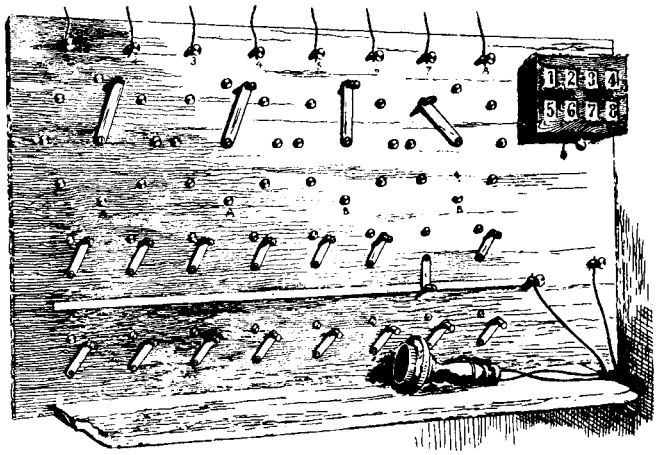

Fig. 4. Sketch of first telephone switchboard installed in New Haven, Connecticut in January of 1878. This board served 21 customers over 8 lines. The primitive switchboard used multiple-contact switches and a magnetic annunciator or "drop" (shown in upper right) to indicate that a connection was wanted. (*AT&T.*)

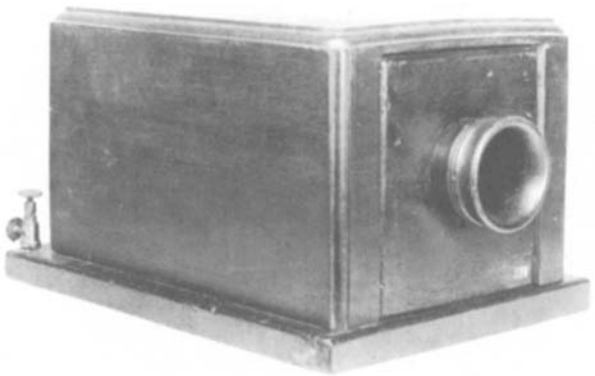

Fig. 5. First commercial telephone (1877). The round, cameralike opening on the boxlike instrument served as transmitter and receiver and thus required mouth-to-ear shifts when conversing. Developed in the fall of 1876, it was introduced to customer service when a Boston banker leased two instruments. These were attached to a line between the banker's office and his home in Somerville, Massachusetts. (*AT&T.*)

first *black box* of technology), of which some 6,000 units were built for customer use. The device did not have a ringer or a dial; it was connected by iron wire to another black box. A user simply shouted into the telephone to attract the attention of someone at the other phone. An electromagnetic converter alternately served as a transmitter and receiver. The next model was the "*butterstamp*" phone, in which a corded wire extending from the box ended with a device that resembled a kitchen implement used in the 1800s to mold patties from bulk butter. The device was alternately held to the mouth when speaking into the phone, or to the ear to hear the other party's voice. Subsequently, a wall-mounted box (called "Williams's coffin" after its maker) used two handheld "butterstamps," one for speaking into and the other for listening.

Until 1894, every phone had its own power source on the customer's premises. This was a wet-cell battery, replaced by a common battery housed in the central exchange. A crank sometimes was used to turn a magneto, sending an electrical signal to the operator. Although the first phones had no ringers, some form of alerting the called party was desirable and thus Watson designed a "*thumper*," a small hammer inside the telephone box and operated with an external knob. That was followed by a buzzer, then by the polarized call bell, which remains a basic design for present ringers.

Within 15 years of Bell's invention, telephone technology was able to meet the designer's long-range design goals — instruments with a usable quality of speech, efficient enough to transmit over a useful distance, simple enough to require no special training, stable enough to need little maintenance or adjustment, and producible by the thousands at a small unit cost. A montage of telephone equipment used prior to the 1930s is given in Figs. 5–11.

While the development of the telephone instrument was vital to the new field of telephony, other factors also were important. The telephone sets had to be connected by wires and switchboards in cities and towns, and eventually the cities were interconnected as well. Long distance lines were constructed up and down the eastern coast of North America, and finally, in 1915, across the continent. (During the ceremonies inaugurating the first transcontinental telephone line on January 15, 1915, Alexander Graham Bell in New York City connected a replica of his 1875 gallows-type telephone to the line and repeated the first sentence ever spoken over the telephone, "Mr. Watson, come here, I want you." Thomas A. Watson, Bell's former assistant, was in San Francisco for the occasion and replied that it would take him a week to get there.)

The man chiefly responsible for driving the expansion of telephone service during the years 1907 through 1920 (the year of his death) was Theodore N. Vail, AT&T's president, who in 1908 created the term "Bell System" and originated the theme of "One Policy, One System, Universal Service." Vail's goal was to eliminate dual services by either buying competitive companies or abandoning the market to the competing service. Dual services referred to two competing companies in the same city, a situation which raised costs to telephone users, since

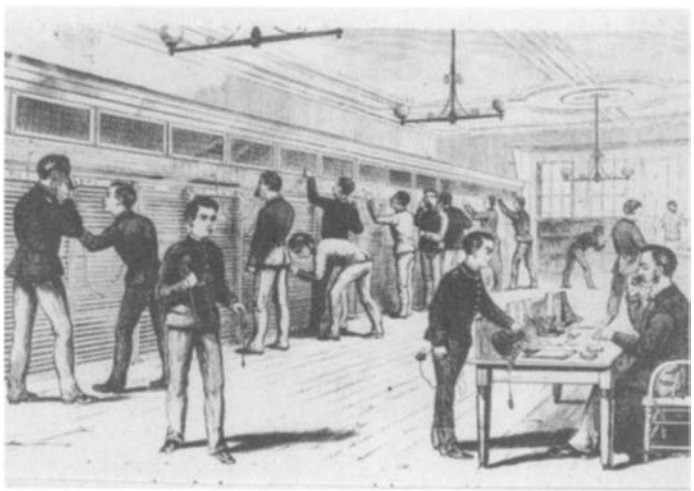

Fig. 6. An early telephone system receiving considerable use was that of the Gold and Stock Company, originally formed to broadcast stock market and banking reports by means of telegraph printers. A large switchboard used by the firm is depicted here. The operators were recruited from the ranks of telegraph messengers. (*AT&T.*)

they often had to subscribe to both services because the competing networks were not interlinked as they are today. Although the concept of assigning telephone service to a monopoly in each market disturbed some people, it remained a fact until the introduction of cellular wireless services in 1984, when the Federal Communications Commission (FCC) designated two competing entities to serve each cellular system market, and 10 years later added more wireless competitors in the field of personal communications services (PCS). Today, there are many competing long distance telephone services, and numerous wireless phone companies — but the wired local networks are still basically a monopoly in each market. There are legal and commercial efforts underway to change that monopoly.

Perhaps the most intensive research sponsored by the telephone companies and others was devoted to automating the call-routing system. Until the dial telephone was invented and automatic switches were introduced, all telephone calls — even those across town — had to be switched by operators plugging cords into sockets after asking what number was desired. The first operators were boys recruited from the ranks of telegraph messengers, but their manners proved to be too crude, so refined young ladies replaced them. As the telephone network expanded and thousands of switchboards were installed, the network planners could foresee the day when the use of human operators to connect long distance calls would become too unwieldy. For example, in the 1920s, the banks of operators in some large

Fig. 7. Magneto wall-mounted telephone set (1882). This handsome instrument, encased in oak and using the Blake Transmitter and Bell's hand receiver, was the first telephone built for the Bell System by Western Electric. It was in service for many years and was one of the first side-winder models on which a crank was turned to signal the operator. (*AT&T.*)

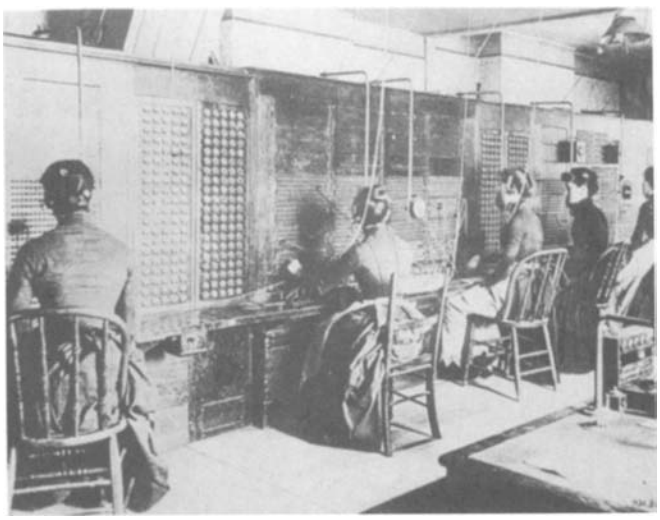

Fig. 8. Switchboard (1883) with operators seated on wooden chairs and separated by panels known as "annunciator drops" between operator positions. The annunciator drops indicated telephone lines requesting service. (*AT&T.*)

cities became so long that agile young ladies on roller skates were used to pick up call charge slips from individual operators to bring them to central desks so they could be sent by pneumatic tube to the billing department. By the 1950s, customers were provided with direct dialing across the North American continent, followed 20 years later by international direct dialing. Billing for toll calls became automated. Operators are now the exception rather than the rule in placing long distance calls, domestic or international.

Modern Telephony

Three basic groupings of equipment are used in modern telephony:

1. Customer premises equipment (CPE) such as corded and cordless telephones, facsimile or "fax" machines, office switchboards or PBXs, and desktop computer terminals or personal computers. Wireless cellular mobile telephones and personal communications services (PCS) pocket phones are included in this group.
2. Transmission equipment, such as metallic and fiber optic cables, wireless (microwave) radio systems and satellites in space.
3. Switching equipment for both local (or central office) exchanges and toll (or long distance) facilities.

Fig. 9. Desk telephone set (1897). In the early 1890s, the telephone began to assume the shape in which it remained familiar to users in North America for the following three to four decades. The ancestor of the upright desk set, shown here, represented a refinement of earlier models. The set was made of cast brass. (*AT&T.*)

Fig. 10. Dial telephone (1919). The first dial telephone exchange is credited to Almon B. Strowger, a mortician, who introduced it in LaPorte, Indiana in 1892. It was many years, however, before switching equipment was developed to permit dial installations in larger cities. Installations commenced in New York City in 1922. (*AT&T.*)

Fig. 11. Toll system operating room (1929) showing 800-line switchboard installed at the Illinois Bell Telephone Company. Note billing messengers on roller skates. (*AT&T.*)

This equipment is linked together as a network by an ingenious assortment of computers and software programs called *operations systems*[2]. Operations systems are software programs designed to help communications companies perform specific network maintenance and administration functions, such as management of customer records, billing, inventory updates, and generating usage forecasts. They also enable the introduction and use of automated customer services. The operations systems employed by telephone companies and other carriers help to improve the reliability of today's telecommunications equipment and services, balancing the ever-increasing complexity behind that equipment.

Because of rapid advances in the technology of telephony, these equipment groups are capable of far more than the traditional basic service, sometimes referred to in the communications industry as "*plain old telephone service*" or POTS. In addition to coping with a rapidly changing technology, the U.S. communications system user must now adjust to organizational changes as well[3]. Similar changes are occurring on other continents. Many countries throughout the world are restructuring their telecommunications organizations in order to match changing technologies to the needs and applications of customers for information services.

[2] Operations systems are not to be confused with *operating systems* such as the UNIX ® system or Microsoft's MS DOS system. *Operating systems* are software programs that manage a computer's hardware and software components, determining when and how to run programs, and are not pertinent to the operation of a communications carrier's network.

[3] The industry's basic structure in the United States was dismantled on January 1, 1984, when the Bell System's operating telephone companies were divested by court order from their parent firm, the American Telephone and Telegraph Company (AT&T). The telephone system serving the United States then included seven separate regional holding companies (RHCs)–Ameritech, Bell Atlantic, BellSouth, NYNEX, Pacific Telesis, Southwestern Bell Corporation, and US West–containing 21 of the 23 former Bell operating companies (BOCs). In recent years a number of mergers have reduced that number to four RHCs–Bell Atlantic, Bell South, Southwestern Bell Corporation (now SBC Communications), and US West. The largest single telephone operating company is GTE, which in 1991 merged with Contel Corporation to form the only nationwide local Telephone Company since the breakup of the Bell System. (In 1998, GTE agreed to merge with Bell Atlantic.) In addition, some 1200 other phone companies of various sizes (formerly called *independents*), serve local customers. Assorted inter-exchange carriers, sometimes called *long-distance companies*, are led by AT&T, MCI, and Sprint. The technology base for AT&T's systems and services is provided by AT&T Labs, since the Bell Telephone Laboratories organization in 1996 was spun off from AT&T with the former Network Systems Group (known for many years as Western Electric), which is now known as Lucent Technologies. Applied research and technical support for the regional holding companies of the former Bell System is now contained in each organization, since the former Bell Communications Research (Bellcore) organization was sold by them in 1998.

In the United States, the responsibility for determining communications standards is assigned to the American National Standards Institute (ANSI), while the authorization and monitoring of standards is assigned to the Federal Communications Commission (FCC). Although each local telephone company and long distance company is responsible for its own equipment maintenance and operation, the American telecommunications network still functions as a single technical entity for most users. A long-distance telephone call may use the facilities of several companies, but their involvement is usually "transparent" to the user, i.e., the call crosses various corporate, state and even international boundaries automatically. In fact, the combined facilities of the American network (which is usually referred to as the *Public Switched Telephone Network* or *PSTN*) have been called "the world's largest computer system," in which each telephone is a terminal that can access any other telephone (terminal), or be accessed from it, via the central system.

As of 1998, the United States telephone network served more than 160-million telephone lines (the actual number of telephones is unknown since a single line can have numerous extensions), more than any other nation in the world. The FCC reports that telephone subscribership nationwide amounts to 94 percent of US households, and has a reliability rating of 99.99 percent. If you, the reader, look around, chances are excellent you will see one or more telephones near you — in many cases, even if you are outdoors.

At the same time, the ratio of fixed telephones to mobile telephones has been changing rapidly. Researchers report that by 1998 there were 50 million *wireless* telephone subscribers in North America, a figure which continues to grow at a startling rate. Part of this domestic growth seems due to the American desire to be mobile rather than tied to a telephone cord.

However, there appears to be a different reason for the growth of wireless systems in other countries. Despite strong efforts in many nations to enlarge their wired phone networks (in 1994 some 38-million new wirelines were added to the world's networks, plus another 45 million new lines in 1995), in 1995 more than 43 million applicants in emerging markets were still on waiting lists for a telephone wireline connection, and the average waiting time was more than a year. In 1994 19 million *new wireless* subscribers were added throughout the world, and this escalated by another 33 million *new wireless* subscribers in 1995. Part of the international growth is caused by the difficulty of financing and constructing expansion of existing terrestrial wirelines.

Wireless systems based on cellular and/or communication satellite technologies provide virtually "*instant*" networks at relatively low cost, especially in difficult terrain. Experts predict that before 2000, there will be 200 million wireless phone users worldwide. This estimate may well be too conservative, depending on the success of new satellite telephone systems.

The growth of international telephone-call traffic averaged 15 percent per year between 1975 (4 billion minutes) and 1995 (over 60 billion minutes), according to the International Telecommunication Union (ITU). Because the world's telecommunications systems are vital to multinational businesses and governmental operations on a global scale, the United Nations is becoming increasingly important as a means to coordinate differing national systems standards. The ITU is a specialized agency of the United Nations, operating with five permanent organs: the ITU General Secretariat (sponsor of the World Administrative Radio Conferences that help write the International Radio Regulations); the Bureau of Telecommunication Development (providing technical support to developing nations); the International Frequency Registration Board (coordinating frequency usage by radio stations within different nations); the Telecommunication Standardization Bureau (TSB), created in 1992 as the replacement for the former Consultative Committee for International Telegraphy and Telephony (CCITT); and the Radio Communications Bureau (RCB), formerly the Consultative Committee for International Radio (CCIR).

Membership in these ITU organizations includes 181 governments, 88 "recognized operating agencies" or licensed network operators and service providers (such as AT&T, MCI, Sprint, British Telecom, France Telecom, Deutsche Telekom, etc.), 146 equipment manufacturers and scientific and industrial organizations, and 38 international organizations whose operations rely heavily on communications technology (i.e., airline companies, banks, stock exchanges, etc.). The task of developing global

standards is assigned to study groups, which can have up to 400 or more participants. These are divided into working parties for each specific area of work, and then subdivided into expert teams. The process is not conducive to expedited approvals, but given the global scale involved, that is to be expected. The reviews extend all the way from individual telephone sets to transoceanic cables and communications satellites. Some governments regard these "standards" as mandatory, while the United States and some other countries view them as "advisory."

An example of an ITU activity is the international numbering plan, developed in 1963 and based on the level of national telephone development forecast by each country for the year 2000. The plan allows a maximum number of 12 digits in the world number, including a single-digit World Zone (there are nine Zones), a two-digit country code if needed, a three-digit area code or two-digit city code, and up to seven digits for the exchange and telephone line number. The actual number of digits varies from country to country. Because of its size and the number of telephone access lines — almost 210 million or more than 41 percent of those in the world — North America was assigned a single digit Zone code (the numeral "1") shared by Canada and the United States, followed by a three-digit area code and the combined seven-digit exchange-and-line number.

In the 1983 Federal Court proceedings that divested the Bell Telephone companies from AT&T, a geographic patchwork of about 160 service areas (each known as a Local Access and Transport Area or LATA) was established across the United States. Wireline telephone service within each LATA is provided only by an authorized Local Exchange Company or LEC, which also is one of the two authorized cellular telephone providers (the other is a separate company) in each major market. The LEC may be either a Bell Operating Company (BOC) or one of some 1,200 "independent" companies. In the mid-1990s, a new wireless service known as Personal Communications Services (PCS) was permitted by the FCC in each city, but these service companies were established by lottery sales of frequency bands, conducted by the FCC. Service between LATAs or across several LATAs is provided by Inter-Exchange Carriers (IECs), also known as long-distance companies. LEC services are priced according to tariffs authorized by state public utility regulators, while IEC tariffs are partially regulated by the FCC.

There is a dark horse in the race for telephone subscribers: the Internet/World Wide Web. Although this amorphous network of personal computers, "servers" and data bases has been focused on linking computers for transmission of text, data, video and recorded sound, the temptation to include two-way voice telephony has been strong. The reason for the attraction is the absence of long distance charges based on the use of a circuit for a specific period of time. On the Internet/World Wide Web, access charges (by many different service providers) are often a fixed monthly fee, regardless of how long a connection may last or how far apart the participants are, even if they are on different continents. The drawback has been the technology — packet-switched transmission — which shreds the message into many small parts and scatters them through many different circuits on their way to its final destination where all the packets are reassembled into the message before delivery to the end customer. This works fine for text, video and recorded sound, but two-way speech is more sensitive to time anomalies caused by the translation from analog sound to digital packets and then from packets back to analog signals. As the technology continues to improve, the Internet/World Wide Web may cause significant drops in long distance telephone revenues — unless changes occur in the billing procedures by either the telephone companies or the Internet access providers. Ironically, many of the same physical transmission and switching facilities are used by both sides.

Customer Premises Equipment (CPE)

A telephone, or *station set*, is actually a *compact transmitter* and *receiver* of electrical signals, either from a wireline or through an antenna. As a transmitter, it uses either a carbon-granule button or an electret microphone that converts sound waves to an electrical signal, produced with analog techniques. See Fig. 12. This means that the electrical signal continuously matches a limited range of speech sounds with changes in amplitude and frequency. As a receiver, the set contains a miniature loudspeaker that converts the incoming electrical signal to analog sound waves, reproducing a limited range of audible voice frequencies that can instantly be identified

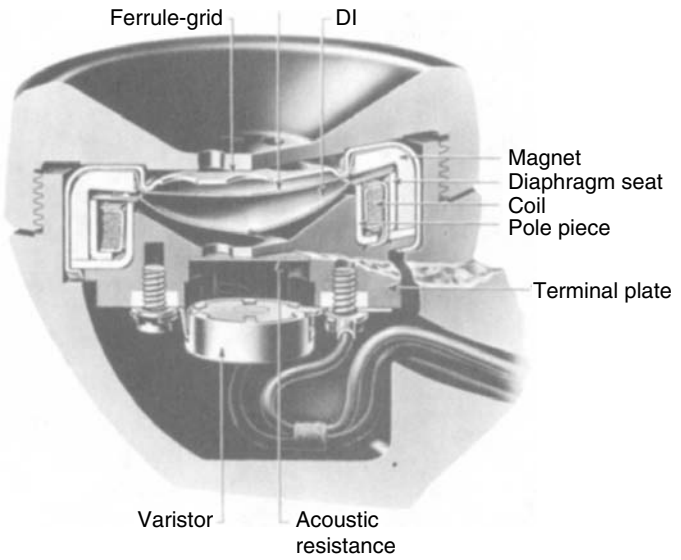

Fig. 12. Sectional view of handset of a touch-tone telephone. (*AT&T.*)

as a "telephone call." Digital telephones operate differently, using a microchip called a "*codec*" — for coder/decoder — to convert the analog speech frequencies into a series of digital number sets called "samples," each transforming the analog signal into an eight-bit digital code. Sampling is performed at the rate of 8,000 times a second, and the digital bits are transmitted and received at the rate of 64,000 bits per second in a network-quality system.

As of 1992, the approved digital voice bit rate could be as slow as 16,000 bits (16 kilobits) per second on wire or 8,000 bits (8 kilobits) per second for cellular wireless transmission/reception. Although a digital telephone may be connected to an analog line, using a device called a "*modem*," most digital phones are connected to digital transmission lines, either within a private network or provided by a telephone company as an extra-cost option.

In addition, the basic telephone apparatus includes a *switchhook* (which lets the power from the telephone line or the handset battery flow through the transmitter/receiver), an electromagnetic or electronic *ringer* (to announce incoming calls), and a *dial* for entering the customer identification number of the telephone being called. See Fig. 13.

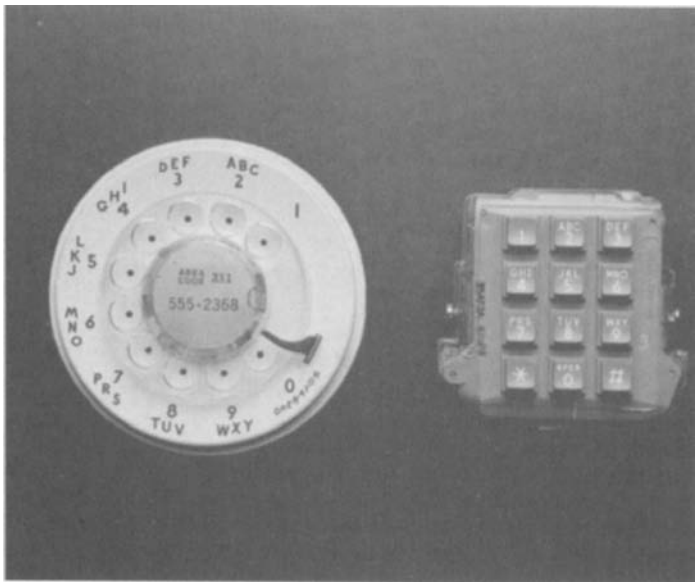

Fig. 13. Closeups of rotary dial configuration and touch-tone dial for desktop telephones. The pushbuttons on the touch-tone dial include special signals (*) and (#), which are used to activate special services provided in digital switches. (*AT&T.*)

In North America, most customer identification numbers consist of ten digits, comprised of a three-digit area code, a three-digit central office (local exchange) code, and a four-digit station number. Each digit is selected from a dial with ten digits, "1" through "0"; eight of these digits are accompanied by a three-letter group ("2" has "**ABC**," "3" has "**DEF**," "4" has "**GHI**," etc.). The letters originally were proposed as a coding method for dialing letters that suggested the exchange name, such as Murray Hill or "**PE**nnsylvania" (as in Glenn Miller's famous big-band tune, "**PE**nnsylvania 6-5000"). Today, the letters often are used as a mnemonic code for commercial names instead of numbers, i.e., **AIR-LINE**.

The digits "0" and "1" have other functions as well. "0" can be used to dial the telephone operator, while the digit "1" can be used to request extra service in long-distance and wide-area dialing, as described under **Switching Equipment** later in this article.

The dialing mechanism on the telephone is either *rotary* or *pushbutton* — often called *touch-tone*. The touch-tone dial is preferred when the user wants to access services associated with the digital telephone network already installed in the United States but still evolving around the world. Some telephones automatically dial a number at the touch of one button (so-called "speed dialing"). The repertory of numbers is stored in electronic memory within the telephone set. Many of these telephones automatically store the last manually dialed number and redial it when the user pushes a button.

A rotary dial usually has ten finger-holes in a rotating finger wheel mounted on a number plate. The user dials by selecting each numeral, turning the dial until the finger stop is met, and then releasing the finger wheel. The rotary dial signals the number being called by means of dial pulses, i.e., controlled interruptions (nominally ten pulses per second) of the 48-volt direct-current power supplied from the central battery serving that customer's area.

The touch-tone pad has 12 pushbuttons — digits "1" through "0", plus an asterisk or star (*) and a pound (#) sign for special services available from electronic switches in modern exchanges. Associated oscillator circuitry in the touch-tone dial phone generates tones in the *voiceband* range (a nominal bandwidth of 4000 Hertz, extending from a low of 300 Hz to a high tone of about 3800 Hz) used in telephony. Each touch-tone digit and symbol is uniquely represented by two tones, one from each of two mutually exclusive groups of four frequencies (a signaling type often called dual-tone multifrequency). The switch acts instantly on each numeral rather than waiting until all the numerals have been dialed.

The telephone switchhook is used to signal the status of the phone, i.e., *idle* or *busy*. When the telephone is idle, or *on-hook*, the switchhook contacts are open, and when the set is busy, or *off-hook*, the switchhook contacts are closed. These basic signals allow other equipment to recognize a call's origination, answer, and termination. The customer is alerted to an incoming call by a bell or tone ringer (or a light in some cases). If the customer picks up the phone to place a call, a *dial tone* must be heard that indicates that a connection exists to the telephone company's nearest exchange. Lack of a dial tone commonly means there is no connection. If a number is dialed, the caller can hear a signal indicating that the called phone is ringing, or if the phone is being used already, the caller hears a *line busy tone* consisting of an on-off buzzing sound with 60 interruptions per minute. A fast busy tone (120 interruptions per minute) indicates the network circuits are unavailable for the call being attempted.

Although the electrical signals representing the voice usually are transmitted over 48 volts of dc power (in wireline systems), the ringer is driven by a nominal voltage of 86 volts root-mean-square (rms) at 20 Hz superimposed temporarily on the telephone line at the switch in the central office or exchange. The power systems serving public telephone network circuits are usually independent of the electric utility lines in a given area, so most telephones can still be used in if the electric utility power is cut off, provided the telephone lines were not damaged. However, some types of customer premises equipment, such as electronic switchboards or answering machines, may depend on utility power for operation, so they may become inoperative if a power failure occurs.

Many shapes and styles of telephone sets are available to telephone customers. Some sets are adapted to the special needs of people with disabilities, such as extra-large dial buttons for the visually impaired, and handset volume controls for the hearing impaired, while others include speakerphones for hands-free conversations. Multikey telephones enable users to connect a single telephone set to a number of different telephone lines, or link a single telephone to various other extensions. *Call director* telephones function as a miniature office switchboard, allowing a receptionist or secretary, for example, to answer an incoming call and direct it to an appropriate desk. Electronic telephones often include a liquid crystal display (LCD) panel or light-emitting diodes (LEDs) that can show the user a number as it is being dialed or, in some systems, display an incoming caller's number before the telephone is picked up. So-called "smart phones" also have appeared in the 1990s. These are usually a combination of a telephone and a small computer with a miniature keyboard and LCD screen, capable of e-mail access and faxing as well as conventional voice calls.

Even the public coin telephone has been upgraded and now includes phones activated by inserting a special credit card that either identifies the user's billing account or automatically deducts the call charges from the card's built-in prepaid deposit. Some of the most sophisticated public phone facilities are in developing countries, where special booths are equipped with satellite telephone facilities capable of direct links to new multi-satellite "constellations."

In 1964, AT&T introduced the first public video-telephones, called the "*Picturephone*." They required a special telephone line between the Picturephone and the local switch, and each party on the circuit had to have a Picturephone in order to "enjoy" the black-and-white image, which was about equal in quality to that of commercial TV. For various reasons (the relatively high monthly charges, the need for a special phone line between the switch and each phone, and an individual reluctance to appear "on camera" whenever the telephone rang, among others) the market rejected the product. In 1992, new video telephones were introduced, allowing the user to simply plug the set into an ordinary telephone outlet; of course, the video transmission functions only when the other party also has a video telephone. Again, the product failed to inspire much public enthusiasm, for various reasons (the image quality was mediocre, with poor color and resolution, as well as limited motion, and the public was still reluctant to be seen whenever the phone rang). However, many companies have found it useful to equip or lease special meeting rooms with video cameras that enable groups of people in various facilities to conduct meetings by television via the telephone network, with the signals carried over temporarily leased terrestrial and satellite circuits, a procedure that saves travel time and expense for many participants.

In recent years, the *cordless* telephone has been introduced to business and residential users. This device is actually a small short-range radio set, in the form of a wireless battery-powered handset (or headset) with a short antenna stub, that sends to and receives from a nearby base unit plugged into a telephone wall outlet and a power outlet in the office or home. Depending on the design, the cordless phone can transmit over distances of a city block or more. This design allows the user freedom of movement while still being served by a wireline connection. However, the ringer does not operate if the handset's battery switch is turned off. The handset's wireless mode can operate with either analog or digital transmission, depending on the model selected. Some models employ a variety of optional security techniques to prevent or minimize unauthorized access by other nearby cordless phone sets.

Early cordless analog phones (ca. 1980s) and some modern, inexpensive models operate within a radio frequency range of 46 to 49 megahertz, which is susceptible to interference from various other electrical devices (baby monitors, computers, electric motors, etc.) as well as signal reflections or blockage due to building materials. Newer cordless telephones are designed to operate at 900 megahertz, which is much less prone to such problems. In addition, the newer telephones are available with various accessories such as headsets, answering machines, spare battery packs, speakerphones, caller identification, and even a flip-up LCD screen and computer keyboard on the base component, enabling sending and receiving of e-mail via the Internet. Most users are aware that the voice signal quality of cordless telephones is not as good as that of a wire line, due to signal compression techniques.

The battery of a cordless phone is in the transmitter-receiver handset, and is charged while the handset is resting on the base unit. When the battery power in the cordless handset drops too low, due to extended use, the phone will "go dead," so a conventional line telephone is recommended as a backup.

Another version of cordless or "mobile" telephones is designed to be used in vehicles such as cars, vans, and trucks. The communications industry reported that, by early 1991, more than five million customers were using such mobile telephone equipment, called "cellular" telephones. More information on this technology, called "*cellular*" telephones, is provided in the "**Transmission**" section of this article.

The wireless mobile telephone sets themselves have shrunk in size since the technology was introduced for the general public in 1946. Those early mobile telephones, accessing a single large antenna serving an entire city, required the handset to be wired to a large, bulky transmitter/receiver, usually installed in the trunk of an automobile. Today a cellular telephone unit need be no larger than a cordless handset, and includes the entire necessary transmitter and receiver components as well as the power supply. In fact, many users carry their cellular telephone with them in a briefcase or purse and use it while walking, shopping, riding in mass transit facilities, sitting in a car (although it is strongly recommended that the user avoid telephoning while driving the car), etc. This technology has revolutionized the communication habits and availability of many people, especially in the business community. Travelers with "*cellphones*" no longer have to search for a pay phone and businesses such as restaurants and luncheonettes find that offering patrons a cellular phone as a convenience can offset the cost of installing a pay phone booth. However, like the cordless telephones described above, the sound quality of a cellular transmission is usually lower than that of a wired line.

By 1990 a new form of wireless telephony began taking shape — the Personal Communications Network (PCN), also known as *Personal Communications Services* (*PCS*). The PCS customer uses a small, pocket-sized telephone equipped with a tiny stub antenna, similar in appearance to the cellular telephone, but different in its operation. In the PCS concept, a network of small radiotelephone relay antennas is spaced much more closely than conventional mobile-telephone cell sites (possibly mounted on alternate street lampposts, for example). The relatively weak signal from the PCS telephone is strong enough to reach the nearest cell antenna, which emits microwave radio signals at far lower energy levels than are needed for vehicular mobile telephony.

The battery of a PCS phone provides enough power for several hours of talk-time and 50 to 200 hours of standby time. By 1998, numerous models with many different features were available for purchase, and PCS networks were installed in many cities. Operating in the radio frequency range of about 2 gigahertz for customer connections, the PCS caller often is linked to cellular networks as well. PCS telephones are all digital, using either of two different signal coding methods, depending on the type of antenna used by the service provider. Like the cordless and cellular telephones, the PCS phones do not equal the sound quality of a wire line.

During the past few decades, customer equipment has been expanded to include signals other than acoustical sounds. These signals are generally classified as "*data*" because they consist of text or images coded as digital pulses. Generally, the data signals are received or transmitted by facsimile (fax) machines or personal computers. An electronic peripheral device called a *modem* (for MOdulator-DEModulator) is used to couple a digital[4] computer or terminal to an analog telephone line so it can exchange data with another computer or terminal. The transmission capacity of a modem is usually stated in "*baud*" or "*kilobits-per-second*." In 1998, the maximum transmission rate for consumer-market modems was about 56 kilobits/second, based on the technical limitations of a conventional four-wire telephone line, but scientists are pushing that barrier and aiming at transmission of multi-megabit signal streams over ordinary phone lines equipped with special terminals at each end. Two-way signal flow is known as *duplex* transmission (one-way voice transmission is called a *simplex* circuit, in which each speaker, when ready to cede the channel to the other person, says "over," and when the transmission is ended, says "Roger and out") and occurs on either a *dial-up* telephone line, accessed by manual or automatic dialing, or on a *dedicated* or *reserved* private line. When a telephone and a computer/modem combination share the same line, they cannot be used simultaneously except in special systems. In the late 1990s, some special arrangements were devised to enable voice transmission over the digital Internet and World Wide Web, which employ packet signal transmission rather than conventional dedicated circuits. Wireless modems are now available that permit portable computers to interface with wireless voice systems.

Computers generally operate with digital technology, so the modem converts the digital data signals into a form of analog signal, discrete in time value, that is suitable for transmission over analog voiceband circuits, and vice-versa for incoming data signals. Various speeds of operation, measured in bit-rate-per-second or "*baud*," are available, with the cost of the equipment rising as the rate increases. The fastest practical speed of a modem over normal telephone lines is about 56,000 bits (56 kilobits) per second. But some telephone lines are incapable of handling such data speed without causing transmission errors, so bit rates as slow as 300 baud are used, depending on economics as well as system considerations. The modem may provide an acoustical coupler, a cradle into which the telephone receiver is placed for transmission, or the modem may be wired directly to the telephone outlet. In addition to computer terminals and personal computers, modems also may be linked to facsimile machines used to transmit images of printed, typed, or illustrated documents. Many modern fax machines already have a modem built into their circuitry.

Fax machines are an example of the handicaps imposed by proprietary, incompatible standards. The effects of a change in such standards can be seen in what happened after the issuance in 1980 of the Group 3 facsimile standard, which suddenly enabled different brands of fax machines to communicate with each other. Prior to this, a Brand X machine could not send or receive a fax involving a Brand Y or a Brand Z machine. Fax machines that previously were installed only in corporate mailrooms suddenly appeared in individual offices and in small businesses, even pizza parlors, and in homes as well. All that had been needed was a standard to overcome the same-brand hurdle that blocked universal application of the technology.

Earlier fax machines required six minutes to transmit a single page at a nominal resolution of 100×100 dots per inch. With the Group 3 standard, transmission time for a typical business letter is 20 to 30 seconds per page, and resolution is adjustable to as fine as 200 dots per inch vertically and horizontally. (A Group 4 facsimile standard was set in 1984, designed for use with digital networks, in particular the *Integrated Services Digital Network* or *ISDN*, at resolutions of up to 400 dots per inch and transmission speeds of 56 or 64 kilobits per second.)

Other CPE items linked to telephone lines include: teletypewriters; private branch exchanges (PBXs, both manual and automatic) that resemble small exchange switches and link private telephone extensions, such as in an office, hotel, or hospital, to each other and to the public switched network; key system sets (often found on receptionists' desks); and various sensors, monitors, and alarms. Until recently, all these devices used analog signal techniques to link to an analog telephone line. However, modern PBX systems, capable of handling up to 100,000 lines or extensions, can link directly into a digital telephone trunk. The analog-to-digital (A/D) or digital-to-analog (D/A) conversion takes place inside the PBX instead of in a modem at the telephone.

Business customers and other organizations that do not want to install a PBX on their premises can use a telephone company service called *Centrex*, in which their telephones are connected to a reserved portion of the telephone company's local exchange switch. Incoming and outgoing calls are handled by the Centrex system as if it was an on-premises PBX.

Digital communications lines on customer premises are usually part of private networks called LANs (*Local Area Networks*) with circuits that are not switched by public network equipment. However, digital switched lines are becoming more prevalent on customer premises as a concept of telephony, called *Integrated Services Digital Network* or *ISDN*, is accepted by businesses and organizations — and residences as well. Special new telephones, known as ISDN sets and often paired with personal computers

[4] Digital signals are a method of coding a transmission with binary digits, i.e., 1 and 0, in which each components of the signal is structured as a "*bit*" and assembled with other bits into a "*byte*," which in turn is assembled into a "*word*." Analog signals that make up the voice signal for telephony are limited to a bandwidth of 4000 Hertz, including control signaling; when coded as a digital signal, the voice transmission frat for network quality on a wireline is 64 kilobits per second. Because human speech is analog in nature, the digital signal must be decoded before it can be heard by human ear.

or other terminals, permit direct connection to digital lines via universal wall outlets, and can be moved from one location to another without rewiring telephone lines or making other changes in the system. Modems are not necessary when digital equipment is connected to a digital line. Elimination of the analog/digital conversions improves the quality of end-to-end digital data transmission.

A very special telephone set, now available only to authorized agencies of the U.S. federal government, is certified by the National Security Agency as a secure telephone terminal. Its genesis was the innovation of radio-telephony between Los Angeles and Santa Catalina Island in 1920. At that time, persons with radio receivers could listen in to the wireless telephone conversations, so a transmitter/receiver system was devised that "*scrambled*" frequency bands to prevent unauthorized eavesdropping. Scrambler phones were commonplace in military operations in World War II, but enemy engineers quickly found ways to decode these radio voice transmissions. A unique radio scrambling system known as SIGSALY (and often called "*The Green Hornet*" because the signal sounded like the buzzing theme of a popular radio program) eventually was developed by Bell Laboratories for use by President Franklin Delano Roosevelt and Prime Minister Winston Churchill; the system's voice-coding technique remained unbroken for the duration of the war and many years after.

Today's secure telephone units, available from several manufacturers, are known as the STU-III model and use digital voice-compression techniques as well as controlled access systems. STU-III terminals can make ordinary calls if so desired, but with the use of a crypto ignition key (equipped with a memory chip that unlocks the phone's security features) they can encrypt/decrypt voice, data, and fax transmissions as well as scanned photographs and other graphics. Variations on the secure telephone units are available for state and local governments, as well as for commercial applications in the U.S. and abroad.

Transmission Equipment

Signals used in telephony and telecommunications are carried on a variety of media. These include metallic wires, terrestrial and satellite microwave channels, and optical fiber or lightwave systems.

At the customer premises, the customary link is called *telephone station wire*, which is a four-conductor color-coded copper wire in a plastic jacket, suitable for installing inside walls or structures. Between the handheld receiver-transmitter and the body of the telephone set is a coiled cord that usually is modular (i.e., it can be unplugged at both ends and replaced by another cord of similar design or different length). Today, the station wire between the body and the telephone line in the wall also is modular, allowing easy replacement of the cord with a selection of lengths. Premises wiring is of the twisted pair cable type when it carries signals from several sets on separate circuits; the wires are twisted to minimize the accidental mixing by induction of two separate signals, which would produce "*cross-talk*."

Local Telephone Loop. The wiring between the customer premises and the switch in a local exchange office is called the loop. See Fig. 14. In its simplest arrangement, this wiring is connected directly from each premises to the switch, establishing a single-party line. (Before World War II, many residential telephones were on multiparty circuits or so-called *party lines*, in which up to ten different telephones shared the same line. Distinctive rings enabled subscribers to identify who was being called — but privacy depended on the cooperation of the party-line customers, who could listen in on other conversations if they so chose. By 1981, multiparty lines were rare; about 97 percent of the former Bell System was single-party in 1984 when the Bell companies were divested from AT&T.

Most loops today are arranged in a tree-like structure. A paired cable is the primary transmission facility in the loop network. Individual drop cables connect to a distribution cable that combines a number of customer wire pairs. The distribution cables in turn are connected to feeder cables. Near the central office serving the loop, the analog feeder cables are generally quite large — 1200 to 3600 wire pairs.

To reduce the number of cables required, digital loop carrier systems use digital multiplexing and transmission techniques, thereby enabling a number of customer loops to share a smaller number of wire pairs and electronics. This is done by using analog/digital conversion and

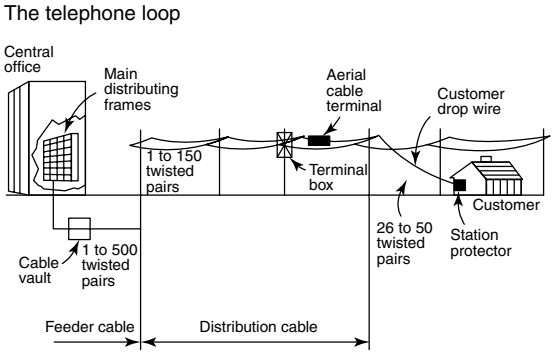

Fig. 14. Local telephone loop connects customer's premises with the local switching machine. The loop is actually an insulated pair of wires protected from the elements by a cable sheath. Telephone cables contain many such "pairs" and these cables may be buried in underground conduit, strung on poles, or buried directly in the ground. Telephone personnel usually refer to "*feeder*" and "*distribution*" cable. Feeder cable runs from the central office through major population centers to a given geographical area. At various points, the distribution cable branches off from the feeder cable, bringing cable pairs closer to the customers. Distribution cables themselves may branch into smaller entities. Each of these cables is separately identified in telecommunications company records and in the predictive system's database. The system attempts to locate a cable failure by correlating trouble messages with different cables and combinations of pairs. For example, it may point to a failure in either the feeder cable or in a segment of the distribution cable, or both. This information helps identify where the outside craft personnel should begin to look for the problem (*AT&T*).

time-division multiplexing at a collection point in the loop, between the customer premises and the switch. This equipment is small enough to fit individual systems onto a pedestal but is often installed underground. Customer signals are transmitted digitally from the loop carrier remote terminal to the exchange office, called the *central office* or *CO*.

The communication link is usually a T1 digital carrier system, with a transmission capacity of 1.544 million bits (megabits) per second (Mb/s). An individual T1 carrier, composed of two wire pairs and regenerators, can handle 24 voiceband channels, each rated at 64,000 bits (64 kilobits) per second, or 64 kb/s. The first T1 digital carrier, a short-haul (metropolitan area) system using paired cable, was introduced into the network in 1962 near Chicago, IL. At that time, there were no digital switches in the network, so digital-to-analog converters were required at the T1 system's end points to make it compatible with the analog network connections. Today, converters are unnecessary when the T1 connects to a digital switch or other digital terminal.

When equipped with digital repeaters[5] to regenerate the signal at critical points (about a mile apart) in the transmission path, the T1 digital line can extend up to about 50 miles between the remote loop carrier site and the central office. The maximum distances between consumer premises and the remote loop carrier sites can be 26,000 feet (7,900 meters) with 22-gauge loaded cable and almost 50,000 feet (15,240 meters) on 19-gauge cable. Microwave radio systems that handle T1-type transmission also can be used between the remote and central office terminals, with relay stations every 20 miles (32 kilometers) or so at horizon points.

In some rural areas, telephone customers are still served by open-wire lines, which consist of uninsulated pairs of wires supported on poles spaced

[5] In trunk systems between offices, the telephone circuit may pass through a series of repeaters. These are devices that equalize or amplify the analog voice signal to correct losses of strength so the signal does not fade away before it reaches its destination. Earlier analog repeater designs often amplified electrical "noise" as well, so the signal was sometimes masked by crackling or other disturbances after transmission through many repeaters. Repeaters are now increasingly rare in telephone circuits. Modern repeaters, when their use is necessary, normally filter out unwanted "noise," and digital circuits virtually eliminate the problem. When digital signal weakens during transit, it is *regenerated* rather than simply amplified.Regeneration eliminates electronic "noise" by retiming and restructuring the square-wave pulses that characterize pulse-code modulated (PCM) digital signals.

about 125 feet (about 38 meters) apart. The wires range in diameter from 0.08-inch (2.03 millimeters) with 12 gauge to 0.165-inch (4.19 millimeters) with 6 gauge and may be copper, copper-clad steel, or galvanized steel. Such systems are, of course, becoming increasingly rare as the nation's telecommunications network is upgraded.

Coaxial Cable. In 1936, a new type of cable, called coaxial, was experimentally demonstrated as the first broadband transmission long distance system. *Broadband* systems transmit a band of electrical frequencies several million cycles (megahertz) in width. Terminal equipment at each end subdivides the bandwidth into frequency bands (in the case of analog transmission) or time slots (in digital transmission). These subdivisions keep the various voice and data signals distinct as they follow their assigned paths.

Today, a coaxial conductor is usually a flexible 3/8th-inch copper tube in which a No. 10 gauge (0.102-inch or 2.59 millimeter) copper wire is held precisely centered by small plastic insulators spaced about 1 inch (25.4 millimeters) apart. A coaxial cable containing eight tubes is about 2 inches (5 centimeters) wide and weighs almost 3 pounds (1.3 kilograms) per linear foot (30 centimeters), while a 20-tube cable is about 3 inches (7.5 centimeters) thick and weighs 9 pounds (4 kilograms) per foot (30 centimeters).

Most cable television networks are equipped with coaxial cable networks, which may be utilized for voice telephone calls in the future if proposed mergers between long distance companies and cable TV operators take place. However, satellite TV distribution systems are not designed to handle two-way signal feeds through small earth antennas. See also **Satellites (Communication and Navigation)**.

The availability of coaxial cable in the 1930s and 1940s made it possible to provide commercial radio networks with an efficient method of distributing their programs from a central source to various affiliate stations around the nation, over telephone circuits. Actually, the first ideas of using telephone wires for one-way transmission of radio broadcast signals developed after World War I, when radio was still in its infancy. Coaxial cable improved the quality of sound transmission to match the improved quality of the transmitters and receivers as the years progressed. Although still widely in use, especially by the cable television industry, coaxial cable is no longer favored in specifications for new broadband communications systems in the public switched telephone network, having been replaced in preference by microwave radio and optical fiber lightwave systems.

Microwave Links. After World War II, television broadcasters set up similar arrangements with the telephone companies. Although their first broadcasts were sent over coaxial cable lines, hundreds of voice circuits were displaced to carry a single TV channel, so more facilities were needed. Fortunately, A new broadband transmission technology evolved during the early 1940s and became a major component of the national network for a time. Known as *microwave radio* systems, these lines did not need copper wire or other physical media to link points in a network. Instead, they employed antenna towers and radio transmitters that sent extremely high-frequency signals from relay tower to relay tower along a line of sight. The distance between relay towers usually ranged from 15 to 30 miles (24 to 48 km). One of the electromagnetic spectrum ranges assigned by the Federal Communications Commission (FCC) for this service extends from 3.7 billion to 4.2 billion hertz (gigahertz) to carry voice signals over 12 channels in each direction. Each channel can carry one television transmission or 1800 voice circuits; however, one channel is reserved as a spare or protection channel. Other bands in use for commercial terrestrial microwave radio transmission are in the vicinity of 2, 6, 11, 18, and 23 gigahertz (Ghz).

The first commercial system using microwave radio in telephony was placed in service between New York and Chicago in 1950. Before the end of the following year, a transcontinental system was in operation. From then on, these systems grew in several ways: they covered an increasing number of routes, they also increased in capacity, and they eventually expanded their versatility through the introduction of digital transmission.

Eventually, microwave radio filled the majority of the former Bell System's needs for high-capacity long-haul transmission. In 1986, about 70 percent of long-distance traffic in the United States domestic network was handled by microwave carrier. However, this dominance was challenged by the rapid development of fiber optic lightwave systems, which were impervious to atmospheric disruptions. By 1990, terrestrial microwave transmission systems had been replaced by high-capacity fiber optic cables in AT&T's long-distance network, except for certain leased routes serving private networks.

Satellite Systems. A special class of microwave radio systems involves satellite systems. See also **Satellites (Communication and Navigation)**. A communications satellite system of the 1990s is an extremely complex combination of fixed and mobile earth stations (transmitter/receivers equipped with dish-shaped earth antennas ranging in diameter from about one yard or meter to more than ten yards or meters) and massive cylindrical or rectangular assemblies orbiting the planet above the atmosphere. Each satellite, often weighing two to four tons or more at launch, is equipped with multiple transponders (receiver-amplifier-transmitter devices which relay voice, video, fax and data signals from one earth station to another over precisely tuned microwave frequencies) as well as power supplies and appropriate electronic control equipment. Depending on their design, each of these huge structures can handle tens of thousands of two-way telephone calls simultaneously and has an orbital life expectancy as long as 15 or more years. Shortly before 2000, new low-Earth orbit communications satellite fleets were introduced, providing direct signal links between pocket-size telephones and the satellites used to relay the calls to other terrestrial telephones.

The world's first broadband (high-capacity) international communications satellite was AT&T's *Telstar I*, which was placed in a low non-synchronous orbit around Earth on July 10, 1962. *Telstar II* was placed in orbit on May 7, 1963. They were both experimental in nature, providing the first domestic and international TV transmission by active satellite, using an earth station in Andover, Maine, USA, another in Goonhilly Downs, Cornwall, England, and a third in Pleumeur-bodou, Brittany, France. Two other experimental low-orbit satellites, known as *Relay I* and *Relay II*, were placed in orbit in the same time frame. But the experimental satellites most resembling today's communication satellites were *Syncom II* and *Syncom III*, which were positioned in high orbits 22,300 miles (35,881 kilometers) above the Earth's equator in 1963. The first commercial communications satellite, *Intelsat I*, was launched in 1965; known as "*Early Bird*," the 85-pound (38 kilograms) satellite transmitted the equivalent of 120 simultaneous analog telephone conversations between the United States and Europe. *Early Bird* also was the first commercial satellite to be placed in a geostationary or synchronous orbit, in which its orbital velocity exactly matched the Earth's rotation around its axis, so the satellite appeared to be fixed in space above an assigned spot along the equator, from which its antennas could reach almost half the planet. Succeeding generations of *Intelsat* satellites orbit above the Atlantic, Pacific, and Indian Oceans, handling telephone messages and color television signals among scores of nations around the globe.

A new class of satellite communications equipment designed primarily for private networks operating outside the public switched telephone network is called the *Very Small Aperture Terminal* (*VSAT*, pronounced vee-sat). An example of a VSAT network would be an automotive manufacturer with a computer center in Michigan which is linked by satellite to several thousand automobile dealers across the U.S. The network center in Michigan would be equipped with a satellite transmitter-receiver capable of broadcasting the same one-way program (voice and video, data, fax) to all the dealers simultaneously, or setting up a multi-party videoconference or voice conference call, or connecting the center to a single dealer location for voice, video, data or fax transmission. VSAT systems operate with digital packet-switching technology over leased transponders. U.S. businesses were the first VSAT users, starting in the 1980s.

Another type of telephony equipment intended for land-based digital private networks is increasingly being adapted for satellite use by remote communities, especially in Alaska. Known as the *integrated access and cross-connect system* (*IACS*), this wideband packet product can be used for digital compression of voice, video, fax and voiceband data. A remote community can link its local telephone lines (usually about 100 or so) into a digital PBX that feeds its multiplexed circuit signals into the IACS for transmission up to a satellite for relay down to a land station connected to the global terrestrial telephone network. The system is capable of

compressing 120 digital voice channels into a North American satellite transmission standard link for 24 digital channels, using bit compression, statistical multiplexing, and packetized transmission. This technology thus replaces a public radio broadcast system with a public telephone system offering communications privacy. During Operation Desert Storm in 1990/91, more than a dozen such systems were installed in Saudi Arabia, enabling U.S. troops to telephone home from remote locations in the Middle Eastern desert.

Telephony between continents actually began as radiotelephony in 1927. Although crude by modern standards, the wireless system worked well enough so that callers were willing to pay $75 (the equivalent of more than $800 in 1998 currency) for three minutes or less. During the first year of service, only six to eight calls per day were made, but the public warmed up to the concept and by mid-1928, the volume reached more than 30 calls per day. On October 16, 1928, one call between New York City and Paris lasted one hour and 37 minutes, costing the caller $1,527.50 in 1928 money.

However, the wireless technology was susceptible to interruption and fading caused by atmospheric disturbances, especially sunspot activity. Sometimes it was out of service for days, even weeks.

Submarine Cables. In 1956, the first transatlantic undersea telephone cable was installed between North America and Europe, using two cables, each carrying 36 analog voice circuits in opposite directions. The cable landing sites were in Oban, Scotland, and Clarenville, Newfoundland, Canada — the shortest undersea distance between North America and the networks linking the United Kingdom and European nations: 1950 nautical miles (or about 2200 statute miles or 3550 kilometers). Each cable required 51 repeaters to amplify the signal along the route, but since solid state electronics were still evolving, those repeaters were equipped with vacuum tubes. (Transatlantic telegraph cables were introduced during the middle to late 1800s, but could not carry speech.) By 1985, seven submarine coaxial copper cables had been laid by special cable ships across the floor of the Atlantic Ocean, See Fig. 15, and other cables criss-crossed the Pacific between the U.S., Australia, Japan, Hong Kong, Taiwan, and Southeast Asia, See Fig. 16. For the map of submarine cable service to Europe, see Fig. 17.

Undersea telecommunications cables are susceptible to damage from fishing trawlers. In the relatively shallow waters of continental shelves, the cables have to be buried a few feet under the ocean bottom. This is done by a remote controlled vehicle which uses water jets to plow a furrow and then cover the cable as the laying procedure moves along the planned route. The route is carefully laid out according to the shortest distance between the two landing points, but also to avoid deep canyons and jagged ocean bottom features that could damage the cable. The cable plow is not needed after the cable ship reaches the end of the continental shelf, where the cable slowly drops to the ocean floor.

All the copper submarine coaxial cables used analog signal technology, so any computer transmissions were limited to modem signals carried within the voiceband circuit.

Satellite circuits could be used for high-speed digital transmission of computer signals, but the long distances involved [22,300 miles (35,881 kilometers) of uplink, 22,300 miles (35,881 kilometers) of downlink, for a total of 44,600 miles (77,761 kilometers)] caused problems for some systems due to the time lag incurred. But, as often happens, a new technology — replacing copper with fiber or lightguide cables — emerged from the laboratories and development facilities to meet the challenging growth of both data and voice in global telecommunications traffic. See Fig. 18.

Optical Fiber Cables. The medium now favored for broadband (sometimes called "*wideband*") digital transmission is called *lightguide* or *optical fiber cable*. Introduced during the late 1970s for terrestrial systems, lightguide cables consist of hair-thin glass fibers specially formulated and manufactured for communications use. The fibers are solid, not hollow. Instead of transmitting electrons (as is done with metallic conductors), the lightguide carries pulses of light from the infrared end of the electromagnetic spectrum. These pulses are generated by either light-emitting diodes (LEDs) or semiconductor lasers at a rate of many millions of bits (megabits) or even billions of bits (gigabits) per second, using pulse code modulation (PCM) techniques. At the receiving end, a special semiconductor detector diode converts the incoming light pulses into coded electrical pulses. Copper wires run parallel to the fibers, carrying control pulses. When the submarine fiber cable is buried in the continental shelves, and emerges to drop to the ocean floor, special cable armor is used in that critical point to sheath the electrical and optical fiber components from damage by sharks. Tests have shown that the sharks are attracted to the cable by the electrical fields emanating from the control circuits. When the sharks bite the cable, they can puncture the insulation and allow sea water to short out the electrical components. (Some people seriously think that the optical fibers in new cables are hollow, and that shark bites compress the fiber and block the light signals from passing through. This is not true.)

Lightguides are not yet used to feed signals directly out of or into telephone sets, but are now specified as the transmission medium of choice on most new trunk routes because they are much lighter and less expensive than metallic cable of comparable capacity.

The communications fibers are supplied as either multimode or single-mode designs. The fibers are made up of layers of various types of glass, so a cross-section resembles that of a solid tree trunk. A multimode fiber has a relatively wide core and can use either lasers or light-emitting diodes (LEDs) as light sources. Single-mode fibers require better sources such as lasers, but have a much greater capacity for carrying signals. All long-distance lightwave lines now use single-mode fiber, while multimode fiber is often used in short links, especially if the light source is to be an LED. The highest bit rate for multimode fiber, without incurring significant modal dispersion problems, is about 180 megabits per second; single-mode fibers are already handling more than 3.4 gigabits per fiber in commercial trunks between selected U.S. cities.

In fact, demonstrations of experimental lightwave systems often are followed within a year or two by the commercial introduction of systems matching the new super transmission speeds. Multi-gigabit submarine cables already are on the drawing boards, and ultra-long-distance cables without digital signal regenerators have been demonstrated, using novel, high-speed all-optical logic gates and transmitting solitons (light pulses that retain their shape over long distances without blurring).

In September 1991 a nine-member Bell Labs team transmitted solitons at 32 gigabits per second over 55 miles (90 km) of optical fiber. Another researcher has transmitted solitons more than 6,000 miles (9,666 km) through optical fiber without electronic regeneration. The elimination of regeneration repeaters in transoceanic submarine cables would significantly lower their cost, improving the economics of global communications.

Major communications routes throughout the United States now use lightwave systems that replaced metallic or wireless radio systems. New transatlantic and transpacific submarine cable systems also are designed to use single-mode lightguide fiber. High- speed digital transmission on the first fiber-optic submarine cables, deployed in 1988, uses six single-mode optical fibers carrying laser signals at the rate of 296 megabits (million bits) per second. Only four of the fibers are operating at any given time to provide the equivalent of 40,000 digital voice circuits; the remaining pair of fibers are standby. The first Atlantic fiber cable has fewer than 125 regenerating repeaters along its 3145-nautical-mile length, while the first Pacific fiber cable has fewer than 250 repeaters along its more than 10,000 nautical miles (18,520 km). Both systems featured the first underwater branching of submarine cables, so the single landing point at the American end of each cable is linked to two landing points at the other end, i.e., the United Kingdom and France, or Japan and Guam. The projected life of both lightwave cables is 25 years of operation (to about 2013).

The public's growing enthusiasm for international telephony required the enormous increase in traffic-handling capacity provided by fiber optic cables. The first transatlantic copper cable, known as "*TAT-1*," carried 10 million telephone calls during its 22-year service life (from 1956 to 1978). The first new fiber optic cable, known as "*TAT-8*," carried 10 million calls in only two days.

In 1992 a second-generation fiber-optic system was installed, operating at 560 megabits (million bits) per second and adding the equivalent of 80,000 digital voice circuits. The *TAT-9* Atlantic cable has three branching units, one to enable two North American landing points, the others to provide separate landing points in England, France and Spain. The *TAT-10* Atlantic cable, activated in 1993, was the first direct cable between North

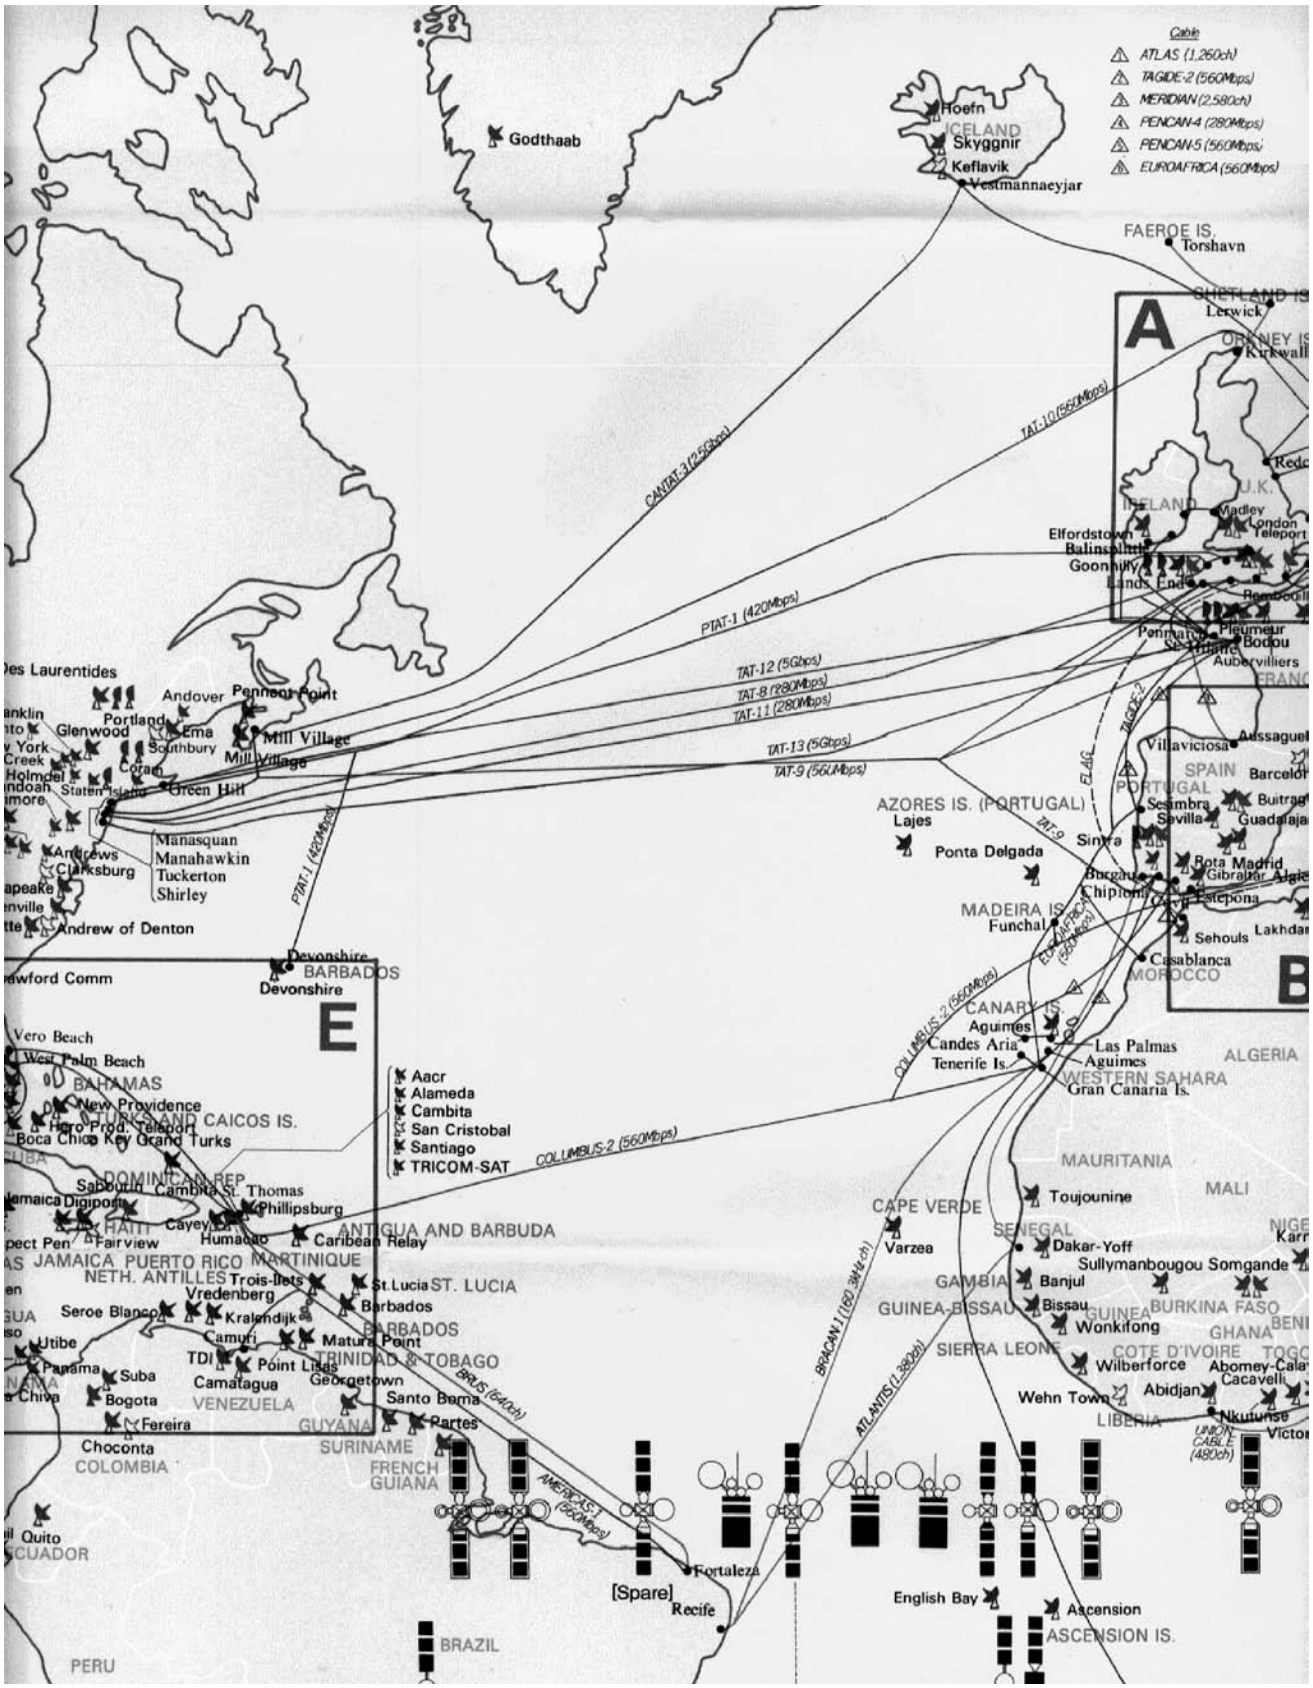

Fig. 15. Map of submarine telecommunications cables across the Atlantic Ocean (1996). (*KDD Co.*)

America and Germany, and added the equivalent of 80,000 digital voice circuits. Three more cables quickly followed these to European landing points, including in 1995 the *TAT-12* and *TAT-13* fiber-optic cables, each of which transmits at the astonishing rate of five *gigabits* (five *billion* bits) per second.

Yet even a 5-gigabit per second transmission rate seems slow compared to the upcoming fiber-optic cables. In the Pacific, where telecommunications traffic between Japan, Hawaii and the United States

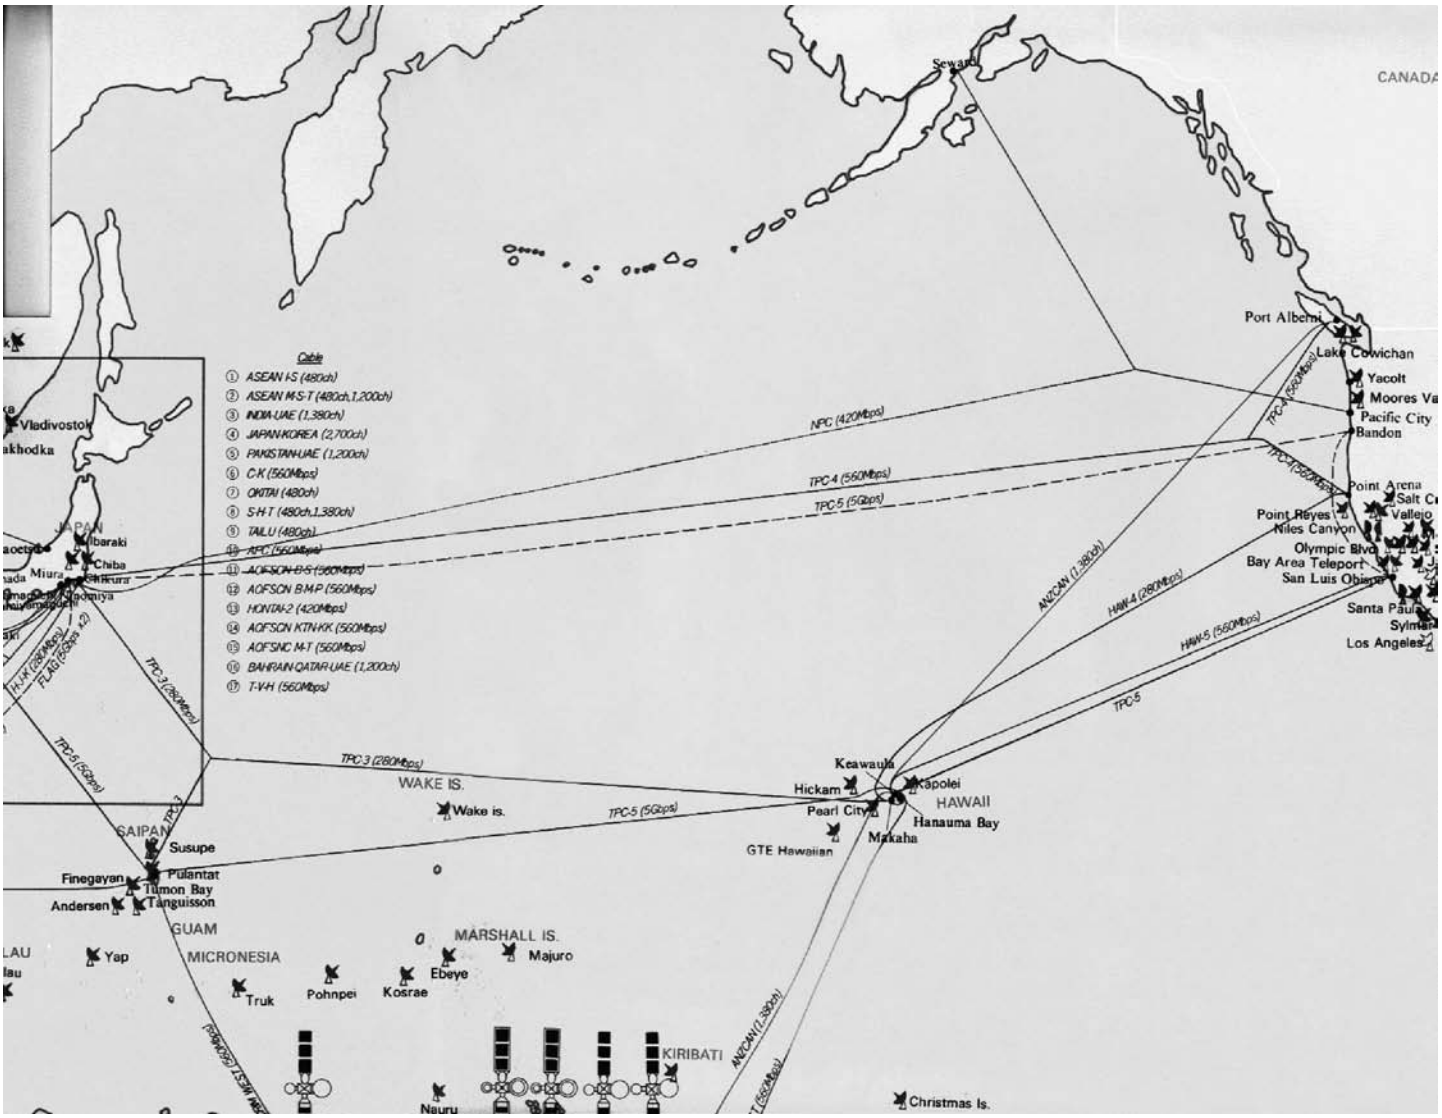

Fig. 16. Map of submarine telecommunications cables across the Pacific Ocean (1996). (*KDD Co.*)

seems to fill the cables almost as soon as they are installed, a new design has been created for the combined transpacific TPC-6/WorldCom Japan-U.S. fiber-optic cable, scheduled to begin operations in mid-2000. It will operate at 80 gigabits per second at the start (equivalent to 967,680 simultaneous phone calls), and has the potential to expand to 640 gigabits (equivalent to 7 million, 741 thousand, 440 simultaneous calls). And scientists at Bell Laboratories have demonstrated new cables transmitting in the *terabits* (*trillion bits*) per second.

Trunks. A major method of keeping telephony economical is to concentrate high volumes of traffic onto relatively few transmission media linking two major points. The high-volume media are known as trunks, and usually serve as links between central exchange offices or toll offices (which handle only long distance calls). In 1983, the communications network then operated by the former Bell System contained over 11,000 switching systems connected by over 7.5 million trunks arranged in 400,000 separate trunk groups.

Multiplexers. Calls are concentrated or consolidated by means of equipment called a *multiplexer*. For analog signals, the multiplexer uses a technique called *frequency division*, in which voice channels are sandwiched into broadband frequency layers by means of sophisticated filtering systems. For example, 12 analog voice channels are stacked to form a *basic group* within a bandwidth of 60 to 108 kilohertz (kHz). Then 60 circuits are multiplexed in layers to form a *supergroup* signal (312 kHz to 552 kHz). The next stage is assembling of 600 circuits into a *mastergroup* signal (564 kHz to 3084 kHz), followed by the highest analog level, 3600 circuits in a *jumbogroup* signal (0.546 to 17.548 megahertz, or MHz) to be fed to a microwave radio or cable transmission system. The four multiplexing steps are called the *transmission hierarchy* by telephony engineers.

Digital signals also have a hierarchy, but the multiplexer uses another technique: time division. The digital signals use thousands of coded bits per second that are interleaved with bits from other channels into high-speed signal streams of millions or billions of bits per second. *Time-division multiplexing* (*TDM*) relies on increases of bit-rates per second at each of five levels of the *digital hierarchy*. The basic rate for a digital voice channel in North America is 64 kb/s (known as the DS0 signal). Of course, a computer terminal equipped with keyboard input operates at a much slower rate, so most such lines function at 9.6 kb/s or less; these slower speeds are known as *subrate data* and are usually multiplexed onto a DS0 signal before entering the network.

The lowest digital network transmission rate, equivalent to 24 voice channels combined, is DS1 (1.544 million bits or megabits, per second). The next step up isDS1C (3.152 megabits per second), followed by DS2 (6.312 megabits per second), and DS3 (44.736 megabits per second), which is the highest digital signal rate provided to customer premises by the telephone network. The DS4 rate (274.176 megabits per second) is the highest level of hierarchical transmission and is used exclusively for international communications links. Internally in the AT&T network, even higher digital signal levels are used with lightwave (fiber optic) technology. These super-links operate at 417 megabits per second, 1.7 gigabits per

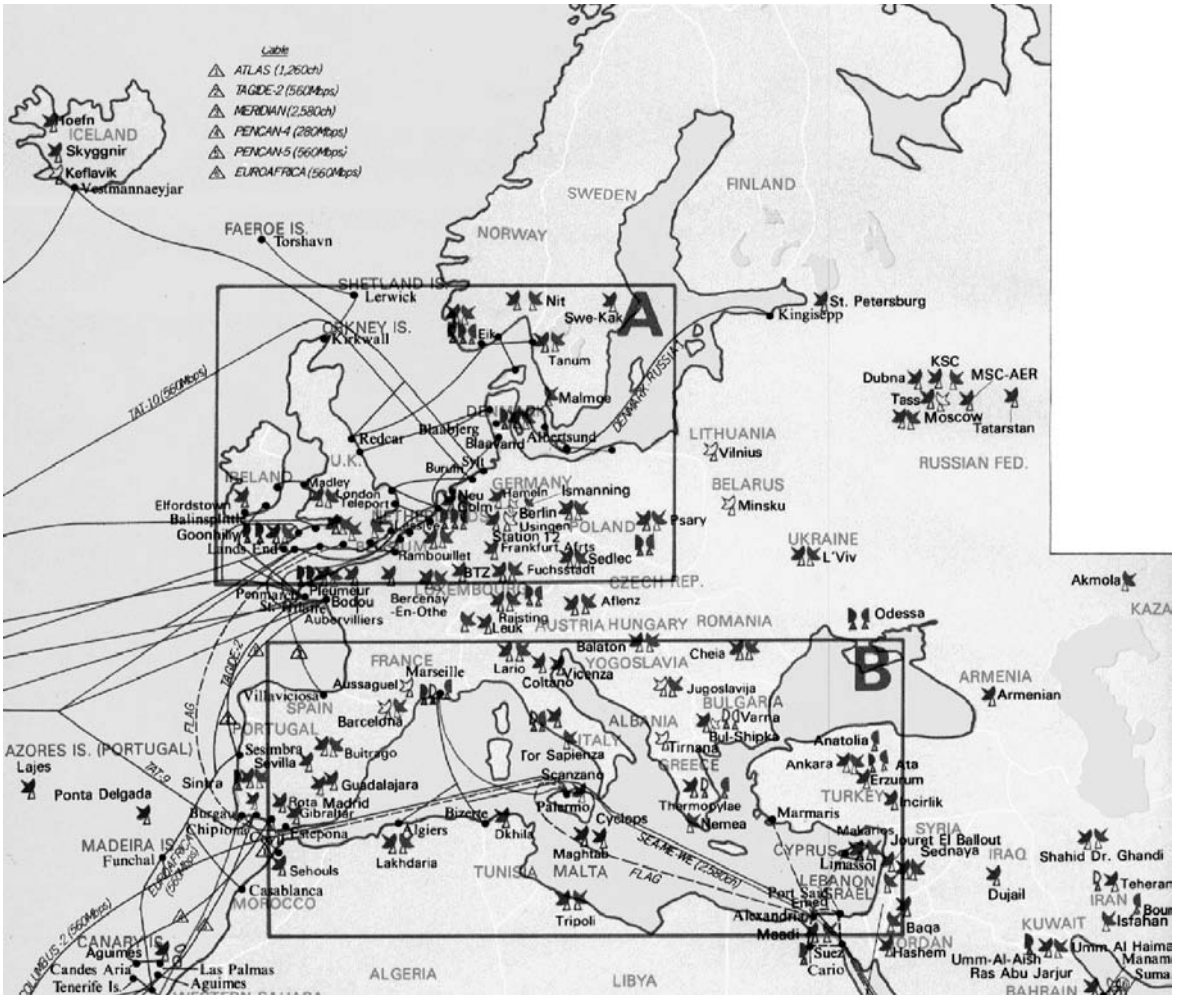

Fig. 17. Map of submarine telecommunications cables serving Europe (1996). (*KDD Co.*)

second, and 3.4 gigabits per second between special terminals but are not assigned a DS hierarchy code.

In the 1990s, plans were introduced for implementing a new optical transport system in the world's public switched networks. The worldwide designation for this eight-level hierarchy is *SDH* (*Synchronous Digital Hierarchy*), but the slightly different U.S. version is known as *SONET* (*synchronous Optical NETwork*). The basic optical signal of SONET is OC-1, operating at a line rate of 51.840 megabits (million bits) per second. This is multiplexed in seven different stages to the highest SONET level, OC-48 operating at 2.488 gigabits (billion bits) per second. Higher transmission rates are currently used in major transmission cables, but these are not rated for switching.

Digital multiplexing circuitry is much simpler than that of analog equipment, so digital terminal costs are considerably lower. In addition, the digital multiplexer provides more versatile means of monitoring system performance and isolating faults. All lightwave systems in the North American telecommunications network use digital coding and multiplexing.

Cellular Mobile Transmission. Another important technology in transmission media is known as *cellular mobile* transmission. This wireless design dramatically expands the number of mobile telephone circuits previously available with conventional mobile telephone systems. (Mobile telephones differ from other mobile radio service in that the conversations are individually connected to the telephone network, while other radio services are usually of the broadcast type, i.e., police or radio dispatchers, and can be overheard on any receiver tuned to the frequency being used.)

The previously allocated frequency spectrum limited the number of mobile telephone circuits to fewer than 25 in major metropolitan areas, such as New York, Chicago, or Los Angeles. Cellular technology expands that to thousands of available circuits for each market by reusing a given frequency many times without interference among the callers.

In a cellular mobile communications system for an urban area, the region is divided into relatively small neighboring *cells*, each containing a base station [a small radio tower with a service radius of 1 to 8 miles (1.6 to 13 kilometers)]. The cells are generally depicted on plan layouts as octagon-shaped areas butted against each other. The mobile telephone set transmits and receives an analog or digital voiceband signal, depending on the cell type. As the vehicle moves from one cell to another, the call signal is "*handed off*" from one radio tower to the other, an intricate process controlled by a special digital switch and software at the heart of the cellular system. Landlines connect the towers to the central switch, which in turn is connected to the rest of the telephone network by an access line feeding into the nearest exchange or central office of the local Telephone Company.

The first mobile telephone system for the public switched network was authorized by the FCC in 1946 and was based on a single radio tower for an entire metropolitan area. Because of the limited frequency spectrum allocated for the new service, and the relatively primitive available technology of the time, the network could serve only a few hundred customers in any major city, so long waiting lists quickly developed. Bell Laboratories proposed a cellular subdivision of the service area in 1946, which would re-use the same frequencies in some of the cells, thus enabling the system to handle more calls simultaneously. But the technology of the day was not capable of providing such facilities.

Work continued until the early 1970s, when installation of cellular systems became feasible. However, the FCC repeatedly denied permission for introducing the new approach while arguments raged in the industry as to whether the technology was developed enough. Finally, cellular mobile

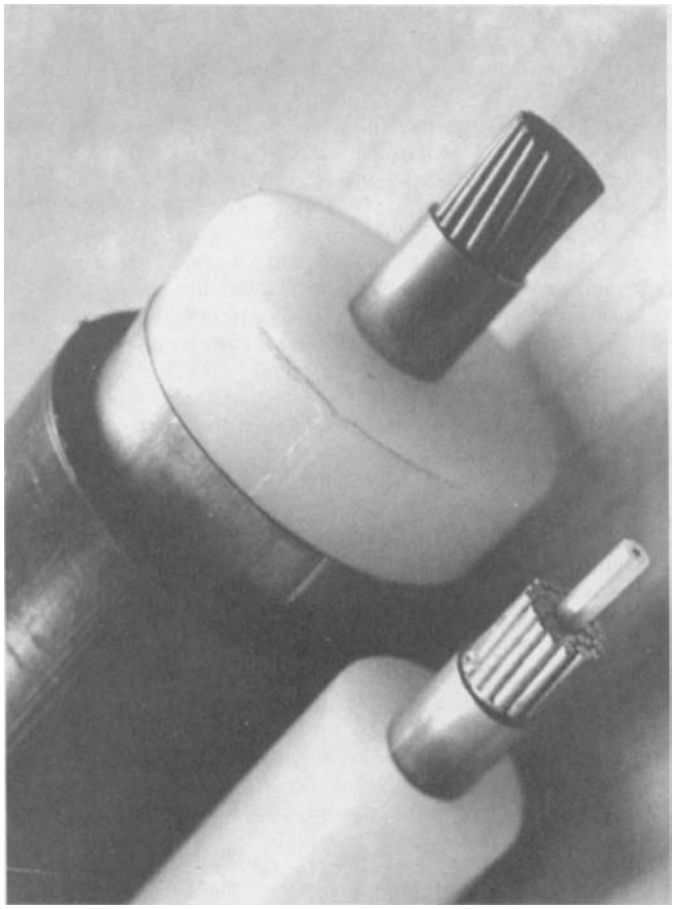

Fig. 18. The single submarine lightwave cable shown here (bottom) more than doubled the number of available transatlantic cable circuits when the TAT-8 system was completed in 1988. The fiber cable is half the size (and one-third the weight) of the TAT-7 coaxial copper cable shown in photo (top). New submarine lightwave cables use fiber optic technology that far exceeds the capacity of the first such system. (*AT&T.*)

phone technology was test-marketed in 1979 in Chicago, servicing 2000 customers in an area of 2100 square miles (ca. 5460 sq. km.) divided into ten cells. About 100 cars could be served simultaneously by a single analog cell, depending on the system's design. The trial system operated between 825 and 890 megahertz. Each radio channel connecting the mobile phones with the cell towers consisted of a pair of frequency-moduled (FM) one-way channels, each channel 30 kilohertz wide, separated by 45 megahertz. The radio spectrum assigned to cellular technology in the United States started with the 800 megahertz band, but now includes 1200 megahertz as well because of the influx of European transmission equipment.

In 1991, the first digital cellular system was tested in the U.S., using new terminal sets provided by six different manufacturers. The system was based on a technology known as *TDMA* (*Time Division Multiplex Access*) and tripled the service capacity of each cell, compared to analog technology. In the U.S., the terminal must be a dual digital/analog design, capable of automatically switching back and forth to accept signals coming from either digital or analog antennas. The digital bit-rate approved for this service is eight bits per second, accomplished through innovative voice signal compression techniques, but the acoustical quality of speech is not as clean as that of wireline systems.

Some cellular telephones are designed to be portable and can be removed from the vehicle so that they can be used by a pedestrian if an antenna is within transmission range. Other mobile telephone systems include fax and small ("laptop" or "notebook") portable computer equipment operated in a wireless mode. In the early 1990s, such data transmissions to and from analog towers were made via modems from a stationary point, with the vehicle parked.

As cellular mobile phone systems continue to be installed throughout the world, it may become possible to transmit and receive speech, data, fax and video from a moving vehicle anywhere to a location anywhere else in the world. And because digital data transmission to and from portable computers would be possible with these systems, the communications potential for the future is staggering.

Switching Equipment

Obviously, it would be impractical to extend separate wires from every telephone to all other telephones. For example, four interconnected telephones would require six lines, while 40 phone would need 780 lines and 400 telephones would require 79,800 direct lines.

To conserve transmission media and dollars, each telephone is instead connected by a pair of wires to a nearby central point, called an exchange or central office, where individual connections to other telephones can be made as requested. The device that makes those connections is called a *switch*. The telephone network consists of many thousands of switches connected to each other as well as to millions of telephones.

In 1951, when engineers at Bell Labs prepared to introduce automatic long-distance dialing with the Nationwide Numbering Plan, each dial office was designed to serve up to 10,000 numbers with a limitation of four digits, plus the three digits that identified the central office switch. Smaller communities often used only four digits for cross-town calling if only one switch was involved, but bigger cities with multiple switches had to assign extra digits to identify which switch had the destination number.

Switching apparatus evolved in five major successive phases:

1. *step-by-step* switches, controlled directly by power pulses fed from the telephone dial;
2. *panel* switches, controlled indirectly by relays operating the switch from the dial;
3. *crossbar* switches, introducing a common-control concept that greatly increased the efficiency of switching operations;
4. *analog electronic* switches, which replaced electromechanical switching with solid-state electronic switching and introduced stored-program control (SPC) or software concepts using switching programs called "generics"; and,
5. *digital electronic* switches, which added time-division concepts to the technology (all previous switches were based on space-division concepts). By combining digital switching and digital transmission, synergistic benefits were obtained. Although most customer premises connections were still analog in 1998, the goal of a total digital network capable of extremely sophisticated features is now in sight.

The earliest switches were electromechanical machines, activated either by the pulses from the telephone dial or by relays. Stored-program control replaced the hard- wired logic of common control with software consisting of detailed instructions for a program guiding a computer that operated the actual switch hardware. Changes in services, features, and other switch functions could now be done by program changes instead of hardware changes. The first electronic switching system using stored-program control for a commercial installation was placed in use ("*cut over*" in telephone parlance) in 1963 at Succasunna, New Jersey. The 4000-line office was served by an analog system known as a No. 1 ESS switch, using space-division switching. Many of these switches were still in use by local exchange companies in the early 1990s.

The concept of analog space-division electronic switching dominated the field until challenged in the mid-1970s by the first digital time-division electronic switching system, the AT&T No. 4ESS toll switch. The new digital switch was first used in the AT&T Long Lines Trunk Operations Center in Chicago. The current era of switching technology is now based on digital signals and time-division multiplexing in which the *pulse code modulated* (*PCM*) signals are separated and switched by a time-slot interchange. Time-division switching lowers the cost of voice communications, is compatible with high-speed transmission of digital data, and can be modified to fit the packet switching systems used in the Internet, World Wide Web, and Integrated Services Digital Network (ISDN) applications. The goal is end-to-end digital connectivity, automatic switching of every type of voice, data, and image signal without any analog carriers.

In the first half of the 20th century, switching was automatic only for local telephone calls. Long-distance, or toll, calls were placed by human operators. In 1951, nationwide customer-dialed calling began when *direct-distance dialing* (*DDD*) was introduced in several areas of the country. A substantial telephone company investment in new equipment was required nationwide, including the "independent" telephone companies that were not part of the former Bell System. Further modifications resulted in international direct distance dialing (IDDD), starting in 1970 with calls to the United Kingdom and later into some 140 other countries throughout the world. Americans can reach about 250 countries by long distance, more than 100 of those do not qualify for IDDD service for economic reasons or because their governments restrict direct dialing to their telephone users from outside their national borders, so operators serve as intermediaries in those nations.

The need for direct dialing was clearly evident in the data compiling the escalation of long distance calling. In 1987, AT&T alone handled about 85 million long-distance calls during a typical 24-hour business-week day. Three years later, that number had risen to circa 115 to 120 million long-distance calls for the same period, by 1995, the average volume of long-distance calls was up to 185 million calls per day.

For nationwide DDD toll dialing, complete end-to-end connectivity is required for universal service through the network. The switching plan had to restrict the maximum number of links to a specific number for transmission stability, uniformity, and efficiency.

A system, now known as the *hierarchical plan*, was devised that permitted as many as nine toll switching centers to function in tandem on a single dialed call. That concept was changed to an arrangement called *dynamic nonhierarchical routing* (*DNHR*), which was replaced in 1991 by a newer system called *real- time network routing* (*RTNR*).

Routing calls from step-by-step central offices into the toll network on the basis of area codes would have required expensive modifications of the switches to detect the dialing of area codes. Such major equipment changes were avoided for most step-by-step offices by having the customer dial an initial "1" on most toll calls. The "1" is known as a toll barrier prefix and is also used in some states to distinguish between calls in a given area code and toll-calling within a numbering plan area. Also, with the introduction of DDD it was necessary to provide codes in the numbering plan for operators, but not customers, to reach other operators in distant centers for assistance in reaching points not yet accessible by DDD, or for other forms of routing or special call-handling procedures.

The interpretation of the dialed digits was the most important element in the design of switching systems for DDD. The changes in the step-by-step offices were relatively simple. For common-control local offices, register-sender capacity for the additional three digits of the area code was needed. The crossbar toll offices were to become the backbone of the DDD network; features for implementing DDD service were assigned to those offices. The nationwide number, transmission, and routing plans not only required the ability of local and toll offices to receive 10 digits, but also required the common control to interpret the three area code and three office code digits. The area code pool of 152 three-digit numbers, with the second digit limited to 0 or 1, was exhausted before the year 2000. By lifting the second-digit restriction, the feasible selection was expanded to 792 area codes. The program, called the Interchangeable Numbering Plan Areas, was transferred from Bellcore in early 1998 and is now administered by Lockheed Martin Information Systems. Even with 792 area codes, experts predict that North America will run out of area codes by 2025, so various proposals are under consideration to resolve the problem.

Network planners assigned the first area codes based on the ease of dialing (on a rotary phone) and the volume of calls to a particular city. That's why the area code for New York City is 212, Chicago is 312, and Los Angeles is 213, and so on. The combinations 211 to 911 were disqualified as area codes because they were reserved as service codes. The combinations of 200 to 900 were also set aside for special uses: 700 is the prefix for special services such as AT&T's switched digital services and teleconferencing calls, while 800 is for *WATS* (*Wide Area Telecommunications Service*) or *Freephone*, and 900 is for "*dial-it*" calls in which the caller is charged a fee by the party (usually a business) being called.

The first digital switching system was the AT&T 4ESS switch, introduced for long-distance (toll) service in 1976. Today, there are about 100 4ESS electronic switching systems serving the United States toll network, plus others in the Middle East and Far East. A 4ESS digital switch can serve up to 670,000 peak busy hour calls.

Digital switching also is performed by the AT&T 5ESS system introduced in Seneca, Illinois, in 1982. Designed for use in central offices serving from less than 1000 to more than 100,000 lines, the 5ESS switch is now also performing as an international gateway switch in several countries, functioning as the entry and exit point for international calls.

Remote and sparsely populated U.S. areas are provided with sophisticated telephone services by remote switching modules connected to modern central offices as far as 100 miles distant. The main switch serves as a host to the remote module, although the remote switch usually is capable of still connecting its local subscribers to each other even if it is temporarily cut off from its host.

The 5ESS switch was the first such system designed to allow connection to lightwave (fiber optic) links. However, the lightwave, or *optical*, signals must be converted to electronic signals before they can be switched. Switching of optical signals is still experimental and is not expected to become commercially available before the year 2000.

Traditionally, telephone calls across the long-distance network were routed through a hierarchy of switching centers, under the supervision of a technical staff headquartered in New Jersey. During the 1980s, a new concept was introduced, using computers in various locations to coordinate long-distance calling paths while monitoring the status of switches. At first, the new approach reset the predetermined routing paths of calls up to 10 times a day, providing up to 21 paths between each switch. In 1991 an improved system, known as *Real-Time Network Routing* (*RTNR*), was introduced, changing the routing path of a call automatically in "real time" (during the actual call setup) to transit around congested traffic areas or equipment failures. Human experts can still intercede for special purposes, such as selectively blocking calls into an area affected by a catastrophe like an earthquake. This prevents the area's switches from becoming overloaded by incoming calls.

RTNR will not, however, protect dedicated lines that are not switched through the 4ESS toll switches. A different protection system, known as *fast automatic restoration* (*FASTAR*) uses a routing algorithm to monitor the status of dedicated circuit equipment known as digital access and cross-connect systems (DACS), providing remote-controlled cross connections that make possible automated restoration of dedicated circuits.

A key factor in implementing computer-controlled routing was *common channel interoffice signaling* (*CCIS*), a high-speed, high-capacity signaling system for linking electronic switching systems on a network separate from the channels that carry voice signals. This is described as an *out-of-band* packet-switched network, out-of-band meaning that the control signals are outside the voiceband signals. (Typical control signals inside the voiceband are the dial tone, rotary dialing signals, touch-tone signals, busy signals, etc.) See the section titled **Global Telephone Networks**.

Supplementing the American public switched network is the growth of private voice-and-data switched networks, including government, business, and institutional customers. The federal government, for example, has the world's largest private switched network, known as the Federal Telecommunications System (FTS). It is a largely analog system, activated in 1964, which offers voice and low-speed data over 11 million circuit transmission miles with close to 35,000 access lines and 15,000 trunks serving some 3500 government locations in the continental United States, Puerto Rico, and the U.S. Virgin Islands. In size, it equals the former Bell System interstate network of 1957 and accounts for more than 1.5 billion minutes of use each year. A new FTS system was introduced in the 1990s as an option for government agencies, providing a digital voice/data network. Meanwhile, the Department of Defense (DoD) has installed the *Defense Commercial Telecommunications Network* (*DCTN*), a digital system designed to serve users in the DoD and other federal agencies at about 150 locations across the continental United States. Another DoD system is the *Automated Voice Network* (*AUTOVON*), which was the first worldwide switched network for private telephone and data transmission. AUTOVON is a global analog network, divided into two parts, the United States (CONUS) portion and the overseas portion. AUTOVON service began in April 1964.

Many businesses have installed private voice-and-data switched networks that link regional or national offices and plants. Such networks

normally operate outside the facilities of the local or regional telephone companies, although certain trunks or other transmission media may occasionally be leased on an exclusive basis as interfaces with public networks.

In addition, the interexchange (long distance) carriers have created "*overlay networks*" for leased private circuits that partially use the public switched network. Such overlay networks provide reserved or *dedicated* analog or digital circuits for large communications customers, thus minimizing their equipment investments. Sophisticated software packages, plus advanced microelectronics and fiber optics technology, have eliminated much of the *hard wiring* that limited the flexibility of earlier private networks.

Today, private computer networks are often classified as a LAN (local area network) or a WAN (wide area network). A LAN connects computers in a specific area, such as an office building or campus, an industrial park, or a factory complex. A WAN connects computers and terminals spread out over a region, usually communicating over phone lines which are part of the Digital Data System (DDS), a nationwide overlay network operated by AT&T.

Global Telephone Networks

The North American telephone network (continental United States and Canada) has more telephone lines than any other network in the world. However, many other networks are still huge in terms of the concentration of lines within their territories. North America is listed as having 41 percent of the world 500-million-plus telephones, while Europe reports 37.4 percent. The expanding global economy of the 1990s, fostered by many multinational companies, required efficient and reliable linking of the telecommunications networks on all continents.

Until the 1980s, only the U.S. assigned the responsibility for its national telephone networks to business enterprises operating as monopolies. However, these enterprises were — and still are, in the case of local exchange carriers and AT&T — regulated by state public utility commissions in terms of their rates and authorizations for services. Other nations preferred to control the operation of their networks through government ministries, usually referred to as a Post, Telephone and Telegraph (PTT) agency.

Despite the coordinating role of the International Telecommunications Union of the United Nations, various nations established differing technical standards for their national telephone system, often as a means to protect local manufacturers who supplied those systems with switches, transmission media and customer premises equipment. These differing standards are gradually being eliminated in favor of a universal global set of standards. However, certain significant differences still remain by 2000 and must be accommodated for global digital networking.

For example, at the heart of digital signal coding is the process called *pulse code modulation* (*PCM*). The American and Japanese systems use a process named mu-law PCM, while virtually the entire remaining world adopted the A-law PCM process. The two approaches are incompatible, so mu-law PCM/A-law PCM transcoders had to be created. A decision reached within the ITU assigned the responsibility for operating these transcoders to the mu-law PCM countries (the U.S., Canada and Japan). For this reason, the digital signals transmitted over the transatlantic TAT fiber-optic cables are A-law PCM, transcoded in North America from the mu-law PCM signals otherwise used throughout the U.S. and Canadian networks.

The new and expanded telecommunications systems now evolving throughout the world are expected to generate many innovative applications as they become available to wider publics. Although voice transmission is still the dominant traffic component in world communications, the volume of fax, data and video traffic is increasing rapidly. For example, as of 1991 fax transmissions made up more than 25 percent of the communications traffic originating in the United States and connected to Japan. High speed computer data exchange over global digital telephone circuits is vital to many businesses (American Airlines, for example, owns and operates a computer system called *Sabre*, or Semi-Automated Business Research Environment, which provides fares and schedules for 665 airlines, as well as information on prices and availability for more than 20,000 hotels and 52 rental car companies via 85,500 Sabre terminals used in travel agencies in 47 countries). In addition, global videoconferencing is gaining in popularity as connection set-up arrangements are simplified. Compared to time and expense costs for international traveling, multi-point videoconferencing is far more economical, efficient and productive.

Video and data communications require more transmission capacity or "*bandwidth*" than ordinary voice communications, even though video signals are being compressed during transmission with the help of algorithms. A new optical transport system for the global public networks, called the *Synchronous Digital Hierarchy* (SDH) by the ITU's international communities and the *Synchronous Optical NETwork* (SONET) by ANSI in the U.S. is gradually being introduced as a means for providing a greater range of potential services. The eight transport levels for SONET start at 51.84 megabits per second but only 49.536 megabits are traffic — the remaining 2.034 megabits are assigned to the control overhead. Each level is multiplexed into the next level until the highest rate is reached (2.488 gigabits per second). The expanded control overhead enables network operators to develop future services using data bases housed in computers called "servers," which are strategically located throughout the networks.

The most significant program on an international scale is the *Integrated Services Digital Network* (ISDN). ISDN is expected to serve the world's business community initially, replacing the confusing mixture of incompatible computer communications networks with an economical, flexible, and reliable method based on universal access standards. Although the American common carriers are offering ISDN capabilities to limited regions at first, the various "ISDN islands" were joined in late 1992 by the first transcontinental U.S. transmission of ISDN messages. This connectivity was made possible by the widespread implementation of the ITU international protocol using a new out-of-band signaling system which ITU calls CCS7 (common channel signaling system 7) and which North America calls SS7. The individual digital network switches are upgraded to ISDN internetworking by new software packages, known as "*generics*," that reprogram digital switches to enable ISDN transmission between switches.

The ISDN concept is being implemented in two stages, known as "*narrow-band*" ISDN (ranging in capacity from 144,000 bits or 144 kilobits per second to as high as 45 million bits or 45 megabits per second) and "broadband" ISDN (viewed as based on fiber optic technology and starting at 45 megabits per second). Narrow-band ISDN was implemented in the 1980s, but broadband ISDN is still evolving.

Customer premises equipment (CPE) hardware for narrow-band ISDN is usually based on the availability of two bearer or "B" channels operating at 64 kilobits per second, or 64 kb/s of transmission capacity on a telephone line, plus a 16 kb/s data or "D" signaling channel. This capability is expected to enable simultaneous transmission of voice, data, and image signals on the "bearer" channels. In ISDN terminology, this line is known as a digital subscriber line (DSL). The DSL can be connected from the customer premises directly to the switch in the central office, via a basic rate interface (BRI), or multiplexed via a primary rate interface (PRI) that contains up to 23 64 kb/s channels and one 64 kb/s signaling and data channel, carried on a T-carrier link operated at 1.544 million bits (megabits) per second. The PRI functions will usually be served by a digital PBX, linking the premises to the central office.

Voice and data transmissions are integrated in ISDN, so there is no need to run separate wire pairs for each type of signal. Because the terminals in an ISDN system can identify themselves to the system, computer and telephone users can move from one location to another without having to physically rearrange wiring and other hardware connections. In the first application of ISDN in the United States, installed in 1986 in Oak Brook, Illinois at the facilities of the McDonald's Corporation by Illinois Bell Telephone together with various vendors, the ISDN network eventually replaced a variety of different voice and data networks.

A key technological factor in ISDN is the use of packet switching with the "data" or "D" channel. A packet system divides each signal, whether voice or data, into small blocks of information (typically 16 bytes in size, including coded address data identifying the destination). These packets are transmitted on circuits shared by other signals, much like people riding a bus; as each packet arrives at its destination, it leaves the "bus" and enters the module to which it was addressed. The original signal, of course,

constitutes many packets that are separated into numerous channels or "buses," so the packets do not all arrive simultaneously; rather, they must be reorganized at the destination point before being displayed or printed. All this takes place at extreme speed — an average transmission bus can handle 42,000 packets a second. The information in a packet may be voice, data, or image signals.

The chief advantages of packet switching are flexibility and economy. A voice and data network that uses packet switches needs fewer lines to interconnect large numbers of endpoints, because each line can carry simultaneous two-way transmissions of both voice and data. Unlike conventional transmissions, the many parts of a single message can be sent along many different routes to the final address, where they will be assembled in proper order for the receiving equipment.

If the ISDN customer wants to set up a dedicated circuit to a specific number, instead of letting the network ship the messages via the usual packet switching methods, the ISDN packet switching concept allows the user to set up a *temporary* or *virtual* circuit, employing software instead of hard-wired connections. The virtual circuit can remain in place for seconds, days, or years, depending on the customer's needs. Unlike a dedicated circuit, the virtual circuit is paid for on the basis of actual time used rather than for the time in place, since others can use its capacity when no information is being transmitted.

Other applications of packet switching (however, not in the ISDN format) include the *Common Channel Interoffice Signaling* (CCIS) mentioned under the "**Switching Equipment**" heading. Previously used only by the common carriers, an advanced version of CCIS is playing an important role in an optional innovation called *Local Area Signaling Services* (LASS), in which telephone customers are able to use CCIS functions to trace obscene or harassing calls without contacting the telephone company in advance. In addition, LASS enables people — with the proper type of telephone or accessory equipment — to see a display of a calling number and name (or note that the number and name were blocked by the caller) before picking up the phone. They also can block specified numbers from being able to call into the line, or automatically recall someone who hung up just before the phone was answered. Telemarketers, medical services and others with computerized client files use a version of this technology to instantly display customer data on a terminal when a call is received from that customer's telephone.

Another future aspect in telecommunications is the use of lightwave systems in the loop, especially to homes. The high capacity of these fiber optics systems greatly exceeds the amount of telephone traffic currently generated by residences, but video image transmission — especially *digital high-definition television* (digital HDTV) — would quickly fill the available capacity. The fiber optic lines are not susceptible to interference by lightning, induction, or other electrical disturbances. However, most telephone companies want to depreciate their copper wire installations over 25 years before they invest in new fiber optic loop equipment.

The growing sophistication of the global telecommunications system is matched by a growing sophistication of the world's telephone users, large numbers of whom now use computers in their workplace and at home. Communications carriers in many nations are installing or expanding *intelligent networks*, using strategically located computers to provide on-demand services that were impossible only a few years ago. The CCS7 or SS7 signaling protocol enables the interworking of these global networks. By 1995, about three-quarters of the lines served by Bell operating companies had access to SS7 and its potential for intelligent networking.

The SS7 protocol is based on earlier versions of common channel signaling systems (CCSS), transmitted out-of-band between the telephones or customer terminals and the switches, or between the switches along a calling path. A simple example of the "intelligence" provided by the new systems is a national pizza calling line, in which the customer dials an 800 or 888 number from anywhere in the nation and is automatically connected to the nearest pizza outlet operated by the 800 sponsor. That sponsor also can insert customized messages for various outlets, announcing specials, business hours, etc.

Perhaps the most radical change in telephone network traffic in the 1990s was the sudden emergence — especially at the residential user level — of two-way data transmission produced by the Internet and the World Wide Web. Although the explosive growth of this new international "*virtual community*" with its "*chat rooms*" (which use text messages or e-mail) and direct marketing aspects was not expected by the telephone companies, they were quick to meet the demands on their networks. However, the local and long distance carriers are unable to control the quality of speech transmission over the Internet or World Wide Web, since those channels are designed for packet-switched data signals (using the Transmission Control Protocol/Internet Protocol, or TCP/IP rule sets) and are not optimized for the requirements of two-way voice conversations. Various vendors are developing new equipment aimed at improving the quality of speech transmission over the Internet/World Wide Web facilities.

Meanwhile, new approaches to network facilities are emerging as challenges to the existing frameworks. Satellites in geostationary orbit are being challenged by fleets of low-Earth orbit satellites that would permit direct calling from pocket-size telephones. See the **Satellites (Communication and Navigation)** entry. Cellular towers are being challenged by fleets of various types of aircraft, both winged and balloon, that will carry switching and relay equipment while flying in the stratosphere. Among these proposals are "*Halo*" (High Altitude Long Operation, in which the communications gear are located in a pod suspended below the aircraft fuselage, and each of three manned aircraft flies an eight-hour shift circling above a given metropolitan area), "*Pathfinder Plus*" (a propeller-driven unmanned aircraft powered by solar panels in its wings), and "*Sky Station International*" (a fleet of 250 blimps offering video, Internet access, and other types of high-speed data services around the world, as of 2001). Wireline systems are being challenged by such wireless technology as cellular and PCS systems. And the Internet is emerging as a challenge to the long distance telephone companies' billing structure.

A major fiber-optic scheme is a worldwide network called "*Project Oxygen*," a privately funded undersea facility with about 17,000 miles (27,000 kilometers) of special lightwave cable. Lucent Technologies announced in 1998 that its scientists had devised the ability to transmit as many as 10 million calls over a single fiber, dividing the strand into 80 separate wavelengths of light instead of 16. Using a technique called "*erbium doping*," the system will avoid the need for repeaters to regenerate the light signals at various points in the long cable runs. Connecting all the continents, Project Oxygen is seen as a global "*backbone*" network for video (it could transmit up to 10,000 video channels), Internet traffic, images and voice traffic. The promoters claim that costs for international voice calls will become as low as local calls. The entire network is expected to be completed by 2002.

Many other applications are evolving as the telecommunications networks of the United States and other nations apply new technologies. Scientists and engineers engaged in software development as well as microelectronics and photonic technologies are revolutionizing every aspect of communications. Current research into such intriguing concepts as "*virtual reality*" (actually an enhanced approach to techniques used in the aviation industry's advanced flight simulators) could introduce telephone users to a broader range of services featuring computer-driven three-dimensional vision and touch as well as audio.

The International Telecommunication Union compiled a "World Telecommunication Development Report 1996/1997," issued in February 1997 (an executive summary can be viewed on URL http://www.itu.int/ti/publications/world/summary/wtdr96.htm). The "Overview" section concluded: "The convergence of the telecommunications sector with the computer and broadcasting worlds is creating new synergy, most evident in the growth of the Internet, which continues to double in size every year. At the start of 1997, there were more than 16 million host computers connected to the Internet and more than 50 million users. The significance of the Internet lies not so much in what it is, but what it could become. It can be regarded as the prototype of a global information infrastructure which will lay the platform for the electronic commerce of the 21st century."

RICHARD Q. HOFACKER, Jr., Retired, AT&T Bell Laboratories

TELESCOPE (Astronomical-Optical). Since the time of Galileo (early 1600s), optical telescopes have been used to study the planets of the solar system and the stars and other objects and phenomena that comprise the cosmos. Essentially prior to World War II, optical telescopes were confined to the visible light portion of the electromagnetic spectrum. Radar and the beginnings of sophisticated electronics for purely scientific purposes were fallouts of military usage during the war, as also were the application of infrared, ultraviolet, x-ray, and other portions of the spectrum for probing the cosmos. *Sputnik* (1957) introduced the space age as a concept of reality rather than a notion out of science fiction.

These and other factors affected, slowly but steadily, the future role of ground-based optical telescopes, which over prior centuries had enjoyed exclusive rights to the disciplines of astronomy, astrophysics, and other so-called astro-related subdisciplines. Over a relatively short time span, a few authorities seriously questioned the long-term role of the optical telescope, but they also appreciated the continuing need in the short and mid term. Later it was established that improved optical telescopes would continue to play an indispensable, but not an exclusive, role in searching for the truth of the cosmos.

By the 1970s and continuing into the present, a true renaissance in optical telescope design and performance is going forward at a rapid pace. These improvements have included not only the telescope's ability to collect more photons from cosmic objects, by way of larger and better mirrors and other aspects of the optical system, but also in vastly improved detectors (sensors) as represented (for example, by charge-couple devices [CCDs]), that have markedly increased the instrument's resolution [image sharpness]). These advantages have become possible through the application of various forms of *adaptive optics* and other means that rely on computer power for their success.

Even with the dedication of several new optical observatories during the past decade, researchers still must wait in queues for instrument availability. Although funding problems worldwide often retard the construction of a new facility, progress has been impressive. Progress has been abetted by much innovative thinking in the astrophysics community. One example of this would be that of increasing the performance of optical telescopes by using them in arrays, as has been done with radio telescopes for a number of years. Serious thinking is now taking place concerning the location of optical telescopes in Antarctica and, at some future time, on the lunar surface. The verve existent at the time of dedication of the 200-inch (5-meter) reflector atop Mt. Palomar (California) in 1949 has returned to the community of research astronomers who use optical telescopes.

Chronology and Principles of Optical Telescopes

Over the centuries, optical telescopes have fallen into two major classifications: (1) refractors and (2) reflectors. Several design modes of each class have been developed.

Refracting Telescopes. Galileo, accredited with the development of the refractor (circa 1609), used the instrument to explore the Milky Way, which he referred to as a "vast crowd of stars." Over a brief span of time, Galileo discovered the craters on the moon, noted the phases of Venus, and found some of the moons of Jupiter. His simple refracting telescope was well suited for observing the coarse features of nearby astronomical bodies. The Galilean telescope operated along the lines of what was later described as an *opera glass*. See Fig. 1.

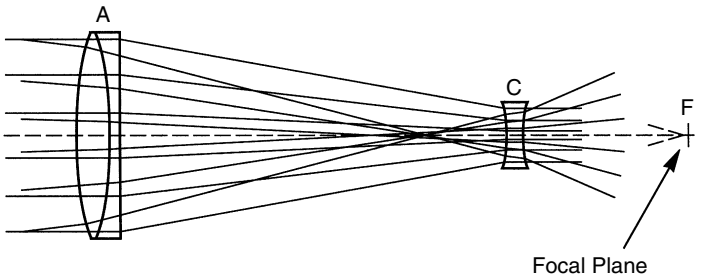

Fig. 1. Galilean telescope similar to opera glass. The objective A condenses the light from the object observed, making an image at F. However, before the rays reach their focus, they are intercepted by double concave eyepiece C.

Early scientists found that for more precise observations, the refractor had numerous disadvantages. For example, in a refractor, the light of each color is focused at a different point and thus images are blurred. When extra lenses are used to correct for chromatic aberration, a significant portion of the light received is lost to absorption by the lenses. Also, there are fundamental and practical size limitations of the refractor. Consequently, the largest refractor ever to be constructed was the 40-inch (1-meter) telescope at Yerkes Observatory (Williams Bay, Wisconsin), installed in 1897. However, in terms of large size, the "Great Refractor" was installed at Harvard University in 1843. As pointed out by P.J. Pauly (Rutgers University), "Many average Americans considered the great comet that appeared in early 1843 a confirmation of the well-known evangelist William Miller's prophecy that the world would end that year. Responsible citizens funded the Great Refractor in large part to combat such ignorant apocalyptic beliefs. In succeeding decades, Harvard astronomy prospered as part of international science. See Fig. 2.

Essentially, small, portable refractors find favor among many amateur astronomers. See Fig. 3.

The size and location of several famous refracting telescopes constructed over past years are given in Table 1. The current status of these instruments is indeterminate as of the early 1990s, but several have been retained for educational and experimentation purposes for which they are capable of handling.

Reflecting Telescopes. Sir Isaac Newton appreciated the limitations of the refractor at an early date and, in response, invented in 1668 the reflecting telescope that uses mirrors instead of lenses. In the basic reflector design, a mirror collects light and focuses all colors at the same point, while using a secondary mirror to guide the received light to a point for viewing, photographing, or otherwise processing the image. Reflectors are well suited for research in the infrared (IT) as well. See also **Infrared Astronomy**.

Herschel, in the 1780s, built reflectors up to 40 feet (12 meters) in length with primaries as wide as 48 inches (1.2 meter). A diagram of one of Herschel's telescopes is given in the article on **Astronomy**. Herschel discovered Uranus with one of these instruments.

The optical paths, as compared with the refractor and as used in representative telescopes over the past several years, are shown in Fig. 4. The pathways of the more recent, new-generation instruments are shown later in the article.

The major reflecting telescopes located worldwide prior to 1988, a time just prior to phasing in the new-generation instruments, is given in Table 2. The latter instruments are addressed separately later in this article. See Figures 5, 6, 7, 8, and 9.

Although the larger instruments are given the most attention in the literature, there are scores of smaller instruments that serve very useful

TABLE 1. LARGE, WELL-KNOWN REFRACTING TELESCOPES
(Current Status Not Known in All Case)

Diameter			
Approx. Meters	Inches	Geographical Location	Operator
1	40	Williams Bay, Wisconsin	Yerkes Observatory

purposes, not only for education, but also frequently in connection with special surveys and projects where their light-gathering power suffices. It is interesting to note from the table that relatively few observatories are located in the Southern Hemisphere. Astronomers have been aware of this shortcoming for a number of years and this fact demonstrates the significance of the Cerro Tololo (Chile) and the Las Campanas (Chile) installations. Some of the *new-generation* instruments are scheduled for the Southern Hemisphere.

Fig. 3. A wide-field refractor popular with amateur astronomers. The instrument provides a wide range of astronomical observations. (*Orion.*)

Optical Fundamentals of Telescopes

The larger telescopes offer advantages of light-gathering power and resolution, but there are limitations on the latter. If a wave front of photons falls on Earth from a distant star, the number of photons per unit area is constant; thus a large telescope of area A 1 collects A 1/A 2 more photons than a telescope of area A 2. Since the intensity is proportional to area, the difference in limiting magnitude will be

$$\Delta m = 2.5 \log \frac{A_1}{A_2}$$

Hence, a telescope with ten times the area of another will see 2.5 magnitudes fainter.

Since the resolving power of a telescope is given by

$$2.52 \times 10^5 \lambda / a$$

where λ and a (the aperture) are in the same units, the larger the telescope, the finer the separation observable. This is certainly so for telescopes up to a certain size; but at some point, resolution is not increased, because the resolving power meets the limitation on seeing. The seeing disk is seldom better than 1′ of arc. Hence, the smallest resolution possible is 0′ .5 of arc, which is obtainable with a 30-centimeter (12-inch) telescope. For larger telescopes, the only gain is in light-gathering power.

The magnification of a telescope is given by $m = f_t/f_e$, where f_t is the focal length of the telescope and f_e is the focal length of the eyepiece.

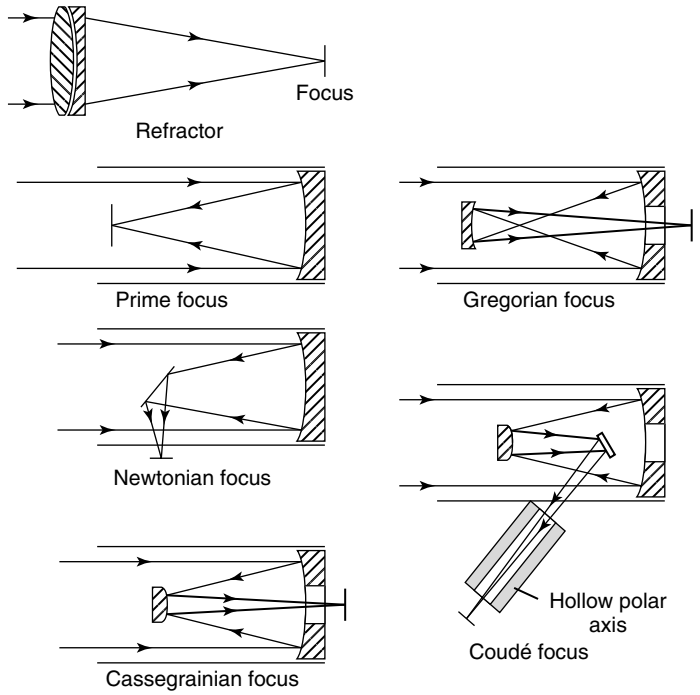

Fig. 4. Optical paths of representative traditional telescopes.

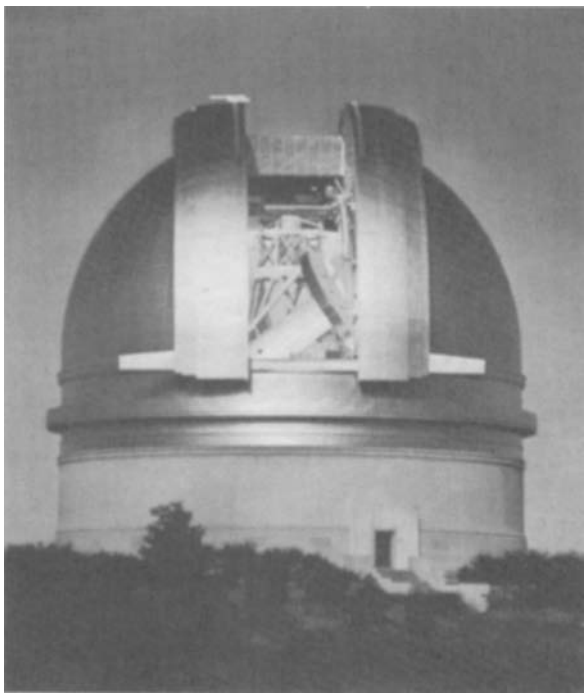

Fig. 5. The Hale telescope and dome located atop Mt. Palomar, California. The primary mirror is 200 inches (approximately 5 meters) in diameter.

It is important to note that there is usually no magnification when a telescope is used photographically. Since observatory telescopes are used photographically rather than visually, it is more customary to speak of a telescope's F number and scale factor. The F number is simply the ratio of the focal length to the diameter of the objective: $F = f_t/D$. It may be seen that for a given diameter D, the optical speed of a system increases as the F number increases. This is because the seeing disk is finite, and hence the telescope is putting all the photos into a smaller spot. An F 6 telescope is faster than an F 18 telescope of the same aperture.

The scale factor s is usually given in seconds of arc per millimeter on the plate and is $s, = 206.265/f_t$, where f_t is in meters.

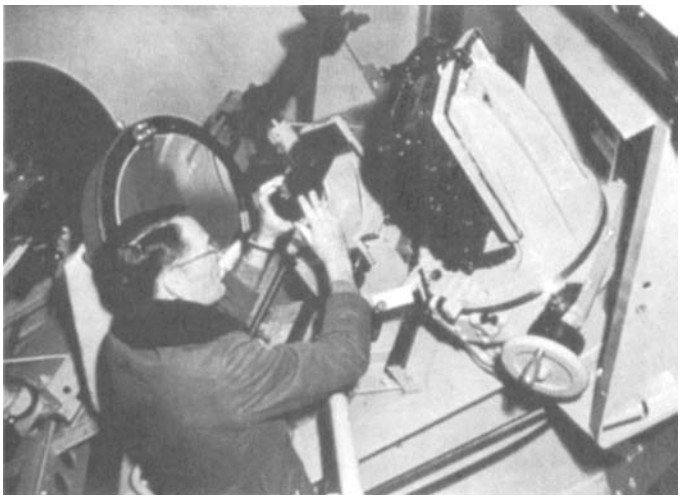

Fig. 6. Interior of the Tode grating spectrographs used with the Hale telescope.

Refracting telescopes are divided into two classes: (1) astrographs, and (2) long-focus refractors. The astrographs, having small F numbers ($\sim$6) and large fields are used for statistical and survey work. For large field surveys, the Schmidt telescope has superseded the astrograph. The long-focus refractor has large F numbers and large plate scales; hence, it is ideally suited for astronomical position measurements (astrometry). The aperture of a refractor is limited by the plastic nature of glass, and all refractors are subject to chromatic aberration. See also **Schmidt Objective**.

Reflectors are of various types: the paraboloid, the Schwarzschild, the Ritchey-Chrétien, etc. Each type has variations that are named according to the position of the secondary or focus. Thus, a paraboloidal instrument may be said to be prime focus, Newtonian, Cassegrainian, Georgian, Coudé, etc. The various positions or secondaries and/or usable foci serve distinctive purposes. See Fig. 4. The prime focus and the Newtonian focus (which diverts the prime focus to the side of the tube by means of a flat diagonal mirror) supply a fast system, i.e., low F number. The Cassegrainian position uses a hyperboloidal secondary to reflect the beam back to an aperture in the primary, and is thus at a position of convenience. By using different hyperboloids, different effective focal lengths can be achieved, and hence, different F numbers and plate scales. The Coudé always has a large F number and is advantageous because its fixed position allows the use of large cumbersome equipment. The catadioptric telescopes are the Schmidt and the Maksutov, and the correction-plate and two mirror systems. See also **Coudé**; **Maksutov-Bouwers Telescope**.

Low Light-Level Detectors and Image Sharpness

Methods for improving telescopic images date back about 70 years. In 1921, Michelson and Pease introduced interferometric techniques to telescopes. Speckle interferometry was pioneered by Labeyrie many years later (1972) and an intensity interferometer was proposed by Brown and Tiss in 1974. Some of the early methods required the use of a bright nearby reference star (a difficult requirement for most observations).

The principles of active and adaptive optics have been known for several years, but it required the technological fallout from the Strategic Defense Initiative (SDI) and the availability of appropriate computer power to enable their present rapidly advancing applications to astronomy.

Traditional Photographic Plates. For over a century, astronomers have used photography for capturing the images of celestial objects. The photographic plate has had many advantages. Over the years, emulsions have improved immensely.

The photographic plate can read huge amounts of information — as many as 10^8 pixels on a single plate. The information is furnished in a way that is easy to comprehend, as contrasted, for example, with digitized presentations. The photographic plate also permits the integration of information over long exposure spans, making it possible to detect very faint objects. Plates are easy to study and to store

permanently. As astronomical research advanced, however, the limitations of photographic plates became increasingly important. These limitations include: (1) photographic plates are nonlinear in their response; (2) they have a limited dynamic range; (3) there is a reduction in sensitivity with increased exposure time (reciprocity factor); (4) there are so-called adjacency effects, e.e., adjacent pixels may not be individually resolvable; (5) there is a low quantum efficiency; and (6) there are limitations as the result of finite granularity. Some of these limitations have been reduced or alleviated through advances in image processing, notably the use of digital technology. See also **Photography and Imagery**.

Even with the success of photography over many years, in the 1950s researchers began to seek photodetectors with comparatively high quantum efficiency and an efficiency that would extend over a wide range of wavelengths. This search was spurred, of course, by the increasingly available devices stemming from solid-state and semiconductor technology. During the 1970s, a number of approaches were taken, one being that of using a silicon intensified target (SIT) vidicon. Experiments were conducted at Mt. Palomar and Kitt Peak with considerable success.

Traditionally, astronomers analyzed photographic sky surveys by inspecting photographic plates on a light box, using powerful jeweler's-type magnifiers, a slow and tedious task. Among the modern analytical systems developed during the past few years is the Automatic Plate Measuring System (APM), developed at the University of Cambridge. In this particular system, each photograph is laser scanned in connection with a microdensitometer, which digitizes the information. A plate may contain as many as 4 gigabytes of information.

Fig. 7. Aerial view of Kitt Peak, Arizona, a site which includes the telescopes of six observatories: (1) Kitt Peak National Observatory; (2) National Solar Observatory; (3) Steward Observatory (University of Arizona); (4) Warner and Swasey Observatory (Case Western Reserve University); (5) McGraw-Hill Observatory (Massachusetts Institute of Technology, Dartmouth, and University of Michigan consortium); and (6) the National Radio Astronomy Observatory (NRAO). The large dome in the lower left foreground of view is the 4-meter (158 in.) Mayall telescope and beside it is the Steward Observatory instrument. In the left background is the McMath Solar Telescope. The white dome at the upper center of view is the 2.1-meter (83-in.) instrument. The NRAO and McGraw-Hill domes are not shown. (*National Optical Astronomy Observatories*.)

Charge-Coupled Device. The CCD, invented in 1969 (AT&T Bell Laboratories) consists of a three-layered semiconductor device, one layer of metallic electrodes and another of silicon crystal, separated by an insulating layer of silicon dioxide. The CCD uses the familiar phenomenon found in many microelectronic devices, namely, the ability to permit negatively charged electrons (or positively charged "holes") to move about controllably in semiconductor material. Most devices use this characteristic to change the electrical current flowing through them — as amplifiers or switches. The CCD stores and transfers information in the form of packets of electrical charge analogous to the tiny magnetic domains in bubble devices.

After wide acceptance of the CCD for use in television cameras, they were incorporated into a number of astronomical imaging systems. The topic is described in considerable detail in the Kristian-Blouke article (reference listed). See also **Charge-Coupled Device (CCD)**; **Microelectronics**; and **Semiconductors**.

Adaptive Optics. This expanding technique for use in optical telescopes largely is based upon technological fallout of the Strategic Defense Initiative (SDI) program in the United States during the 1980s. The original objective was that of eliminating atmospheric distortion of images of foreign satellites in orbits so that laser beams fired into space could disable such missiles at great distances. In early 1982, astronomers at the Mount Wilson Observatory (Pasadena, California) commenced applying the principles of adaptive optics to the 60-inch (1.5-meter) telescope at that

Fig. 9. The Curtis-Schmidt telescope of the University of Michigan/Cerro Tololo Inter-American Observatory. This is a twin of the Case Western Reserve University's instrument on Kitt Peak, Arizona. The Schmidt type telescope is designed to take wide-angle photographs and spectrographs of the sky. (*National Optical Astronomy Observatories*.)

location. The driving force for this was the researchers' estimate that the technique may allow telescopes to see images of objects 10 to 20 times sharper that may be from 100 to 400 times fainter than as captured by traditional optical telescopes. In addition to objects in far outer space, the technique also can provide more detail of the planets in the solar system, including the study of dust storms on Mars, weather conditions on Jupiter, and volcanic eruptions on Jupiter's moon, Io. It is predicted that adaptive optics ultimately will resolve, at least partially, the tens of thousands of stars that make up the globular cluster that occurs near the center of our galaxy. As one observer states, "The effect is that of a zoom lens focusing in on previously unattainable details."

Transfer of the previously exclusive military technology is proceeding at a good pace. Prior research in the military phase was conducted at the Kirtland Air Force Base, New Mexico, the University of Chicago, MIT's Lincoln Laboratory, and several independent military contractors. There is a consensus among researchers that upgrading land-based optical telescopes may be less costly than operating huge telescopes, such as the Hubble instrument. As of late 1993, much of the SDI information has not been declassified. Thus, the technique may be considered as still being in an early phase of practical development.

Central to a contemporary adaptive optics system is a small deformable mirror (in the range of 4 inches (10.2 cm)) that is capable of deforming and thus reshaping its surface at a rate of hundreds of times per second in the interest of neutralizing atmospheric effects. In one design, a laser beam is reflected from the upper atmosphere onto sensors within the telescope. The reflected light is analyzed by computer through the use of light sensors. Based upon this, very small mechanical fingers can "tweak" the surface on the order of. 001 millimeter. Currently, there are a number of detailed design options. For example, some researchers prefer to rely on a guide star, wherein the computer would reference that as a sharp point for compensating any blurring. Johns Hopkins University, the Georgia Institute of Technology, and Georgia State University, among others, are engaged in the development of new designs.

Adaptive optics research requires a thorough understanding of light pathway optics and mathematics.

Adaptive optics does have some limitations. The corrected field of view astronomers see in the sky covers only a partial area of the field of view of a large telescope (i.e., smaller than some galaxies appear).

The atmosphere over Mauna Kea (Hawaii) is one of the cleanest in the world, which is the reason, of course, why that particular mountain at an elevation of 13,780 feet (4200 meters) above sea level was selected for the Keck telescopes and other important instruments. Some astronomers have suggested that instruments at that location, when equipped with some form of adaptive optics, should be as close as one can come to an orbiting or a lunar-based optical telescope. Adaptive optics is particularly effective in the infrared range, where atmospheric distortion tends to be less than that for visible light.

Even with the power of telescopes located on Mauna Kea, stars do not appear as tiny bright points, but as jittery blurs approximately one-half of 1 arc second across, because of fine-grain atmospheric turbulence. Some mechanisms of adaptive optics can correct the image.

The use of a laser as a measure of atmospheric turbulence was first suggested by the French astronomers Renaud Foy and Antoine Labeyrie. The procedure suggested by these researchers, as reported by A. Finkbeiner: "Create an artificial star by shooting a laser into the atmosphere, where it is reflected by dust or creates a spot of fluorescence in the thin layer of sodium ions 900 kilometers up: Place the artificial star next to the dim object; Do the adaptive corrections on the artificial star; Apply the same corrections to the dim object you really want to see."

An ultrasimplistic diagram of this form of adaptive optics is given in Fig. 10.

In another related technique, a reimaging lens is used. After light enters the telescope, the light will strike a mirror of flexible *Mylar* stretched over a bundle of piezoelectric actuators. The latter deform the *Mylar* lens in response to computer commands. A second rigid mirror tilts to perform larger-scale corrections.

Active Optics. H.W. Babcock (The Observatories of the Carnegie Institution of Washington, Pasadena, California) has made serious reference to the use of *active optics* in optical telescope design. Babcock observes, "Closely related to adaptive optics there is a much slower type of system now known as *active optics*. It may be used for occasional adjustment of the several supports of the primary mirror; through flexure, the adjustments improve the effective optical figure. This procedure which I proposed in 1953, may be conducted with any reasonably bright reference star; it does not require rapid response."

It is interesting to note that active optical systems were demonstrated by researchers at the European Southern Observatory in the late 1980s and have stated that active optics provides improvements in performance that warrant its serious consideration for all large telescopes in the future.

Interferometry in Optical Telescopes

Interferometry at optical wavelengths first was demonstrated by Albert Michelson (Case Western Reserve University, Cleveland, Ohio) in 1887, for which he was awarded the 1907 Nobel Prize (physics). While Michelson's work figured prominently in connection with the Michelson-Morley experiment, which disproved the presence of an "ether" and served as an initiating point in Einstein's development of the theory of relativity, the serious application of interferometric principles in astrophysics occurred in the late 1940s and early 1950s when researchers, applying early electronics technology developed during World War II, found that the interferometric techniques were much more easily applicable to energy at radio wavelengths, culminating in such impressive installations as the Very Large Array radio telescope in New Mexico.

A simple Michelson interferometer is shown in Fig. 11.

Closure Phase. The principles of the closure phase, a number measured by triplets of Michelson interferometers, is fully independent of certain types of otherwise severe instrumental errors. Since the 1950s, when the principle was first noted, it has been applied to several problems involved with astronomical imaging. As pointed out by T.J. Cornwell (National

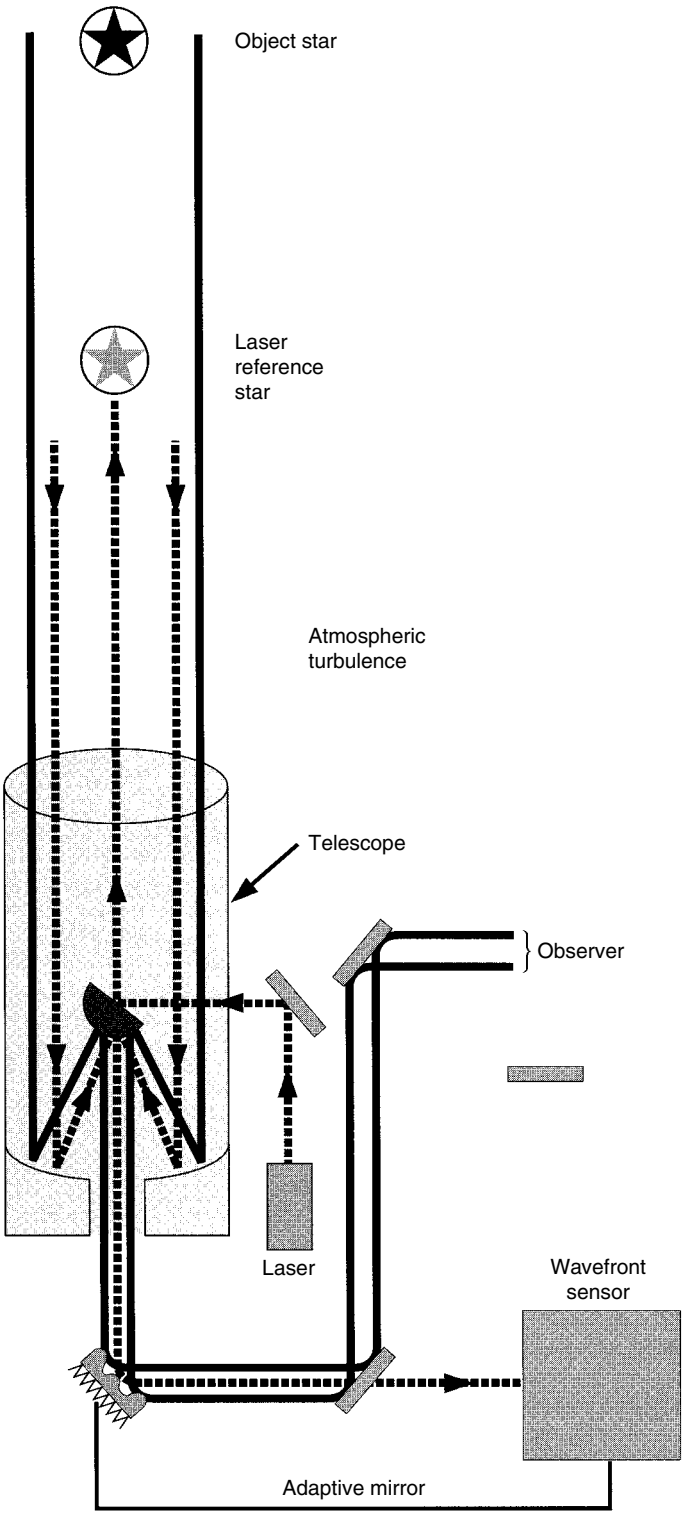

Fig. 10. Highly schematic diagram of one technique for achieving adaptive optics.

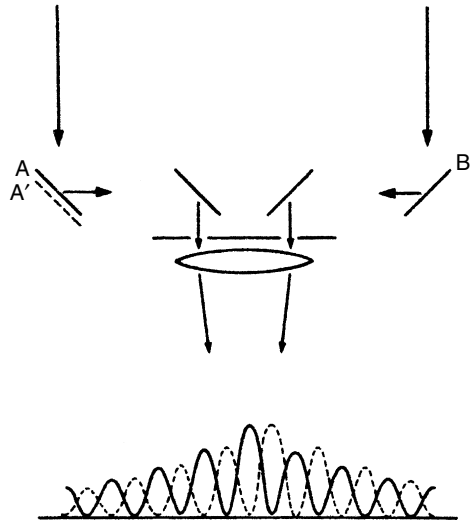

Fig. 11. Elements of a Michelson interferometer. Light collected at the outlying mirrors A and B is brought to a common focus where fringes are observed. Shifting the mirror at left from A to A′ in the one arm shifts the fringes as shown below. (*After Cornwell, National Radio Astronomy Observatory*.)

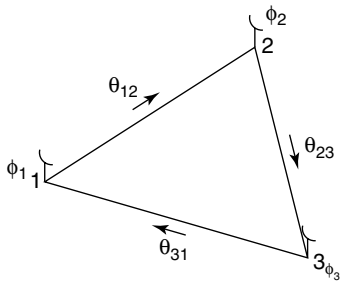

Fig. 12. Demonstration of closure phases. The element-based errors 01 vanish in the sum of the observed phases around a loop, a phenomenon that is known as Jennison's closure phase. (*After Cornwell, National Radio Astronomy Observatory*.)

Radio Astronomy Observatory, Socorro, New Mexico), "Methods based on the closure phase now allow imaging of complex objects in the presence of severe aberrations and are vital to the success of modern, high-resolution astronomical imaging both at radio and at optical wavelengths. Over the past 10 to 15 years, the concept of closure phase has been extended and generalized. One of the most important advances has been the development of automatic or self-calibration techniques."

As applied to optical imaging, Cornwell observes that closure phase can be applied to optical imaging by "forcing the optical aperture to mimic the sparse filling found in radio interferometry." In so doing, the aperture of a conventional optical telescope can be considered as being made up of many interferometers formed between constant atmospheric phase. See Fig. 12. Thus, an image at the telescope's focal plan can be considered as being made from the combination of all these many interferometers. It is essentially impossible to sort out the contributions of the individual interferometers. However, a mask in the pupil can be used to force nonredundancy of measurement, thus making it "possible to derive closure phases from the Fourier transform of a single short snapshot."

A primary disadvantage of the masking approach is the loss of most incident photons. This problem, however, can be overcome by using the so-called "speckles" technique. Observers with years of experience have noted that fine detail (speckles) can be seen in the seeing disk for very brief periods of time. The use of this technique, plus other applications of the closure phase, are well explored by Cornwell, who summarizes his paper (reference listed) as follows: "Closure phase methods are applicable to any instrument that measures correlations between the quantities measured by error-prone sensors. The closure phase principle underlies the imaging in many different astronomical contexts: radio interferometry, high-resolution imaging with single optical telescopes, aberration correction in single radio telescopes, and scintillation phenomena."

Fully-Filled Aperture Technique. A computerized imaging technique first was used in connection with the 200-inch (5-meter) Hale telescope on Mount Palomar, California, as early as the late 1980s. Astronomers (California Institute of Technology) have reported that this technique and another technique known as Non-Redundant Masking have virtually eliminated the distorting effects of the atmosphere, making it possible for this (and any other optical telescope) to approach its theoretical

maximum resolution. Improvements at the Hale installation have been estimated as a factor of 20, from roughly 1 arc second to about 50 milliarc seconds.

The fully-filled aperture technique requires no direct telescopic hardware. The blurred image simply utilizes the *speckle interferometry technique*. The computational demands have been described as horrendous, requiring the full parallel processing power of Caltech's 512-node "hypercube" supercomputer.

In the non-redundant masking technique, an opaque screen pierced with from five to seven very small holes is placed at the prime focus of the telescope. The separate rays of light that pass through the screen are recombined into an *undistorted* image through the application of mathematical algorithms. The latter are available from developments for use with radio telescope observations.

In either case, a satisfactory, clear image results, but at a high cost of computer power.

Mirrors and Lenses. From the time of Galileo, lens grinding for telescopes has been an arduous, painstaking task. The measurements required to control the process and the final results of the process traditionally have been inadequate for assuring perfection. New and revolutionary optical component facilities that utilize laser measurement devices and computer controls have appeared during the past decade. For example, at the Optical Science Laboratory (University College, London) a 30-ton grinding and polishing machine is capable of making mirrors and lenses with diameters up to 2.5 meters for cutting telescope blanks to within one micrometer or better.

During the period of the renaissance in telescope design commencing in the early 1980s, much attention has been given to mirror design and production. In addition to monolithic main mirrors, new honeycomb, segmented, and meniscus mirrors have been produced. With the emergence of various forms of adaptive adoptics, mirrors must be engineered as components of the total telescope system. Innovative designs are shown in Fig. 13.

In connection with the new WIYN (University of Wisconsin, Indiana University, Yale University, and National Optical Astronomy Observatories) telescope, under construction as of early 1994 and which will be the second largest telescope on Kitt Peak, unprecedented attention has been given to mirror design and production. The 3.5-meter (137.8-in) mirror was spun-cast and then polished at the University of Arizona Mirror Laboratory. A polishing technique known as stressed lap polishing, developed at the U of A laboratory, involves the use of a computer-controlled shaping tool that makes it possible to control the final figure of the mirror over the entire surface to a high degree of accuracy. Just over 150 hours of machine grinding and polishing, plus ten sessions of hand polishing, led to the final, extremely smooth surface.

Smoothness of a mirror's surface is one criterion of mirror quality, and it usually is expressed as a measure of the average amount of "bumpiness" on the surface. This "root mean square" measurement for the WIYN mirror is 16 nanometers, or less than one millionth of an inch. As one researcher stated, "One can visualize this degree of smoothness by picturing a mirror of a size stretching between Los Angeles and New York. In that case the rms measurement would show the average bump height of the mirror to be about an inch."

An important advance made during the polishing of the mirror was the application of pressurization polishing the cavities that exist within the mirror. Because of the honeycomb structure of the mirror, the top surface of the mirror is supported by honeycomb-shaped ribs around open cavities to minimize the weight of glass in the mirror. A problem called "print-through" can occur during polishing. As the polishing tool, called a lap, pushes on the mirror, portions directly over a supporting rib tend to be stiffer, leading to unevenness near the positions of the ribs. This problem was solved by putting the cavities between the ribs under air pressure equal to the downward pressure of the polishing lap, thus stiffening the glass over the cavities so that the surface was polished evenly.

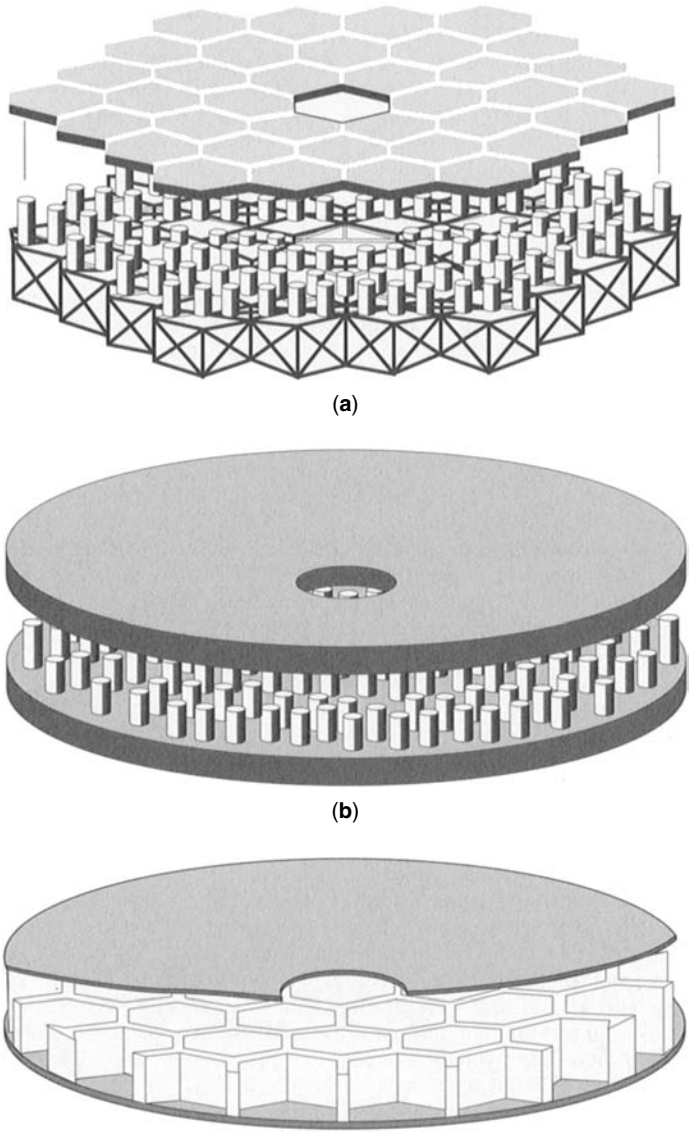

Fig. 13. Types of telescope mirrors: (**a**) Segmented mirror. Rather than using a single (monolithic) large mirror, small, hexagonally shaped mirrors can be used. The segments are aligned by motorized controllers to maintain the correct shape for creating a single image. (**b**) Meniscus mirror. A solid reflecting surface is used. The reflector surface is so thin that it cannot maintain a rigid shape unless supported from below. Mechanical actuators are used to maintain the desired shape. (**c**) Honeycomb mirror. A thin reflective surface rides on the top of a glass honeycomb structure. Although such mirrors are stiff, they are relatively lightweight because of honeycomb-supporting structure. (*Source: C.F. Powell reference listed.*)

Gravitational Lensing — Gratis Magnification!

The phenomenon of gravitational lensing may become an important strategy for astronomers in probing the currently uncharted regions of dark matter that permeate regions of the universe. Dark matter remains poorly understood. Some authorities believe that it may be made up of dead stars, planets, mini black holes, *or exotic particles* (?).

Although gravitational lenses are not part of a researcher's costly optical equipment, but exist naturally in certain situations in space, these "free" lenses can be put to use. The existence of a gravitational lens is consistent with earlier observations made by Einstein in connection with the general theory of relativity. As pointed out by the article on **Quasars**, a discovery of a "pair" of quasars noted in 1979 by researchers ultimately was concluded to be a pair of images of a single quasar, as the consequence of a nearby gravitational lens. The interesting and illusory effects of a gravitational lens were discovered by the Hubble Space Telescope some time after it was launched. At first considered to be an artifact caused by the telescope's "fuzzy" imaging, it later was diagnosed as "the most spectacular example of gravitational lensing yet," according to R. Ellis

(Durham University) and D. Weedman (Pennsylvania State University). The researchers commented further, "Gravitational lenses are nothing new for astronomers, but normally the image of the galaxy that is stretched or multiplied by the intervening mass turns into *just a blur of light*. This latest example — mirror images of a galaxy about 10 billion light years away — is the first to preserve the detail in the distant galaxy. And that makes this image a powerful probe of the object that is doing the lensing, i.e., a cluster of 799 galaxies perhaps 4 billion light-years away called AC 114."

For some years, a Laser Interferometer Gravitational Wave Observator (LIGO) experiment has been underway. The project, largely a development of the California Institute of Technology and Massachusetts Institute of Technology, would be directed toward locating the presence of gravity waves in the cosmos. In essence, the objectives of the LIGO experiment have been debated within the science community. One researcher on the project observes, "We're talking about the collapsing cores of supernovas, or the collisions of black holes and neutron stars — events you have no hope of seeing with light. A prime example of such an event would be the death spiral of a binary pulsar." Our own galaxy is already known to contain at least one binary pulsar. Other scientists comment that LIGO is a costly project just to verify a prediction of general relativity, particularly because a majority of physicists believe in the theory without further proof.

Renaissance in Telescope Design

When the 5-meter (200-in.) Pyrex glass disk was cast for the huge reflector on Mt. Palomar. California in 1948 that instrument represented the acme of telescope making technology. A number of similar, but somewhat smaller instruments were put in place at various locations in the years to follow, but there were no real breakthroughs in telescope design until the early 1980s. Arthur F. Davidson (Center for Astrophysical Sciences, Johns Hopkins University) has observed. "Historically, apertures have doubled every 40 or 50 years, which means that we're due for the next phase in the 1990s. And, in fact, the technologies are falling into place."

Announcements made in later 1986 provided evidence of a renaissance in ground-based astronomy, emphasizing the continuing and expanding role of the reflecting telescope. Some of the programs planned already have reached fruition; others are in a late stage of development. Some more recently proposed programs are in the planning stage.

Keck I and II Telescopes on Mauna Kea, Hawaii

Keck I features a 10-meter (394-in) segmented primary mirror, composed of 36 separate hexagonal pieces. Construction commenced in the late 1980s. Keck I is a joint project of the University of California and the California Institute of Technology. In 1985, the W.M. Keck Foundation made a $70 million gift toward funding the project. Because the huge mirror is built up of segments, the individual segments are thin and lightweight. Each mirror segment is precisely controlled by computer commands for maintaining the mirror surface as optically perfect as possible. A complex of sensors and mechanical actuators is required. The optical path of Keck I is shown schematically in Fig. 14.

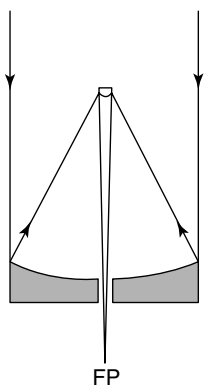

Fig. 14. Optical pathway of the W.M. Keck Observatory reflector. Main mirror is made up of 36 hexagon segments FP = focal point.

As a preliminary test of the optics, when only 9 of its total of 36 mirror segments were in place, the instrument was turned skyward to gather in its first light. This image was that of the galaxy NGC 1232. Results of the pre-trial were very satisfactory. As of 1993, the entire system essentially is operational.

The gigantic mirror rests on complex machinery. Springs and flex discs keep each segment stress-free as the telescope angles toward different parts of the sky. Hydraulic actuators align the segments into a single 32-foot (3.8-meter) reflector.

Keck I incorporates a 256-by-256–element indium antimonide infrared array. The $94 million Keck I, the first of a new generation of superscopes, is among four infrared telescopes atop the 14,000-foot extinct Mauna Kea volcano in Hawaii with optical and infrared capability. The Keck telescope is expected to complement spaceborne optical telescopes, such as Hubble, by reading the chemical "signatures" provided by the space telescopes.

As of 1993, a companion (side-by-side) Keck II instrument is in the late planning phases. It will be jointly by the Keck Foundation, Cal Tech, and MIT. The two Keck telescopes essentially will be identical, but Keck II will incorporate any improvements as noted in the early operations of Keck I. When completed, the two Keck telescopes will have eight times the light-collecting power of the 200-inch (5-meter) Hale telescope on Mount Palomar (California).

The National New Technology Telescope (NNTT)

This project of the National Optical Astronomy Observatories, as designed, will include four 8-meter (315-in) telescopes mounted, as shown by the optical pathway diagram of Fig. 15. When operated together, the combined telescopes will equal the power of a 16-meter (630-in) single telescope. The project throughout its history (first conceived in 1978) has been the subject of some controversy and budgetary problems. Early on, it was envisioned that the NNTT essentially could serve the interests of astronomers across the board, whereas priorities for working time on large, privately funded instruments could be somewhat biased. The original charter for funding the project emanated from the National Science Foundation (NSF).

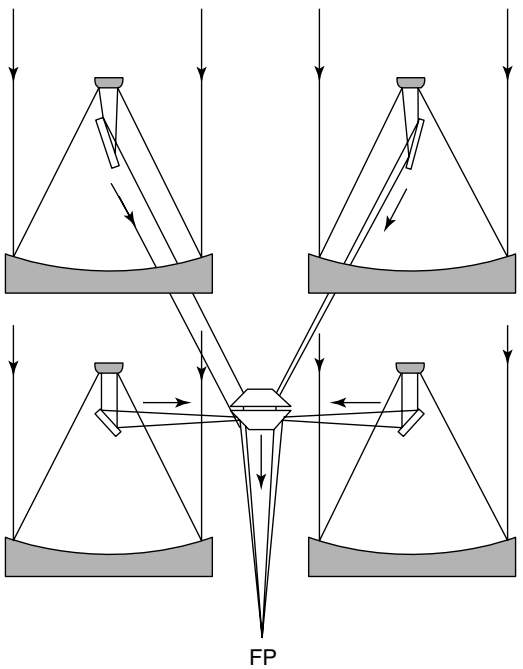

Fig. 15. Optical pathway of proposed National New Technology Telescope (NNTT). The system includes four 8-meter (315-in.) telescopes, which when operated together will be the equivalent of a 16-meter (630-in.) instrument. FP = focal point.

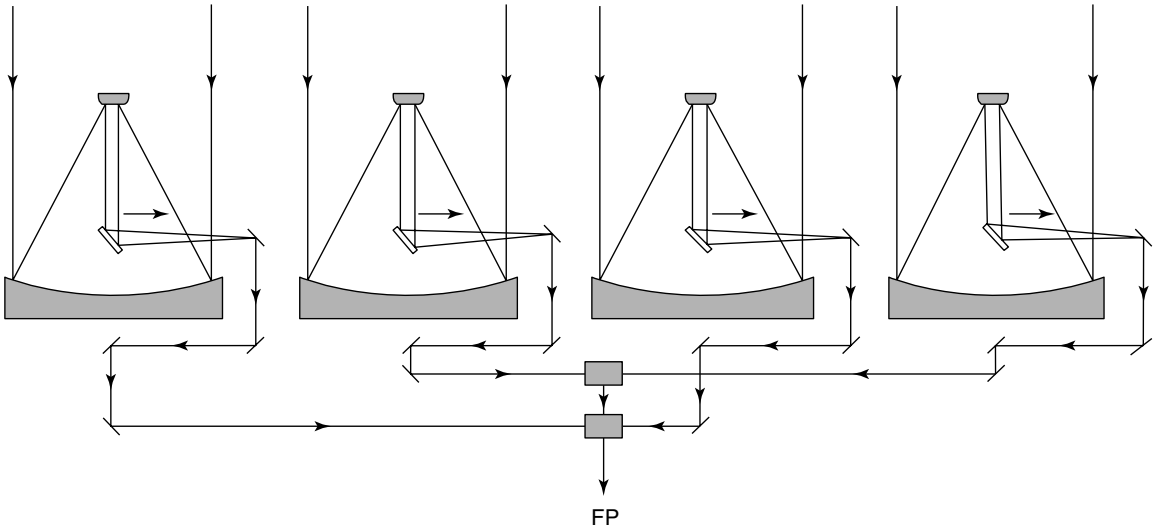

Fig. 16. Optical pathway of proposed Very Large Telescope (VLT) intended for installation at the European Southern Observatory. The system will comprise four 8-meter (315-in.) reflectors mounted in a linear array. Each of the instruments may be used alone or in varying combinations. FP = focal point.

Very Large Telescope (VLT) at the European Southern Observatory (ESO)

This design consists of four 8-meter (315 in.) reflectors mounted in a linear array. The telescopes may be used independently or operated together to provide the equivalent of a 16-meter (630-in) reflector. The light pathway is shown schematically in Fig. 16. The VLT now under construction will be located on a mountaintop site in Cerro Paranai, Chile, nearby the location of ESO's New Technology Telescope (NTT), which was completed in 1990 and located at La Silla, Chile. The latter is a 3.5-meter (138-in) reflector.

Columbus Telescope (Mount Graham, Arizona)

In October 1986, the University of Arizona, Ohio State University, and the University of Chicago, with the participation of the Osservatoril Astrofiscio di Arcteri (Italy), announced a joint effort to construct a "binocular"-type telescope on Mount Graham, Arizona, with the intent of completion during the early 1990s. Each of the two telescopes will be 60% larger than the veteran Mount Palomar instrument in California, and the light-gathering power will be 2.5 times greater. The proposed light pathway is indicated in Fig. 17.

The project was slowed, partially due the pullout of Ohio State from the venture. Until the needed funds are fully available, the consortium plans to commence construction with only one of the twin 8.4-meter (33-in) mirrors called for in the original design, but with the intent for ultimate completion of the initial plan. Very early construction procedures commenced in mid-1993, after authorities gave approval, thus denying the objections of a limited number of environmentalists.

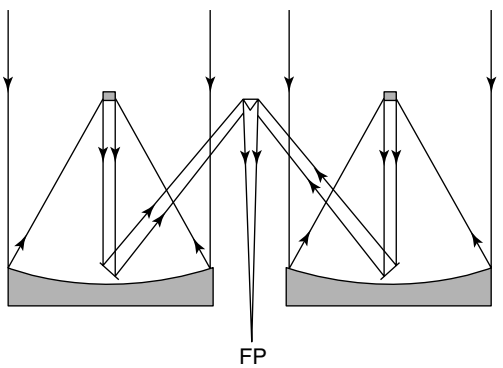

Fig. 17. Optical pathway of the proposed Columbus (Two-Shooter) telescope that is designed like a pair of binoculars. FP = focal point.

Summary of Expansion Plans

There is insufficient space available in this article to cover numerous other examples of the new-generation telescopes, completed or in the planning phase. A few brief mentions are in order.

In the fall of 1986, the Carnegie Institution of Washington, the Johns Hopkins University, and the University of Arizona announced a collaborative effort for the construction of a new 8-meter (315 in.) telescope for installation at Carnegie's Las Campanas Observatory in Chile. Although the instrument will have only one mirror, the telescope will become the largest in the Southern Hemisphere, with an excellent view of the Magellanic Clouds and the center of the galaxy.

Other projects include the Multiple Mirror Telescope Upgrade (Smithsonian), Mount Hopkins, Arizona; Magellan Carnegie Institution and Johns Hopkins University, Las Campana, Chile; and the Japanese National Large Telescope, proposed for Mauna Kea, Hawaii.

In 1988, the University of Texas and Pennsylvania State University proposed a new Spectroscopic Survey Telescope (SST) for location at McDonald Observatory in Texas. The proposal promised twice the light-gathering power of any existing instrument at a strikingly low cost. The basic concept is that of constructing an instrument that does nothing but spectroscopy. The essence of the concept is the mounting. The SST would be permanently offset from the vertical direction by 30° and could only pivot around the vertical axis. Unlike conventional telescope designs, the instrument would not track stars across the sky, but rather, as it is positioned and pointed toward a given object in space, it would remain fixed in place while the earth's rotation would carry the object across the instrument's field of view.

Large Arrays of Smaller Telescopes

Some authorities have voiced the opinion that at some future date large arrays of smaller optical telescopes (along the lines of large-array radio telescopes) may play a major role in astronomy some years ahead. It is interesting to note that since 1986 researchers at the Mount Wilson (California) Observatory have experimented with two mobile light collectors that can be placed up to 31 meters (102 feet) apart, and, using interferometric measurements, surprisingly good results have been obtained.

Optical Telescopes in Antarctica

Although not a new topic, increasing interest is being shown by researchers in the location of telescopes in the Antarctic. Martin Pomerantz (Bartol Research Institute, University of Delaware) has been pointing out to the scientific community the benefits that may derive from telescopes installed

in that region. He does concede: "It's a hard place to do science, unless you compare it to space." However, the benefits of thin, clear, and dry atmospheres of the region cannot be denied. Cosmic ray research from that area has been successful for many years. It is interesting to note that much of Antarctica is quite high (above sea level). For example, the Amundsen-Scott experiment station is located atop nearly 1.9 miles (3 km) of ice. Low winter temperatures reduce air pressure, adding an extra half kilometer to the effective altitude.

Some researchers have observed that unmanned balloons launched from Antarctica compete with Shuttle flights for observing hard x-rays and gamma rays. For observing in the infrared and submillimeter wavebands, the Antarctic is particularly attractive because of the very low concentration of water vapor, which absorbs radiation at this end of the spectrum.

As pointed out by J. Bally (AT&T Bell Laboratories), "Carbon provides a way to study how newborn stars literally destroy their placental cloud environments by radiation and winds." But sub-millimeter radiation from atomic carbon is absorbed by water vapor in most locations on Earth, causing interested astrophysicists to reserve time on NASA's Kuiper Airborne Observatory (a converted jet transport).

In early 1991, the National Science Foundation (NSF) established the Center for Astrophysical Research in Antarctica (CARA), with a plan for building a series of long-wavelength telescopes near the south pole.

Lunar-Based Telescopes

Concurrent with plans for visiting the Moon early in the age of space exploration, the concept of using the moon as a base for astronomical observations has been debated. Most of the arguments, pro and con, of lunar observatories are well covered in the literature, and particular reference to the J.O. Burns and B.F. Burke references listed is suggested.

The Hubble Space Telescope

This instrument named after Edwin P. Hubble, a renowned astronomer (1889–1953), is an imaging, plarimetric, astrometric, and spectroscopic 2.4 meter (94.5 inch) mirror observatory designed to operate in low-earth orbit. It is a combined ultraviolet (UV) and optical telescope. It is the first of several space telescopes; later generations are to be designed for more specialized service. See also **Hubble Space Telescope (HST)**.

TELESCOPIUM. A southern constellation located near Scorpius.

TELEVISION INFRARED OBSERVATION SATELLITE (TRIOS). See **Polar-Orbiting Operational Environmental Satellite (POES)**.

TELEVISION (TV). Once simply called "seeing at a distance," television is defined by the Institute of Electrical and Electronics Engineers (IEEE) as "the electric transmission and reception of transient visual images." Kiver and Kaufman stipulate TV as "the science of transmitting rapidly changing pictures from one place to another."

In the modern interpretation of TV, the term *television system* more appropriately connotes not only the visual (video) transmission of information, but the accompanying transmission of sound (audio) information, as well as means for storing and retrieving both video and audio data to extend the utility of the system beyond the simultaneous transmission and reception of information in real time. Video recording in the form of video cassette recorders (VCRs), for example, has significantly enhanced the value of TV in that the user not only can record "live" programs for later and innumerable "playbacks," but a large variety of prerecorded (video and audio) programs, ranging from individually and commercially made movies, educational, etc. presentations, may become "alive" on the TV set. Television is rapidly becoming a *multimedia* communications tool for education and entertainment.

In terms of the video elements of a television system, the principal elements required include: (1) a camera-type device for picking up the scene, (2) a transducer to convert the light impulses of the scene to corresponding electrical signals, (3) a transmitter to convert the electrical signals into suitable form for transmission to a distant receiver, (4) a receiver to pick up the transmitted signals and convert them to the appropriate form to apply to a further transducer, which (5) converts the electrical signals back into light and thus reproduces the original scene.

Chronology of Television

The concept of television, unlike some inventions that can be attributed to a single individual or group of individuals, represents a melding together of the findings of numerous scientists and inventive-type persons in a number of countries. Most of the early research commenced in the 1880s, during which period several rather crude systems for transmitting pictures over electrical wire were introduced. The concept of scanning was first suggested by Paul Nipkow in 1884 when he invented the *scanning disc*.

During the course of TV development, a breakthrough occurred with the realization that a "picture" should be broken up prior to transmitting it. Introduction of the cathode-ray tube (CRT) in 1900 represented a major accomplishment, and, of course, this basic technology remains today as a key element of a TV system. It was learned, however, that the early CRT, although well qualified for *reception*, was not useful for *transmission*. It was not until 1933 that the *iconoscope* was designed by Vladimir Zworykin and was used in early systems (TV camera). The iconoscope essentially was the inverse of the receiving CRT, in that it was capable of translating into electrical currents the light images that were focused upon a plate inside the tube. Further innovations were made, including the design of a scanning tube (image dissector) by Philo T. Farnsworth just a few years later.

Television on a very limited basis commenced in Britain in 1936. The system employed 405 lines operating at 50 frames per second. The range of the initial service was only 35 miles (56.3 km), and thus the number of viewers was too small for the transmission service to have any impact as a social force. In Britain, the 405-line system persisted for about 40 years, until adoption of the 625-line system in 1964. Television broadcasts of any major proportion did not commence in the United States until after World War II.

Color TV was introduced in the late 1960s. With color TV came the need for the application of digital techniques. Cable television, a system in which signals from distant stations are picked up by a master antenna and sent by cable to paying individual subscribers, was introduced in the United States in the early 1960s. During approximately the same time, closed-circuit television, in which the signal is transmitted by cable rather than by radio waves, was introduced for applications in business for staging remote conferences, in hospitals for observation medical procedures, and by industry for remotely operating heavy equipment. Satellite-direct-to-home television became possible, in lieu of community antenna television service (CATV) in the early 1970s and continues. In the early 1980s, the so-called "Sky Cable" concept was proposed. The system also is called *DirectTv*. The *Hughes HS601* satellite is scheduled for very early launching. The satellite will deliver news, sports, movies, and specialty TV programs to households equipped with low-cost, 18-inch (45.7-cm) antennas that, for example, will be attachable to any flat surface, such as a windowsill. The system is described further in the article on **Satellites (Communication and Navigation)**.

High-definition television (HDTV) and flatter, thinner TV screens are addressed later in this article.

Fundamental Television Principles

Scanning. In television, it is necessary to break up the scene into minute elements and utilize these elements in an orderly sequence. This process is called *scanning*[1] and is somewhat similar to the process of reading a text line-by-line from a printed page. In reading, the eye progresses along a line word by word and then returns to the beginning of the next line until, in essence, the entire page has been scanned. The basic principle involved in scanning a picture is shown in Fig. 1.

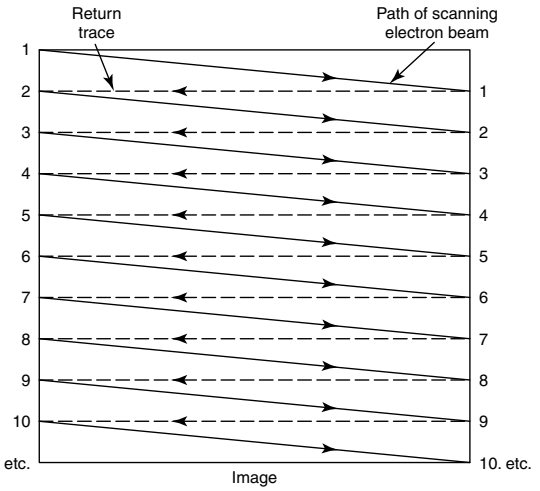

Fig. 1. Sampled representation of procedure for scanning a television picture. Solid lines indicate actual scanning; dashed lines indicate beam retraces.

Starting at the top left side, an electron beam moves from left to right across the screen along line 1–1. After the beam reaches the right side of the screen at point 1, it rapidly moves to the left side again along dotted line 1–2. During the motion from right to left, no picture information is transmitted and thus there is no "mark" made on the screen. Marked line 1–1 is called a *trace*; unmarked path 1–2 is called a return trace, or *retrace*. When the standards for television were established, a rectangular picture (or rectangular *raster*) was selected and the relationship between the height and width of the rectangle was established. Width of the rectangle divided by the height is termed *aspect ratio*. This ratio is 4/3 in the United States and United Kingdom. The aspect ratio holds regardless of the screen size. By adjusting voltages to the picture-tube circuitry, it is possible to produce a rectangle with different aspect ratios. However, the picture is transmitted in an aspect ratio of 4/3. For minimum distortion, the receiver picture should have an identical aspect ratio.

Because of the physical principles involved, there is a relationship between brightness and the rate of scanning, brightness going down with

[1] Scanning (television) — the process of analyzing or synthesizing successively, according to a predetermined method, the light values of picture elements constituting a picture area (ANSI-IEEE). *Interlaced scanning (television)* — a scanning process in which the distance from center to center of successively scanned lines is two or more times the nominal line width, and in which adjacent lines belong to different fields (ANSI-IEEE).

increased scanning rate. As with motion pictures, to provide a true and realistic feeling of motion to all actions displayed, it is necessary to present a number of pictures or *frames* per second. Early designers in compromising on brightness, utilizing a reasonable transmission bandwidth, and frame frequency, selected a rate of display of 30 complete pictures per second. A frame frequency of only 30 pictures/second would result in a flicker discernible to the eye, so each picture is divided into two parts called *fields*. Two fields must be produced in order to make one complete picture or frame. The field frequency, then, is 60 fields/second and the frame frequency is 30 frames/second. Each field contains one-half of the total picture elements. The system is fundamentally similar to that used in motion picture projectors wherein each individual picture is moved into the projector and flashed onto the screen — then a shutter comes down in front of the picture momentarily and the same picture is shown again. In motion pictures, each frame is shown 24 times per second and each frame is divided into two parts, or fields, so that the actual repetition rate is 48 fields/second. No flicker is observed by the eye. The choice of 60 fields/second and 30 frames/second was made so that the television picture could be synchronized to the standard power-line frequency of 60 Hz in the United States. With each frame divided into two parts, each field has one-half of 525 lines[2] from its beginning to the start of the next field. With *interlaced* scanning, each frame is broken up into an even-line field and an odd-line field. At the transmitter, all scanning frequencies are derived from the 60-Hz line frequency, and the receivers are automatically synchronized to the transmitted synchronizing pulses. As a result of this power-line frequency synchronization, the effects of hum on the picture, which might be caused by imperfect power supply filtering, will be stationary on the television receiver screen. If this synchronization did not occur, the hum effects would cause vertically moving patterns to pass through the picture. Adjacent cities, having television transmitters, sometimes use synchronized power-line frequencies to prevent this unwanted type of interference. When color television programs are broadcast, the field frequency is not 60 Hz, but is reduced slightly to 59.94 Hz. Thus, while hum interference patterns are not perfectly synchronized for color broadcasts, they move vertically at the rate of only 0.06 Hz, which is a slow rate and not readily detectable.

Basic Circuitry. A simplified complete television system is shown in Fig. 2. Note that there are two transmitters — one for transmitting the picture (video) signal; and another for transmitting the sound (aural) signal. The television camera converts the scene being televised into electrical impulses which are amplified and transmitted. Scanning and synchronizing voltages must be delivered to the camera. A *synchronizing signal* must also be transmitted so that the scene in the receiver can keep in step with the scene at the transmitter. The required scanning and synchronizing signals are also delivered to the video amplifiers and mixers in the transmitter. The output signals from the video amplifier and mixers are delivered to an amplitude-modulation (AM) system. Instead of both sidebands being transmitted, as in an AM broadcast transmitter, only one full sideband and a part of the other is contained in the output signal. Elimination of most of one sideband conserves the electromagnetic spectrum so that more stations can transmit in a given range of frequencies. Transmitting with one full sideband and one partial sideband is termed *vestigial sideband transmission*, not to be confused with single sideband transmission in which one of the sidebands is fully removed.

If a color television scene is being transmitted, then the output from the color television camera goes through special color-processing circuits. These are shown by the dashed lines on Fig. 2. In the United States, when a color signal is being transmitted, an equivalent monochrome signal also is being transmitted, necessary so that color and black-and-white systems will be compatible. Basically, color transmission involves the use of special color television circuits to superimpose the color signal onto the already-existing monochrome signal. The audio system in a television transmitter

[2] The number of 525 lines was selected because of: (1) the frequency bandwidth available to the transmission of TV signals (required bandwidth increases with the number of lines), (2) the amount of detail required for a well-produced image, and (3) the ease with which the synchronizing (and blanking) signals can be generated. These figures will be altered when the final standards for HDTV are worked out.

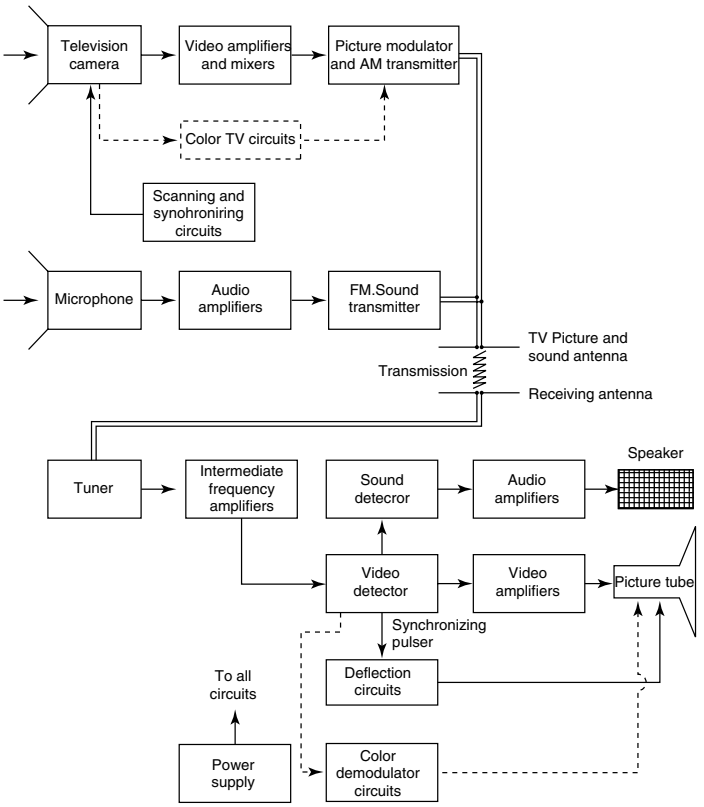

Fig. 2. Simplified block diagram of television system — transmitting and receiving.

is fully separate from the video section. It consists of a microphone, audio amplifiers, and a standard frequency-modulation (FM) transmitter. Both signals are transmitted from the same antenna by use of a special coupling device known as a *diplexer*.

In Fig. 2, the television receiver is depicted in the bottom portion of the diagram. There are four sections common to all receivers — an *antenna* system, a method of *selection*, a method of *detection*, and a device for *reproducing the intelligence*. For television receivers, the antenna is considerably more elaborate than those for radio receivers. This is the case because the signal is affected much more by reflections from large objects and also because the signal has a more limited distance over which it can travel. However, instead of transmitting the television signal by means of electromagnetic waves, it may be transmitted along cables in what is known as *closed-circuit television*. The signal is transmitted from the camera to one or many receivers along a coaxial cable. Such signals cannot be received by the general public. However, in *cable television* (cablevision), television signals can be transmitted over coaxial cables from stations that are normally out of range of the viewer's receiver. Cablevision permits the viewer to select from a larger number of programs. Subscribers usually pay for the service on a monthly basis. In areas where television may be difficult to receive because of interference by hills and mountains, for example, a *master antenna system* may be used. The master receiving antenna is located on top of the hill, for example, where reception is excellent. From this point, the signal is distributed by coaxial cable to subscribers. A system of this type usually is referred to as *community antenna television*.

The selection portion of the television receiver is accomplished in the tuner, as shown in Fig. 2. It makes possible the selection of one channel and rejection of all others. Contemporary television receivers use superheterodyne types, so the tuner section includes a local oscillator for converting the RF signal to an intermediate frequency. The output of the tuner is delivered to the intermediate-frequency (IF) amplifiers and then to a detector. Detection involves two steps. The video signal is amplitude-modulated and, therefore, an AM detector is needed for that part of the signal. The sound portion is frequency-modulated, so obviously an FM detector is needed for that portion of the signal. The picture and sound signals are amplified by the video and audio amplifiers, respectively. Video

signals are reproduced in the picture tube; sound signals in the receiver speaker.

The previously mentioned synchronizing pulses (sync pulses) required to synchronize the received picture with the one that is transmitted, are used to control the frequency of the deflection circuit currents. These currents cause the electron beam to scan the picture-tube screen.

If a color signal is present, special color circuit demodulators are present as shown by the dashed lines of Fig. 2. There is an automatic circuit in a color television receiver that prevents the color demodulators from operating when there is no color signal present. This is accomplished automatically. The transmitter may switch back and forth between color pictures and monochrome pictures, and the receiver control circuits will automatically determine which circuitry will operate to produce the monochrome or color picture.

Television signals are transmitted in the range of frequencies between 54 and 890 MHz. This range includes frequencies in the very high frequencies (VHF) and in the ultra-high frequencies (UHF). Unlike the lower frequencies used for AM broadcast radio, these frequencies are not reflected from the ionosphere. Instead, their transmission is limited to line-of-sight distances, which means a distance of about 45 miles from the transmitter. The value of 45 miles is an average because the terrain between the transmitter and the receiver antennas, and the heights of these antennas, must be taken into consideration. Transmission across wide spaces, such as the oceans, can be achieved by using active satellites. For transmitting signals coast-to-coast, microwave relay stations are used. These are simply repeater stations that receive the signal, amplify it, and the retransmit it. The relay stations are located at intervals of 50 to 100 miles (80 to 160 km). The use of fiber optics is also increasing. See also **Optical Fiber Systems**.

The television signal as transmitted must comply with strict standards established by governmental regulatory agencies (FCC in the United States). Each VHF and UHF television station is assigned a channel that is 6 MHz wide. The complete signal, called the composite signal, must be fitted into this bandwidth. The composite signal includes the video carrier, one vestigial sideband for the video signal, one complete sideband for the video signal, the color signals, the synchronizing pulses, and the FM sound signal.

It will be recalled that the video part of the composite signal is amplitude-modulated. In order to obtain the same number of frequencies for the video signal, using FM, the required bandwidth would be prohibitive. The synchronizing pulses are also transmitted by AM, and these pulses are superimposed onto the video signal. The color information is transmitted by slipping the color signals in between spaces in the monochrome video signals — a process called *interleaving*. There are 525 scanning lines generated for each frame, but only about 480 of these are actually used to make up the picture. Those lines that are used for producing the picture are called active lines. The lines that are not used for making the picture are generated during the time that it takes to get the beam from the bottom of the picture (at the end of the field) back to the top of the picture (at the start of a new field). The sound signal is frequency-modulated, and as with FM broadcast systems, it may also be produced by the indirect FM method. This actually produces phase-modulation (PM), but any FM detector that can demodulate FM signals can also demodulate a PM signal. The maximum deviation for television is plus or minus 25 kHz.

It should be mentioned once again that, with the advent of HDTV, channel widths assigned by the FCC and other communications regulatory agencies will have to be altered — because HDTV requires the transmission of considerably more information than is required by current TV transmission.

Development of TV Cameras. In order to assure high-quality images at the TV receiver, the camera system must resolve the scene into as many picture elements as may be practical. The quality of the reproduced picture increases with the number of picture elements. The scanning beam in the pickup tube must produce electrical signals that accurately represent each of the picture elements. Thus, the optical-electrical conversion must have a signal-to-noise ratio sufficiently high to assure effective pickup sensitivity at the lowest-light-level scenes that may be telecast. When no incident light is present, there must be very little or, ideally, no output signal.

Even though color TV cameras are the most widely used, for simplicity the diagram of a typical monochrome TV camera is given in Fig. 3. Color cameras are described later. In the early years of television, vacuum tubes were used in the electronic circuits of the camera. A major problem was the production of heat by the vacuum tubes, this requiring that the electronic circuits had to be realigned several times each day during regular program production. Tubes also contributed to the bulk and weight of camera handling. Transistors, integrated circuits, and modular construction have made remarkable improvements in the design and use of TV cameras. Temperature-compensated deflection circuits, the use of feedback, and improved regulated power supplies have resulted in at least a hundredfold improvement in camera stability. Because of reduction in bulk, it no longer is unusual for one person to operate several TV cameras.

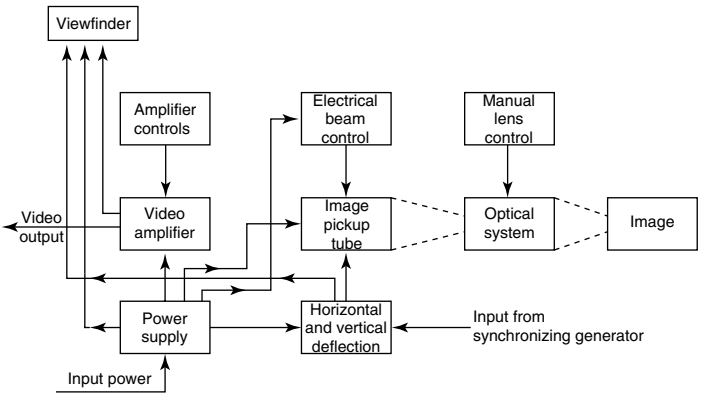

Fig. 3. Monochrome television camera. Light reflected by the scene is focused by an optical system onto the faceplate of the camera tube. By way of a photoelectric process, the light image is transformed into a virtual electronic replica in which each picture element is represented by a voltage. A scanning beam in the pickup tube next converts the picture (element by element) into electrical impulses. At the output, an electrical sequence develops, representing the original scene. Camera tube output is then amplified to provide the video signal for the transmitter. A sample of the video signal also is provided for observation in a cathode-ray tube (CRT) viewfinder mounted on the camera housing. Electronic circuits that provide the necessary control, synchronization, and power supply voltages operate the TV camera tube. A deflection system in the TV camera tube controls the movement of the camera tube scanning beam. In some situations, the cameras receive their synchronizing pulses from a studio-controlled unit. Such a unit also provides the synchronizing pulses that keep the receiver in step with the camera. Some TC cameras generate their own control signals. Manual controls are provided on the camera for setting the optical lens and for zooming.

When color television was introduced, a number of far reaching changes in TV camera technology were required. Some of the color-associated specifications which the color TV camera must meet include:

1. *Light-Transfer Characteristic*. This may be defined as the ratio of the faceplate illumination (in footcandles) to the output signal current (nanoamperes, nA). This is sometimes regarded as a measure of the "efficiency" of a camera tube. Typical values of output current range from 200 to 400 nA.
2. *Gamma Value*. This characteristic applies both to camera tubes and picture tubes and is a number that expresses the compression or expansion of original light values. Variations of gamma are inherent in the operation of some camera or picture tubes. With most camera tubes, the gamma value is unity — a linear characteristic that does not change the light values from the original scene when they are translated into electronic impulses. (Because of the desire for better contrast in a picture tube, a gamma value up to 3, depending upon tube manufacturer, may be in the specifications.
3. *Spectral Response*. As nearly as possible, the spectral response of the camera tube should match that of the human eye. This is necessary to render colors in their proper tones and also important in producing the proper gray scale in connection with black-and-white pictures. Color

TV cameras have a greater response to each of the primary colors. Spectral response distribution has made it possible to manufacture camera tubes that are also sensitive to infrared (IR), ultraviolet (UV), and even X-radiation for special requirements.[3] Variations in spectral response have little effect on the other operating characteristics of the camera tube.

4. *Lag*. This term applies to the time lag during which the image on a camera tube decays to an unnoticeable value. Camera tubes inherently have a tendency to retain images for short periods after the image is removed. Lag is detected on a television picture in the form of smears (comet trails), which appear following rapidly moving objects. Lag can be expressed as a percentage of the initial value of the signal current remaining 1/20 second after the illumination is removed. Typical lag values for vidicons range from 1.5% to 5%. Other types of camera tubes, such as the "Plumbicon," have lag values as low as 1.5%.
5. *Dark Current*. Characteristic of camera tubes as well as other photoelectric devices is the current that flows through the device even in total darkness. Obviously, for a camera tube, the dark current must be as low as achievable.

Color TV cameras are of two principal types: (1) a single (special) camera tube, and (2) three camera tubes. The single-tube configuration incorporates a vertical stripe filter that separates the colors prior to reaching the scanning beam. In the three-tube arrangement, separate tubes are used for each of the three primary colors (red, green, blue). A color filter system separates the incoming light from the image into the three colors, after which the light is focused on the faceplate of the appropriate camera tube. The three tubes are identical with exception of the photosensitive material used in each tube. The outputs from each tube are then amplified to provide three channels of video signals, one channel for each color.

Evolution of the Vidicon. The vidicon is a comparatively simple and compact device. A typical tube may be about 1/2 in. (~11/4 cm) in diameter and some 31/2 in. (~9 cm) long. Tubes of larger dimensions are not uncommon. Vidicons are widely used for closed-circuit television (CCTV) and for TV studio and film cameras. It is interesting to note that some vidicons can produce acceptable pictures when operating in near-total darkness or, in contrast, in near-direct sunlight.

The operating principle of the vidicon camera tube is shown in Fig. 4. The target consists of a transparent conducting film (the signal electrode) on the inner surface of the faceplate and a thin photoconductive layer deposited on the film. Each cross-sectional element of the photoconductive layer is an insulator in the dark, but becomes slightly conductive when it is illuminated. Such an element acts like a leaky capacitor, having one plate at the positive potential of the signal electrode and the other one floating. When light from the scene being televised is focused onto the surface of the photoconductive layer next to the faceplate, each illuminated element conducts slightly, the current depending upon the amount of light reaching the element. This causes the potential of its opposite surface (the gun side) to rise toward the signal electrode potential. Hence, there appears on the gun side of the entire layer surface a positive-potential replica of the scene composed of various element potentials corresponding to the pattern of light which is focused onto the photoconductive layer. When the gun side of the photoconductive layer, with its positive-potential replica, is scanned by the electron beam, electrons are deposited from the beam until the surface potential is reduced to that of the cathode in the gun. This action produces a change in the difference of potential between the two surfaces of the element being scanned. When the two surfaces of the element, which in effect form a charged capacitor, are

[3] If the photosensitive material in a camera tube was able to emit an electron for each photon of light focused upon the material, the quantum efficiency of the material would be 100%, as shown by $Q_{\text{eff}} = \text{Electrons/Photons}$. Although not achievable, Q_{eff} is a practical way to compare photosensitive surfaces in the camera tube. In this comparison, photocurrent per lumen is measured using a standard light source. The source usually used for the measurement is a tungsten-filament light operating at a color temperature of 2870 K. Inasmuch as the lumen is a measure of brightness stimulation to the human eye, Q_{eff} is a useful way to express the sensitivity of the image-pickup tube.

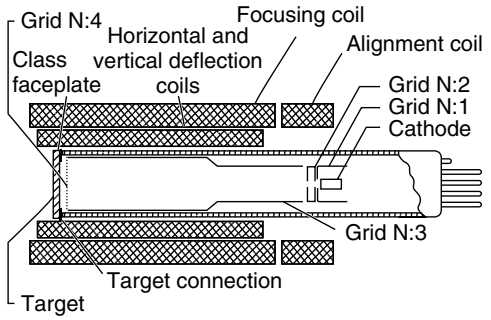

Fig. 4. Sectional view of internal construction of a vidicon.

connected through the external target (signal electrode) circuit and a scanning beam, a current is produced which constitutes the video signal. The amount of current flow is proportional to the surface potential of the element being scanned and to the rate of the scan. The video signal current is then used to develop a signal-output voltage across the load resistor. The signal polarity is such that for highlights in the image, the input to the first video amplifier swings in the negative direction. In the interval between scans, wherever the photoconductive layer is exposed to light, the migration of the charge through the layer causes its surface potential to rise toward that of the signal plate. On the next scan, sufficient electrons are deposited by the beam to return the surface to the cathode potential.

The electron gun contains a cathode, a control grid, and an accelerating grid. The beam is focused on the surface of the photoconductive layer by the combined action of the uniform magnetic field of an external coil and the electrostatic field of a third grid. A fourth grid serves to provide a uniform decelerating field between itself and the photoconductive layer, so that the electron beam will tend to approach the layer in a direction perpendicular to it, a condition that is necessary for driving the surface to the cathode potential. The beam-electrons approach the layer at a low velocity because of the low operating voltage of the signal electrode. Deflection of the beam across the photoconductive substance is obtained by external coils placed within the focusing field.

Evolution of the Plumbicon. In this tube, developed by Philips of Holland, the principles of the vidicon were generally applied. The main difference is in the target.

The inner surface of the glass faceplate is coated with a thin transparent conductive layer of tin oxide. This layer forms the signal plate of the target. On the scanning side of the signal plate, a photoconductive layer of lead monoxide is deposited. These layers are specially prepared to function as three sublayers, each with a different conduction mode. On the inner side of the faceplate, the tin oxide layer is a strong *n*-type semiconductor, commonly found in transistors. Next to this *n*-type region is a layer consisting of almost pure lead monoxide, which is an intrinsic semiconductor. The scanning side of the lead monoxide has been doped to form a *p*-type semiconductor. Together, these three layers form a *p-i-n* junction. The spectral response of the plumbicon can be varied during its manufacture to suit almost any particular application. The tube has gained wide acceptance in color television cameras.

Solid-State TV Cameras. These devices utilize charge-coupled devices (CCDs), which were discovered by scientists at the AT&T Bell Laboratories and first found keen usage in military applications and later in detectors for large telescopes. The devices were incorporated in solid-state TV cameras as probably the most forward step taken in recent years toward upgrading the cameras. Operating principles of CCDs are described in the article Charge-Coupled Devices.

When light from an image or scene is focused on a CCD, a pattern of electrical charges is created. The charges vary in proportion to the amount of light and serve as an accurate electrical representation of picture elements. These charges can be stored, transmitted out of the CCD chip sequentially, and later reassembled on a conventional TV screen or facsimile readout. Thus, the CCD is the basis for an all-solid-state TV camera, greatly simplifying camera design and lessening camera bulk and weight. Other advantages of CCD cameras include long life, low power

consumption, and very significant size reduction. No warm-up time is required, and, importantly, the CCD imaging device is not susceptible to lag (smearing caused by bright moving areas) or to burn-in (damage that can be caused by intense light or electron-beam bombardment). The CCD camera is more sensitive, an important advantage for acquiring pictures at low light levels. At an early stage of development, the first black-and-white camera for commercial use was demonstrated as early as 1971.

Development of TV Picture Tubes. The many decades required to develop a useful technique for converting electrical signals into light were described earlier in this article. In the interest of simplicity, a monochrome picture tube will be described first. This is a specialized form of cathode-ray tube.

An electron gun in the tube directs a beam of electrons toward a fluorescent material on the screen, which glows when struck by the electrons. Between the gun and the screen are deflection coils which deflect the beam horizontally and vertically to form a raster. The brightness of the screen at any point depends upon the number and velocity of electrons striking that point. Therefore, the brightness of the picture may be controlled by varying the grid-bias voltage with respect to the cathode voltage. See Fig. 5. A color-picture tube operates on the same basis principle, except that the screen is coated with different types of phosphors which produce colors when struck by electron beams. Combinations of red, green, and blue produce all colors. In a three-gun color picture tube there is a separate gun for each of the color phosphors. Color phosphor dots or strips are located so close together on the screen of the picture tube that the eye cannot distinguish between them. When all three adjacent colors are stimulated, the screen will radiate a white light. The various mixture colors are obtained by controlling the strength of the individual electron beams striking each color phosphor. In order to insure that each electron beam strikes only one particular color phosphor dot or strip, a shadow mask, or aperture mask, is located near the screen. It is very important, of course, that each electron beam be carefully directed to pass through the desired hole in the mask and thus strike only the desired color phosphor. See Fig. 6.

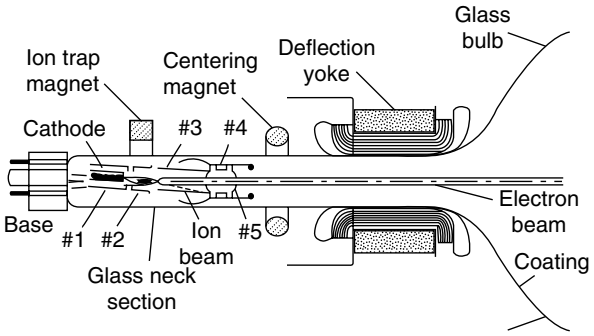

Fig. 5. Internal structure of an electrostatic focus television tube. The deflection is achieved magnetically.

High-Definition Television (HDTV)

Efforts to improve the clarity of television presentations have been continuous since the first experimental transmissions over telephone wires and through the atmosphere. Black and white television gradually became color television, but the process was slowed by bitter competition between incompatible technologies and resistance by broadcasters, who had to invest in expensive new equipment. In the United States, commercial ownership of radio and TV stations as well as their programming is customary, although the Federal Communications Commission (FCC) has certain regulatory powers over them. In addition, in most nations the government (until recently) owned and operated the radio and television stations, providing the programming as well. Individual national television broadcasting facilities were often based on proprietary technology that prevented citizens from receiving broadcasts emanating from neighboring countries. These disparate national arrangements affected the introduction of new technologies.

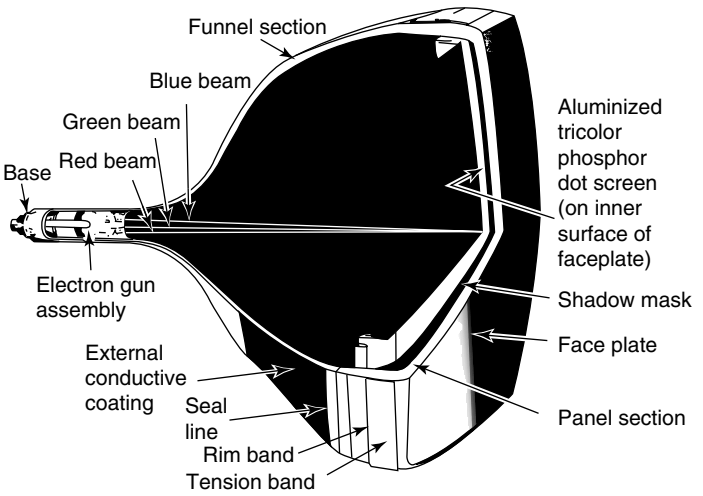

Fig. 6. Cutaway view of delta-gun color picture tube that uses color phosphor dots.

The resolution of a television image is based on the number of horizontal lines and the number of picture elements (*pixels*) across each line, as well as the method of scanning the lines across the face of the picture tube. The conventional television broadcasting standards, known as *NTSC* (*National Television Systems Committee*) in the U.S., were established in 1941 and tailored to the technological capabilities of those days, which were based on vacuum tubes. In the U.S., the scanning rate was set at 525 horizontal lines, of which 480 are intended for display on the face of the "*picture tube*." Actually, most TV sets for decades displayed 300 lines or less, depending on the accuracy of the manufacturer's settings, which meant part of the image was cut off and part of the resolution was lost.

The technology still uses *interlaced scanning*, in which every second line is bypassed during the first scan, which traces 240 lines, after which the scanner returns to the top of the tube face and traces the next 240 lines between the previous tracing, thus forming a complete image with two scanning passes. This results in some disparity between some of the image's elements, creating "*jaggies* " and other artifacts in the image. Interlacing is performed on each of 30 picture frames per second (the standard projection speed for sound motion pictures). The shape of the TV image (its aspect ratio or ratio of width versus height) also was patterned after that of the motion picture industry's projection screens: 4 by 3. See Fig. 7.

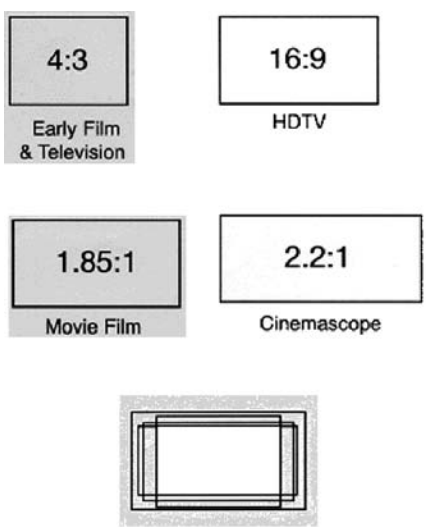

Fig. 7. This figure represents a series of concentric rectangles, each representing a different set of screen dimensions widely in use.

The *interlaced scanning* used in television was rejected by the computer industry, which uses progressive scanning. In this technology, each line is traced in sequence, without skipping any lines, until the entire frame is scanned. The effect is a sharper image, so it is favored for the improvement of television clarity. However, it is more expensive to produce.

The introduction of color TV broadcasting in 1953 was based on its compatibility with the NTSC standards. England, which had set its TV broadcast standards in 1941, accepted a quality that was somewhat poorer than that of the U.S. (405 lines). However, such European nations as France and Germany waited until a few years after World War II, and thus established TV systems — now known as *PAL/SECAM* — with superior resolution (i.e., more scan lines per inch or per centimeter) compared to those of the Americans and British. However, all these standards remained virtually unchanged for more than four decades (except that the British changed to the NTSC standard color standards in 1973).

Again, it was the motion picture industry that triggered the moves toward a new screen format and better clarity. The introduction of various widescreen formats in the 1950s changed the traditional projection screen aspect ratio from the virtually-square 4:3 format to the clearly horizontal 16:9 and even wider formats. See Fig. 8. In addition, the motion picture studios converted from optical sound tracks to electronic sound tracks and added stereo sound to their films, improving the audio quality. The television industry, in turn, improved their image quality by replacing vacuum tube circuits with transistors and other solid-state electronic components, and developing the "simulcast," in which stereophonic audio was broadcast through an FM radio station in synchronization with the TV image broadcast; the viewer listened to the audio from the stereo radio while watching the image on the TV set. This was necessary because the NTSC standards were for monaural audio only.

In the early 1980s, Japanese television specialists introduced a new type of TV standard, which the industry called *high-definition television* (*HDTV*). The first true *HDTV* receivers and broadcasts were made by NHK in Japan in the early 1980s, using analog signals that required enormous bandwidth for each channel. The system was known as "*MUSE*" and operated with 1,125 horizontal scan lines. To the consternation of American television interests, the Japanese proposed worldwide adoption of the *MUSE* technology. However, their *HDTV* programming was limited to experimental broadcasts for demonstration purposes and no sets were available for purchase.

In 1987, the FCC undertook an Inquiry, i.e., a study to determine the effect of the development of *HDTV* on the existing broadcasting service. Most broadcasters were not enthusiastic about the new technology, since it would require expensive retooling of their broadcast facilities and could result in the loss of some of their assigned frequency bandwidth to meet the high capacity required for *HDTV* transmission.

Meanwhile, the American manufacturers and broadcasters, as well as the FCC, were exploring many different options, all of which used analog signal transmission. But in 1990, the General Instrument Company — functioning as a research and development arm of the cable-television industry — developed a digital encoding method. This was preferable to analog because it was much less susceptible to distortions caused by atmospheric conditions and electrical interference. Later, new all-digital systems were announced by Zenith and AT&T, the Philips-Thomson-Sarnoff consortium, and the Massachusetts Institute of Technology (MIT).

General Instrument's method triggered a revolution in the American planning of *HDTV* systems, resulting in the discarding of analog transmission but development of a number of disparate digital approaches that culminated in a so-called "*Grand Alliance*" between the various interested — but often warring — parties [General Instrument, Zenith Electronics, Lucent Technologies (Bell Laboratories), MIT, Philips Electronics North America Corporation, Sarnoff Corporation and Thomson Consumer Electronics].

Defenders of the NTSC standards redesigned some analog receivers and called them "*Improved Definition Television* " or *IDT*, which presented significantly sharper images without requiring changes in broadcasting. Those sets cost several thousand dollars each, significantly more than the standard TV sets of the mid-1980s and did not become a serious factor in the marketplace, perhaps because of the growth of cable TV systems, in which subscribers usually saw an improvement in image quality compared to roof-antenna reception.

Promoters of the *HDTV* concept point out that the public can appreciate the new clarity of this technology only after seeing it on a large screen (*HDTV* sets are now often twice as large as modern *NTSC* receivers) or viewing it at closer range. Early viewing tests in 1987 compared the images of *HDTV* and *NTSC* on side-by-side similar-size receivers (a 26-inch high-end *NTSC* receiver and a 28-inch *HDTV* receiver) but produced discouraging reports: beyond a distance of five picture heights, viewers were unable to tell the difference (except for the different shapes of the picture tubes). See Fig. 9. The most favorable responses came from viewers closer to the *HDTV* receiver (three picture heights), and the most negative from those people seven picture heights away. The first integrated *digital HDTV* receiver offered in late 1998 by Zenith Electronics is a 64-inch diagonal widescreen rear-projection model, providing what the company calls "five times more picture than today's analog TV." It also includes digital audio comparable to the quality of compact-disc audio. It is expected to sell for more than $10,000, plus ca. $6,000 for an *HDTV* receiver/decoder. The Zenith decoder is designed to receive all 18 scanning formats included in the new *Digital TV* (*DTV*) standards accepted by the FCC, although 12 of those are not designated as *HDTV* quality.

As of 1998, *high-definition television* (*HDTV*) was one of several formats that have been proposed for the improvement of television signals and recordings. An international group, the *Advanced Television Systems Committee* (*ATSC*), was formed in 1982 to establish voluntary technical standards for *HDTV* and *SDTV* (standard-definition television), which were released in February 1998. That report states:

"There are six video formats in the *ATSC DTV* (digital television) standard which are '*High Definition Television*.' They are the 1080-line by 1920-pixel formats at all picture rates (24, 30 and 60 pictures per second)

Fig. 8. Compared to standard television (NTSC), the HDTV image has twice the luminance definition — vertically and horizontally — and is twenty-five percent wider. Standard television aspect ratio is 4:3 (four units wide, three units high) — the HD aspect ratio is 16:9.

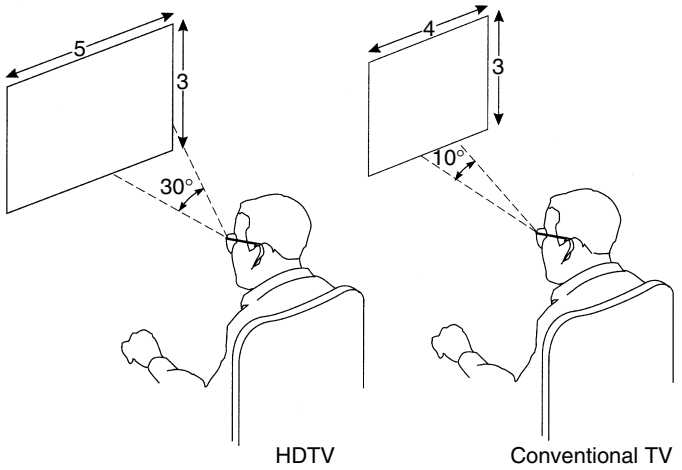

Fig. 9. Approximate viewing difference between conventional TV and HDTV. The HDTV screen is about 25% wider than that of a traditional set and offers double the resolution. The result is a three-fold increase in the viewing angle from 10ñ to 30ñ.

and the 720-line by 1280-pixel formats at these same picture rates. All of these formats have a 16:9 [displayed image] aspect ratio.

The remaining twelve video formats, while representing some significant improvements over analog *NTSC* (*National Television Systems Committee* standards established in 1941 for black and white and the 1950s for color TV) are not *High Definition Television*. They are referred to as '*Standard Definition Television*.' These are the 480-line by 704-pixel formats in 16:9 widescreen and 4:3 aspect ratios, at the picture rates listed above, and the 480-line by 640-pixel format at a 4:3 aspect ratio, at the same picture rates.

These definitions are restatements of terms clearly established and supported by the written record of the ten-year process of the FCC, the FCC Advisory Committee on Advanced Television Service (ACATS), and the ATSC. They also support the industry definitions for digital television receivers established in January, 1998 by the *Consumer Electronics Manufacturers Association* (*CEMA*). These definitions are also fully supported by the technical specifications for the various formats as measured against the internationally accepted definition of *HDTV* established in 1989 by the International Telecommunications Union, and the definitions cited by the FCC during the DTV standards development process."

The Advanced Television Systems Committee is composed of 136 member corporations, industry associations, standards bodies, research laboratories, and educational institutions. Its URL on the World Wide Web is: http://www.atsc.org. The Consumer Electronics Manufacturers Association provides simplified explanations of the technologies and advantages of *HDTV* and *SDTV* on their URL: http://www.cemacity.org/digital.

Every digital TV set will be able to receive any of four main formats: 1080-I (1080 horizontal lines, interlaced scan); 1080-P (1080 horizontal lines, progressive scan — the highest resolution format); 720-P (720 horizontal lines, progressive scan, which some experts contend looks at least as good as 1080-I); 480-P (480 horizontal lines, which look clearer and sharper than today's analog programs that are broadcast using 480-I, a format with the same number of lines, but interlaced).

However, according to a participant, the Grand Alliance system is flawed because it resulted in numerous formats, no provision for inexpensive receivers or set-top converters, and includes image interlace scanning technology as well as progressive scanning technology. Part of the problem results from the broadcasters wanting to maintain their NTSC standards as long as possible by requiring that HDTV be "*backward-compatible* " with NTSC. The FCC was caught in the middle between the warring factions, and — unable to persuade them to reconcile their differences — decided to adopt the DTV standard of the ATSC, which was based on the Grand Alliance recommendations. The broadcasters promised that each of the top ten TV markets will have at least one digital station by the end of 1998. They are required to transition to digital in the top ten markets (reaching half of the U.S. TV households) by November 1999. Some networks say they will broadcast only the *SDTV* signals, while others plan to transmit *SDTV* programs part of the time, and *HDTV* the rest of the time. Since no one knows what the public acceptance of *HDTV* will be in the future, the networks may change their minds later.

When *digital HDTV* was first developed, the signal was extremely bandwidth-hungry. Each color pixel requires 16 bits (binary digits) of information, and there are 1920 pixels in each scan line, times 1,080 scan lines per frame, and 30 frames per second. The result is 995,328,000 bits (995 megabits) per second of video information. In addition, the signal contains 48,000 audio samples per second, with 16 bits per sample — and eight audio channels for surround sound plus a second language, or a total of 6,144,000 bits (six megabits) per second of audio information. Adding in the ancillary services (closed captioning, program guides, system timing and synchronization, etc., totaling 256,000 bits per second), the entire combined video/audio source signal comes to more than a billion bits (a gigabit) per second — requiring XX megahertz of broadcast frequency spectrum bandwidth. The only way to squeeze all that information into the six-megahertz bandwidth assigned to each channel by the FCC was to use a process called *data compression*.

The video compression technique used in *HDTV* employs the MPEG-2 method. (MPEG refers to the Motion Picture Experts Group of the International Standards Organization.) The 995 megabits of video is compressed to 18 megabits (55:1 compression). The audio information is compressed using a method proposed by Dolby Labs. Six of the source channels are compressed together as a "*surround-sound* " package, and the other two are compressed as a stereo pair for second-language use. The six megabits per second of audio information is compressed to 512 kilobits per second (12:1 compression). The ancillary services are typically not compressed. The total payload is thus reduced from more than a billion bits (a gigabit) per second to less than 19 megabits per second. The new six-megahertz digital signal will reach slightly more consumers from a typical transmitter site, and do so with less transmitted power. The picture will be digitally perfect throughout the coverage area, regardless of how far away the receiver is from the broadcast transmitter tower.

A standard NTSC analog broadcast TV channel requires a bandwidth of six megahertz. Each television network was assigned a second six-megahertz channel by the FCC in 1997 for the transition to digital broadcasting, but that same channel can be used either as an *HDTV* channel or to transmit four separate digital channels with ordinary picture quality (*SDTV*). In addition to broadcaster reluctance to invest in *HDTV* equipment, the broadcasters also realize that they can make extra profits in advertising over four program channels in digital technology instead of one *HDTV* channel. However, the entire digital feed of the network will be assigned a single set of call letters and channel positions followed by the letters "DT" (for Digital Television), i.e., WCBS-DT, Channel 2 in New York, even though the actual channel number for the digital broadcasts may be much higher, say Channel 65 or Channel 90. The viewers will not have to know that, since the receivers (under the ATSC scheme) will be programmed to automatically find the correct digital frequency assignment for the selected network. If a network elects to broadcast four different programs within the single six megahertz channel, a system of sub-numbers will have to be devised — but the FCC and the ATSC did not specify how that would work, thus leaving it up to the manufacturers of the *HDTV/digital receivers*.

The proliferation of digital programming channels could create problems among viewers trying to plan a viewing schedule, since the eventual program listings could be too long to print on paper. The plan in new digital sets is to display an on-screen electronic program grid covering nine hours for each channel, encoding each digital transmission with the program's name, length and start time.

Meanwhile, however, the current analog NTSC broadcasting system will continue for a transition period of at least eight years, ending in 2006. During this interim period, *digital SDTV* and *HDTV* will share the broadcast spectrum with the NTSC programming, but the latter will eventually be eliminated. Manufacturers of TV sets were understandably concerned about losing sales of standard NTSC receivers in the interim years, since consumers are confused about the introduction of *HDTV* and *digital TV*.

The availability of *HDTV* programming depends on many factors. Like the introduction of color programming in the 1950s and 1960s, programs in the *HDTV* formats will be sparse at the start, due to a lack of suitable material and the need by local TV stations to install appropriate equipment. Live broadcasts of sporting events and similar programming are the most likely candidates for the first year or two. As of 1999, *HDTV* programming will be available only through atmospheric transmission received by an antenna. If the signal is too weak, the receiver will simply not display any picture; with *HDTV*, it is all or nothing at all. (Experiments in Washington, DC. showed that indoor antennas received *HDTV* broadcasts for less than 60 percent of the test participants, but the percentage was much higher for those using rooftop antennas.)

Satellite owners also are interested in proving their ability to transmit *HDTV*, so in July 1998, the *PanAmSat* Corporation, owners and operators of more than 17 geostationary satellites [see also **Satellites (Communication and Navigation)** entry], sponsored a series of tests during a two-day demonstration involving vendors of *HDTV* equipment Using the same high-definition source material (delivered at 1.5 gigabits per second), each vendor used its own system to encode the *HDTV* signal into a post-production quality video signal at 45 megabits per second or distribution-quality video signal at 19.3 megabits per second. The encoded material was then uplinked to a geostationary satellite (*PAS-2*) in the 1080-I high-definition format in compliance with MPEG- 2/DVB, and the satellite returned each signal to the teleport at Napa, California, where it was demodulated and decoded into *HDTV* format by the respective vendor's integrated receiver/decoder for display on an *HDTV* monitor and spectrum analyzer.

A key question is how the cable television companies will cope with the new technology. The digital set-top converter boxes now offered by some cable TV companies are used with analog TV receivers and were not designed for connection to digital TV sets, so a special digital cable will be required — and nobody knew in 1998 what the specifications would be for that cable. As a result, none of the first generation *HDTVs* have the proper jacks to accept *HDTV* from a cable box.

But these problems are not expected to block the introduction of digital television and *HDTV* broadcasting. The new television sets are now being characterized as "*information appliances*" instead of simply being an entertainment medium.

Flat Display Panels

As of the early 1990s, most authorities in the field sensed that the traditional CRT, which requires considerable depth and hence an awkward dimension for electronic display devices, such as television sets, ultimately will be replaced by flat (picture-frame) displays that can be wall-mounted and carried in a briefcase. Technological development of the flat panel follows an all-too-familiar pattern of early technical leadership, as exemplified in this instance by such firms as Westinghouse and RCA, only to go essentially unattended for a number of years and later to be acted on by progressive firms in other countries.

Fundamentally, in any electronic device, signals are converted to points of light that form patterns and images. For example, in some laboratory and desk-top computers that are finding increasing use, rows and columns of electrodes are used to convey information. Thus, a grid of pixels (picture elements) is formed. At a given row-column intersection, the display (light-producing element) will be activated only when there is a voltage present in the given row and given column. This *multiplexing* technique is inferior by comparison with a CRT display. The problem of "fuzziness" is exacerbated as the number of pixels increases. The voltage that passes through the numerous display elements tends to permeate the element such that pixel displays are not fully turned off. In a busy display, black and white take on indistinguishable shades of gray. Also, multiplexing is unfit for displaying object movement on the screen. By their fundamental nature, a liquid crystal display (LCD) element responds in proportion to the voltage applied. In a technique invented by T. Peter Brody in the early 1980s, the foregoing problems can be overcome by way of what is called an *active matrix*.

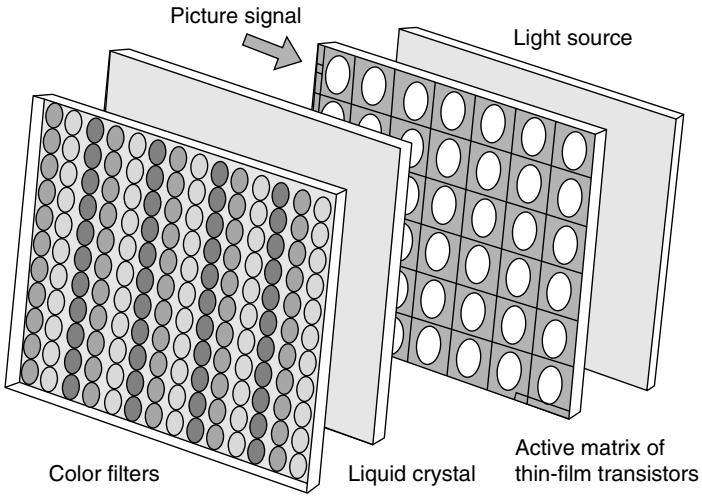

Fig. 10. Principle of active matrix display technology. (*After Florida and Brody*.)

In this technique, a thin-film transistor (TFT) acts as a switch at each pixel. As pointed out by Herb Brody, "The TFT can transfer and store enough voltage to quickly switch a liquid-crystal pixel from light to dark, resulting in a sharp image with no blurring. With the TFT active matrix, the electric charge used to switch one pixel no longer spills over into neighboring ones. As a result, the contrast between an on and off pixel can proach 50 or 100 to one — versus six to one in a typical multiplexed LCD. And because the TFTs are deposited on a transparent glass substrate, the display can be lit from behind, further enhancing its viewability. Red, green, and blue filters can be placed at each pixel to form a color display. Because of its high contrast capability, an active matrix display can produce full color images that look as good as or better than those produced by CRTs." See Fig. 10. See also the family of articles catalogued under **Flat Panel Display**.

TELLURIC LINES. Absorption lines in a solar spectrum produced by constituents of the atmosphere of the Earth itself rather than by gases in the outer solar atmosphere such as those responsible for the Fraunhofer lines. The terrestrial nature of the absorption processes responsible for telluric lines is revealed by their intensity variation with solar zenith angle and by their freedom from any Doppler broadening due to their solar rotation. Water vapor produces the strongest of the telluric lines in the visible spectrum. See also **Adsorption (Process)**.

TELLURIUM. [CAS: 13494-80-9]. Chemical element, symbol Te, at. no. 52, at. wt. 127.60, periodic table group 6, mp 450 °C, bp 690 °C, density 6.24 g/cm^3 (crystalline form at 25 °C), 6.00 (amorphous form at 25 °C). Elemental tellurium has a hexagonal crystal structure with trigonal symmetry. Tellurium is a silver-white brittle semi-metal, stable in air, and in boiling H_2O, insoluble in HCl, but dissolved by HNO_3 or aqua regia to form telluric acid. The element is dissolved by NaOH solution and combines with chlorine upon heating to form tellurium tetrachloride.

Tellurium (Latin *tellus* meaning "earth") was discovered in 1782 by the Hungarian Franz-Joseph Müller von Reichenstein (Müller Ferenc) of the Transylvania region. In 1798 it was named by Martin Heinrich Klaproth who earlier isolated it. There are several natural occurring isotopes ^{120}Te, ^{122}Te through ^{126}Te, ^{128}Te, and ^{130}Te. Nine radioactive isotopes have been identified ^{118}Te, ^{119}Te, ^{121}Te, ^{123}Te, ^{127}Te, ^{129}Te, and ^{131}Te through ^{133}Te. With exception of ^{123}Te which has a half-life something greater than 10^{13} years, all of the other radioactive isotopes have half-lives measurable in terms of minutes, hours, or days. In terms of abundance, tellurium does not appear on the list of the first 36 elements that occur in the Earth's crust and hence is relatively scarce. Terrestrial abundance is estimated on the order of 0.002 ppm. Tellurium is found in seawater to the estimated extent of about 95 pounds per cubic mile of seawater. First ionization potential 9.01 eV; second, 18.6 eV; third, 30.5 eV; fourth 37.7 eV; fifth, 59.95 eV. Oxidation potentials $H_2Te(aq) \rightarrow Te + 2H^+ + 2e^-$, 0.69 V; $Te + 2H_2O \rightarrow ReO_2(s) + 4H^+ + 4e^-$, −0.529 V; $TeO_2(s) + 4H_2O \rightarrow H_6TeO_6(s) + 2H^+ + 2e^-$, −1.02 V; $Te^{2-} \rightarrow Te + 2e^-$, 0.92 V; $Te + 6OH^- \rightarrow TeO_3{}^{2-} + 3H_2O + 4e^-$, 0.02 V; $Te \rightarrow Te^{4+} + 4e^-$, −0.564 V. Electronic configuration $1s^22s^22p^63s^2ep^63d^{10} - 4s^24p^64d^{10}5s^25p^4$. Other important physical properties of tellurium are given under **Chemical Elements**.

Tellurium occurs chiefly as telluride in gold, silver, copper, lead, and nickel ores in Colorado, California, Ontario, Mexico, and Peru, and infrequently as free tellurium and tellurite (tellurium dioxide, TeO_2) [CAS: 7446-07-3]. The anode mud from copper and lead refineries, or the flue dust from roasting telluride gold ores is treated by fusion with sodium nitrate [CAS: 7631-99-4] and carbonate [CAS: 3812-32-6] and the melt extracted with water. The resulting solution is acidified carefully with H_2SO_4, whereupon tellurium dioxide is precipitated, and the dioxide reduced to free tellurium by heating with carbon.

Uses. On the scale of most other commercial metals, the production of elemental tellurium is relatively limited — approximately $\frac{1}{2}$ million pounds annually. Commercial tellurium is marketed at a purity of about 99.7%, although much purer forms are obtainable — up to 99.999%. The application of tellurium and tellurium compounds as catalysts is expanding. Small quantities are used in various electronic components, including solar cells, infrared detectors, emitters, and thermoelectric generators. Tellurium also is sometimes used as a dopant for semiconductor devices. The metal has been used in primer fuses for explosives. The main applications have been in metallurgy. Small additions of tellurium improve the machinability of low-carbon steels, stainless steels, and copper. The metal stabilizes the carbide in cast irons. Tellurium also helps to control pinhole porosity in steel castings. The very small addition (0.05%) of tellurium to lead improves a number of the physical properties of lead sheet, foil, and other shapes. To some extent, tellurium has been used as a curing agent and accelerator in rubber compounds.

Chemistry and Compounds. Tellurium occurs in the same periodic classification as sulfur [CAS: 63705-05-5], selenium [CAS: 7782-49-2], and polonium [CAS: 7440-08-6]. Tellurium, unlike sulfur and selenium, has only two allotropic forms. Due to its $5s^25p^4$ electron configuration, tellurium, like sulfur and selenium, forms many divalent compounds with covalent bonds and two lone pairs, and d-hybridization is quite common, to form compounds with tellurium oxidation states of +4 and +6.

Tellurium dioxide, TeO_2, made directly from the element or by heating tellurous acid, H_2TeO_3, is a solid, subliming at 450 °C (842 °F), insoluble in H_2O, which dissolves in acids and alkalis, exemplifying the increasing metallic character with atomic weight of the main group 6 elements. Tellurium dioxide accepts a proton from strong acids to form the ion $TeOOH^+$. Dehydration of telluric acid [CAS: 13520-55-3]at 400 °C (752 °F) produces TeO_3, tellurium trioxide. It is not nearly as reactive as sulfur trioxide and selenium trioxide, but reacts with alkali hydroxides to form tellurates.

Tellurous acid, H_2TeO_3, can exist only in very dilute aqueous solutions (due to insolubility of TeO_2). It is a weak acid (ionization constants 2×10^{-3} and 2×10^{-8}). The salts of tellurous acid, the tellurites, may often be formed by reaction of TeO_2 with metal salts. Telluric acid, H_6TeO_6, is prepared by oxidation of tellurium with strong oxidizing agents, such as 30% hydrogen peroxide [CAS: 7722-84-1] or boiling HNO_3 and catalyst. Various values of the ionization constants of telluric acid have been reported, on the order of 10^{-7} and 10^{-11}, but the best values would appear to be $pK_{A1} = 7.7$, $pK_{A2} = 11.0$, $pK_{A3} = 14.5$. Telluric acid is a quite strong oxidizing agent, forming halogens from hydrohalides in solution (except hydrogen fluoride). The alkali metal tellurates have the composition $M_2H_4TeO_6$, although metal tellurates with all H's replaced exist, such as Hg_3TeO_6 and Zn_3TeO_6.

Hydrogen telluride [CAS: 7783-09-7] is a stronger acid than H_2S (ionization constants 2.27×10^{-3} and 10^{-11} (?) at 18 °C (64 °F) and is less readily obtained from tellurides than hydrogen sulfide from sulfides. Aluminum telluride, Al_2Te_3, requires heating with H_2O or dilute acids. In general the metal tellurides are prepared by direct combination of the elements. Those of the transition metals and the zinc [CAS: 7440-66-6], gallium [CAS: 7440-55-3] and germanium [CAS: 7440-56-4] families exhibit many instances of both well defined compounds and nondaltonide compositions, as well as substitutional solid solutions. Also six intermediate phases are found in the palladium-tellurium system, Pd_4Te, Pd_3Te, $Pd_{2.5}Te$, Pd_2Te, PdTe, and $PdTe_2$.

Tellurium hexafluoride, [CAS: 7783-80-4], TeF_6, the only clearly defined tellurium hexahalide, is formed directly from the elements at 150 °C (302 °F), while at 0 °C (32 °F) the product is mainly the decafluoride, Te_2F_{10}. TeF_6 is a relatively weak Lewis acid, forming complexes with pyridine and other nitrogen bases. Tellurium tetrahalides of all four halogens exist, the TeF_4 formed from $TeCl_2$ and fluorine, the $TeCl_4$ from $TeCl_2$ and chlorine, the $TeBr_4$ from bromotrifluoromethane, CF_3Br, and molten tellurium, and the TeI_4 directly from the elements. Tellurium dichloride, $TeCl_2$, is prepared by passing dichlorodifluoromethane, CF_2Cl_2, over molten tellurium. $TeCl_2$ is quite reactive, disproportionating to tellurium and $TeCl_4$, and useful in preparing other tellurium compounds. $TeBr_2$ is obtained by distillation of the mixture of tellurium and $TeBr_4$ obtained in the reaction between bromotrifluoromethane and tellurium. The tetrahalides of tellurium form many addition compounds with other halides.

Organotellurium compounds corresponding generally to those of sulfur and selenium are known. Although carbon ditelluride has not been prepared, COTe and CSTe have been.

Toxicity. Tellurium and compounds are toxic. Acceptable concentration limit for an 8-hour daily exposure to dust and fumes in air is 0.1 milligrams of tellurium per cubic meter of air. Even exposure at this level

may cause what is termed "garlic breath." Proper ventilation, appropriate hygienic practices, and good housekeeping should be observed in handling tellurium. Although elemental tellurium causes no apparent problems in contact handling, skin contact with soluble tellurium compounds must be avoided.

TELLUROMETER. See **Geodimeter**.

TELOMERIZATION REACTIONS. In telomerization reactions, a polymerizable unsaturated compound (the taxogen) is reacted under polymerization conditions in the presence of radical-forming catalysts or promoters with a so-called telogen. During the reaction, the telogen is split into radicals that attach to the ends of the polymerizing taxogen and in some instances add on to the double bond of the taxogen and thereby form chains whose therminal groups are formed of the radicals from the telogen.

Organic compounds containing an olefinic double bond, such as thylene, propylene, hexene, octene, or styrene, are normally employedas taxogens. Many different types of compounds can be employed as telogens, for example, halogenated hydrocarbons, such as chloroform or carbon tetrachloride, halogen derivatives of cyanogen, such as cyanogen chloride, aldehydes, alcohols, and the like.

Radical-forming catalysts, such as organic peroxides, hydrogen peroxide, aliphatic azo compounds of the type of azoisobutyric acid nitrile, and redox systems are employed for telomerization reactions.

Telomerization reactions are as a rule carried out at an elevated temperature up to 250 degrees. When volatile reactants are used, the reaction is carried out under elevated pressures, e.g., between 20 and 1000 atmospheres.

TEMIN, HOWARD MARTIN (1934–1994). Howard Temin was an American virologist who made fundamental contributions to the understanding of oncogenic or tumor-inducing viruses and was also one of the first scientists to isolate the enzyme reverse transcriptase. The son of a Philadelphia attorney, Temin studied biology in college and as a graduate student at the California Institute of Technology in Pasadena, trained under Renato Dulbecco in the field of animal virology and received his PhD in 1959. After completing a year of postdoctoral research in the same laboratory, he accepted a position as an assistant professor at the McArdle Laboratory for Cancer Research at the University of Wisconsin in Madison, where he spent the remainder of his career, rising in seniority through the years until his retirement. See also **Dulbecco, Renato (1914–Present)**.

Temin's earliest work — carried out in collaboration with Harry Rubin, then a postdoctoral fellow in Dulbecco's laboratory — was on the *Rous sarcoma virus*, the causative agent of connective tissue tumors (sarcomas) in birds. Using this virus, the two scientists developed *in vitro* techniques for monitoring and quantifying animal viruses in the laboratory, which opened up the hitherto unexplored terrain of animal virology to the scientific community. Also during this time, Temin performed experiments that led him to formulate the provirus hypothesis for the origins of tumors induced by RNA viruses. He postulated that the genetic information in the genomes of such viruses was first copied into DNA in the host cell, and that this DNA became integrated into the host's genome, forming a 'provirus' whose genes then came under the control of the host cell. This idea seemed to run contrary to the prevailing 'central dogma' of biology according to which the direction of the flow of information was from DNA to RNA to protein. In 1970, he was able to furnish direct evidence for his idea by isolating the enzyme 'reverse transcriptase', which catalyzed the synthesis of DNA from RNA templates. This work was corroborated by David Baltimore, who independently isolated the same enzyme. Subsequent work revealed the presence of viral sequences in the host's DNA, which further strengthened the provirus hypothesis. This discovery earned both these scientists a share in the 1975 Nobel Prize for Physiology or Medicine, along with their former mentor Dulbecco. See also **Baltimore, David (1938–Present)**.

TEMPER. A heat-treating process for increasing the toughness and eliminating warping and cracking of hardened steels and other metals. Temper also refers to the degree of hardness induced by a coldworking process, such as sheet rolling or wire drawing.

TEMPERATURE. The thermal state of a body, considered, with reference to its ability to communicate heat to other bodies (J.C. Maxwell). There is a distinction between temperature and heat, as is evidenced by Helmholtz's definition of heat, (energy that is transferred from one body to another by a thermal process), whereby a thermal process is meant radiation, conduction, and/or convection.

Temperature is measured by such instruments as thermometers, pyrometers, thermocouples, etc., and by scales such as centigrade (Celsius), Fahrenheit, Rankine, Reaumur, and absolute (Kelvin).

See also **Absolute Temperature**; **Thermodynamics**; and **Temperature Scales and Standards**.

TEMPERATURE-EFFICIENCY INDEX (T-E INDEX). For a given location, a measure of the long- range effectiveness of temperature (thermal efficiency) in promoting plant growth. Numerically, the T-E index is equal to the sum of the 12 monthly temperature-efficiency ratios (T-E ratio). See also **Temperature-Efficiency Ratio**.

AMS

TEMPERATURE-EFFICIENCY RATIO (T-E RATIO). For a given location and month, a measure of thermal efficiency equal to the departure of the normal monthly temperature above 32 °F divided by 4:

$$\text{T-E ratio} = \frac{T - 32}{4},$$

where T is the normal monthly temperature in degrees Fahrenheit, except that all values below 32° are counted as 32°. No dimensions are assigned to this ratio.

AMS

TEMPERATURE (Human). The normal temperature of the interior of the human body is usually said to be 98.6 °F (37 °C). Actually, this normally varies in the course of 24 hours, so that variation between maximal and minimal temperatures during this period is about 1.8 °F (1 °C). The above Figures are those obtained when the temperature is taken by mouth. The rectal temperature is 1 °F (0.6 °C) higher.

TEMPERATURE-HUMIDITY INDEX (THI). See **Meteorology**.

TEMPERATURE HUMIDITY INFRARED RADIOMETER (THIR). See **Nimbus Satellite Program**.

TEMPERATURE-MOISTURE INDEX. See **Meteorology**.

TEMPERATURE RAINY CLIMATE. See **Climate**.

TEMPERATURE SCALES. See **Heat**.

TEMPERATURE SCALES AND STANDARDS. That property of systems which determines whether they are in thermodynamic equilibrium. Two systems are in equilibrium when their temperatures (measured on the same temperature scale) are equal. The existence of the property defined as temperature is a consequence of the zeroth law of thermodynamics. The zeroth law of thermodynamics leads to the conclusion that in the case of all systems there exist functions of their independent properties x_i such that at equilibrium

$$\phi_a(x_{ia}) = \phi_b(x_{ib}) = \theta \tag{1}$$

where subscripts a and b refer to two systems a and b each described by n_a properties x_{ia}, and n_b properties x_{ib}, respectively. The hypersurface

$$\theta = \phi(x_i) = \text{constant}$$

is called an *isotherm*, and the pairs of hypersurfaces, Equation (1), at equilibrium are called *corresponding isotherms*.

In order to establish a *temperature scale* it is necessary to assign numerical values θ to these corresponding isotherms in an arbitrary manner, subject only to the condition that the resulting function shall be single-valued. A temperature scale is established by taking the following steps:

1. An arbitrary system is chosen (*thermometer*).
2. It is agreed to maintain $n-1$ properties of the system constant, and to use the nth property (*thermometric property* $x_n = X$) as a measure of temperature θ.
3. A single-valued *thermometric function* is assumed. Usually the function is simple, for example

$$\theta = aX \tag{2}$$

or

$$\theta = AX + B. \tag{3}$$

The function usually contains one or several constants (a, A, B, etc.).

4. The values of the constants in the thermometric function are determined with reference to fixed thermometric points whose temperatures are arbitrarily assumed. The *fixed thermometric points* most frequently employed are: the *ice point, steam point* and *triple point* of water.

It is not surprising that there exist many different scales of temperature, so-called *empirical temperature scales*, because of the large amount of arbitrariness inherent in the choice.

A *Centigrade* (or *Celsius*) *temperature scale* is obtained by choosing the thermometric function, Equation (3), and assigning the following arbitrary values of temperature, θ, to the ice point (θ_i) and steam point (θ_s) respectively

$$\theta_i = 0\,^\circ\text{C}.$$

$$\theta_s = 100\,^\circ\text{C}.$$

Hence on a Centigrade scale

$$\theta = 100\frac{X - X_i}{X_s - X_i} \tag{4}$$

(X_s measured at θ_s, X_i measured at θ_i).

A Fahrenheit temperature scale is obtained by using Equation (3) but with

$$\theta_i = 32\,^\circ\text{F}$$

$$\theta_s = 212\,^\circ\text{F}.$$

Hence

$$\theta = 32^\circ + 180^\circ\frac{X - X_i}{X_s - X_i}. \tag{5}$$

An *absolute scale* is obtained by choosing Equation (2). Depending on the value assigned to a, we obtain the *Kelvin* or *Rankine scale*. The *Kelvin absolute temperature scale* assigns to the triple point of water the value

$$\theta_3 = 273.16\,^\circ\text{K} \tag{6}$$

which thus becomes a *universal constant of physics*. Hence for the Kelvin scale

$$\theta = 273.16\frac{X}{X_3} \tag{7}$$

where X_3 is measured at θ_3. For the *Rankine absolute temperature* scale we assume

$$\theta_3 = 273.16 \times 1.8\,^\circ\text{R} = 491.69\,^\circ\text{R}. \tag{8}$$

It is clear that by definition

$$1\,^\circ\text{K} = 1.8\,^\circ\text{R}, \tag{9}$$

and that on the Rankine scale

$$\theta = 491.69^\circ\frac{X}{X_3}. \tag{10}$$

Different empirical temperature scales will naturally differ from each other except at the respective fixed thermometric points. Even different scales of the same type (say different Centigrade scales) will differ at all temperatures, except the steam point and ice point, depending on the fortuitous properties of the system chosen as a thermometer. It is, therefore, necessary to remove these differences and to obtain a more universal scale. This has been achieved in two ways. The practical way of achieving uniformity is to lay down detailed rules concerning the thermometer (actually different thermometers depending on the range of temperatures to be measured). Such rules have been agreed on internationally and constitute the *international temperature scale*. Another way is to derive a universal scale from the principles of thermodynamics. The latter is called a *thermodynamic temperature scale*. Some authors refer to it as the *absolute temperature scale* which may be a source of confusion with the Kelvin and Rankine scales described earlier.

The *thermodynamic temperature scale* T is defined by the second law of thermodynamics. It can be shown that the *thermodynamic temperature*

scale is identical with the *perfect-gas temperature scale* defined as follows:

1. The system is a gas thermometer (filled with a *real* gas).
2. The thermometric property is the product *pV extrapolated to* zero pressure, i.e.,

$$r = \lim_{p \to 0} (pV) \tag{11}$$

Hence the *thermodynamic Kelvin scale* is given by

$$T = 273.16 \frac{r}{r_3} (\text{K abs.}) \tag{12}$$

the *thermodynamic Centigrade scale* is given by

$$t - 100 \frac{r - r_i}{r_s - r_i} (\text{degrees C}), \tag{13}$$

the *thermodynamic Rankine scale* is given by

$$T = 491.69 \frac{r}{r_3} (\text{degrees R abs.}), \tag{14}$$

and the *thermodynamic Fahrenheit scale* is given by

$$t = 32 + 180 \frac{r - r_i}{r_s - r_i} (\text{degrees F}). \tag{15}$$

The zeros on the Kelvin and Rankine scales coincide and are termed the *absolute zero of temperature*. The absolute zero of temperature cannot be achieved by any finite process, as stated in the third law of thermodynamics.

The relation between the Centigrade and Kelvin thermodynamic scales is determined by

$$T_i = 273.16\,^{\circ}\text{K} = 0\,^{\circ}\text{C} \tag{16}$$

and that between the Fahrenheit and Rankine scales is determined by

$$T_i = 491.69\,^{\circ}\text{R} = 32\,^{\circ}\text{F}. \tag{17}$$

Hence the absolute zero of temperature is at

$$-273.16\,^{\circ}\text{C or } -459.69\,^{\circ}\text{F}. \tag{18}$$

The Comité Consultative of the International Committee of Weights and Measures selected 273.16 °K as the value for the triple point of water. This set the ice-point at 273.15 °K.

The relation between the *international temperature scale* and the thermodynamic temperature scale must be determined empirically with the aid of careful measurements involving gas thermometers.

See also **Units and Standards**.

TEMPERATURE TRANSFER STANDARD. A device for the transfer of a temperature scale from one standardizing laboratory to another. One form consists of a sample of a purified material, the freezing point of which (when realized by a prescribed technique) is reproducible within narrow limits. Materials commonly employed are metals, such as zinc [CAS: 7440-66-6] and tin [CAS: 7440-31-5], and organic compounds, such as benzoic acid [CAS: 65-85-0], phenol [CAS: 108-95-2], naphthalene [CAS: 91-20-3], and phthalic anhydride [CAS: 85-44-9]. Another form is a tungsten ribbon-filament lamp, characterized by a stable lamp current-brightness temperature relation. This device is particularly useful for temperatures above 1,050 °C (1,922 °F).

TEMPORAL. A bone of the vertebrate skull. In the human skull it lies at the side, centering about the ear. It forms the posterior part of the cheek bone with the articulation of the lower jaw, and bears the mastoid process behind the ear. It included the squamosal bone and the bones of the ear.

TEMPORAL LOBE. See **Central and Peripheral Nervous Systems**.

TENACITY. Strength per unit weight of a fiber or filament, expressed as g/denier. It is the rupture load divided by the linear density of the fiber.

See also **Tensile Strength**.

TENDENCY. The local rate of change of a vector or scalar quantity with time sat a given point in space. Thus, in symbols, $\partial p/\partial t$ is the pressure tendency, $\partial \zeta/\partial t$ is the vorticity tendency, etc. Because of the difficulty of measuring instantaneous variations in the atmosphere, variations are usually obtained from the differences in magnitudes over a finite period of time and the definition of tendency is frequently broadened to include the local time variations so obtained. An example is the familiar three-hourly pressure tendency given in surface weather observations; in fact, the term "tendency" alone often means the pressure tendency. See also **Pressure Tendency**.

AMS

TENDON. Connective tissue structures connecting muscles with their skeletal supports. They are composed of parallel white fibers, closely bound into bundles between which the cells of the tendon are compressed. The entire tendon is surrounded by a fibrous sheath known as the vagina fibrosa, which is split in some cases to form a cavity containing a mucoid liquid. Such a sheath is called a vaginal mucosa. It develops where a wide range of movement is necessary.

Aponeuroses, ligaments, and fasciae are fibrous structures resembling tendons in structure. The first are broadly expanded and usually bind down muscles. The second connect bones. The third are fibrous coverings of muscles and other organs.

TENORITE. A mineral oxide and ore of copper, CuO. Crystallizes in the monoclinic system. Hardness, 3.5; specific gravity, 6.45; color, gray to black with metallic luster. Named after M. Tenore (1780–1861), Naples.

TENRECIDS. See **Moles and Shrews**.

TENSILE STRENGTH. The rupture strength (stress-strain product at break) per unit area of a material subjected to a specified dynamic load; it is usually expressed in pounds per square inch (psi). This definition applies to elastomeric materials and to certain metals.

See also **Tenacity**.

TENSILE STRESS. See **Stress (Structural)**.

TENSIMETER. An apparatus for determining transition points (phase change) of materials in an indirect manner by measuring small changes in vapor pressure.

TENSIOMETER. (1) An apparatus for measuring the surface tension of a liquid by registering the force necessary to detach a metal ring from the surface. (2) A device used to determine soil moisture tension, an indirect measure of soil moisture content. The tensiometer consists of a glass or plastic tube with a porous ceramic tip. It is filled with a liquid, usually colored water. At the top of the tube is a vacuum gauge to allow visual inspection or a transducer to allow analog or digital inspection or logging. The device is buried in the soil, and a hand pump is used to pull a partial vacuum. As water is pulled out of the soil by plants, the vacuum inside the tube increases and can be measured by the gauge. As water is added to the soil, the vacuum inside the tube pulls moisture from the soil and the

reading on the gauge will decrease. The actual reading will vary according to the type of soil and the moisture content.

TENSION. In structural engineering, tension is used to denote the longitudinal force which causes the fibers of a member to elongate, thus giving rise to tensile stress.

TENSION (Interfacial). See **Interfacial Tension**.

TENSION MEMBER. Any member of a structure subjected to a primary tensile stress is called a tension member. The analysis or design depends on that part of the cross-sectional area that is effective in resisting the tensile stress. The effective area at any section is called the net section. It is the gross area minus the area of any holes including those filled by rivets or bolts. The net section may be based on a right section or a zig-zag section. The net section of a threaded member such as a bolt or tie rod is the area at the root of the thread. The strength of a tension member is a function of the minimum net section.

If the member is composed of two or more independent parts other than eye bars, the parts may be connected by the tie plates or by tie plates and lacing bars to equalize the stress and prevent excessive distortion during fabrication, shipping or erection.

TENSION TEST. Next to hardness tests, tension tests are the most frequently used to determine the mechanical properties of metals. Tension test specimens necessarily vary in form with the product to be tested. A machined cylindrical specimen with threaded or shouldered ends for gripping is used when the material is sufficiently thick. Standard flat specimens are used for flatrolled products. While both types of specimens have a reduced central section to ensure breaking within a measured gage length, wires and certain special shapes such as steel reinforcing bars for concrete are tested in full section without preparation. Special cast test specimens are often attached to castings, or cast separately, and these are generally tested without machining.

The significant loads determined in the test are reported as unit stresses based on the area of the original section (Stress equals load divided by area). The elongation is expressed as percent increase in length of the gage-marked section. The initial gage length is generally 2 inches (5 centimeters), although an 8-inch (20.3-centimeter) gage length is used for certain flat specimens and other gage lengths are used for special specimens. The gage length should be specified when elongation is reported since percent elongation values are higher for short than for long gage lengths.

The elongation measured over a fixed gage length, and the reduction of area of the section at the fracture are measures of ductility. In cylindrical specimens, the area is readily determined from the final diameter at the fracture. The percent reduction of area is then determined as: original area minus final area, divided by original area.

Autographic load-deformation curves are often drawn during the test. From such a curve, the modulus of elasticity, proportional limit, and yield strength can be determined.

A typical curve has an essentially linear portion (OA) in which the deformation is proportional to the applied load. See Fig. 1. It follows that the unit stress (load divided by original area) is proportional to the unit strain (deformation divided by original gage length) in accordance with Hooke's Law. The numerical value of this ratio (e.g., in psi) is known as Young's Modulus or Modulus of Elasticity.

The maximum stress that is developed without deviation from proportionality of stress to strain is the proportional limit (the stress corresponding to load A). The maximum stress that can be applied without causing permanent deformation upon release of the load is the elastic limit. Usually, there is little difference between the proportional limit and the elastic limit. Both are dependent on the sensitivity of the measuring devices used and certain details of testing technique. For this reason, the yield strength is generally used as a practical measure of the elastic properties of metals.

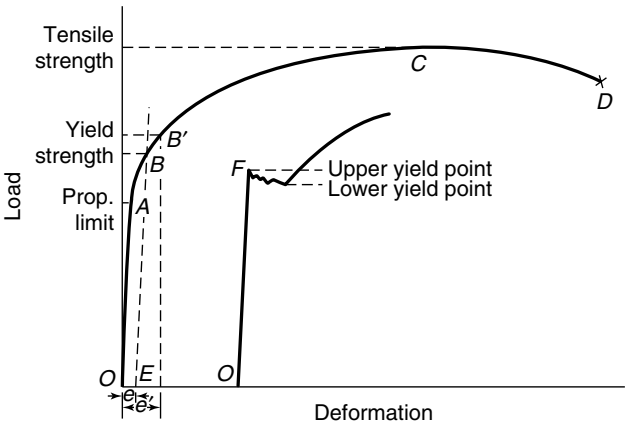

Fig. 1. Stress-strain diagram.

The yield strength is the stress at which the stress-strain curve deviates from the initial straight line by a specified increment of strain. The yield strength corresponding to the load at B is based on the specified strain deviation or offset e. The value of e may be as low as 0.0001 inch (0.0025 millimeter) of gage length but the most commonly used value is 0.002 inch (0.05 millimeter), or 0.2% strain.

If the load should be released after reaching B, the load deformation relationship will follow the line BE, or a curve line terminating between O and E. Thus the permanent strain will be e or a somewhat smaller value. When the final or permanent strain is specified, the stress is known as the proof stress.

An alternate type of yield strength is based on a specified total extension under load, such as 0.5%. If the specified extension is e' the load B' determines the "extension-underload" yield strength. Load B' may be greater or less than B.

The tensile strength, or ultimate tensile strength, is the maximum stress developed in the tension test (load C divided by original area).

The breaking stress, corresponding to load D, is seldom determined or reported.

In loading tension specimens of many soft irons and steels, a point is reached where stretching continues without increase in load. The unit stress obtained by dividing this load, F, by the original area of the section is called the yield point. The elongation of the specimen at the yield point may reach 8% in some instances, after which the load will again increase to a maximum in the normal manner. Upper and lower yield points are indicated at F; both are used, but the upper yield point is influenced by variations in testing technique such as alignment of the specimen in the testing machine and speed of test. Yield points occur only rarely in the nonferrous metals.

Conventional stress-strain curves are necessarily similar to the load-deformation curves from which they are derived. True stress-strain curves can also be derived in which the stress is based on the actual or instantaneous area of the cross-section. Such curves do not have a maximum corresponding to C, but increase continuously to the breaking load.

TENSOR. A set of n^r components, which are functions of the coordinates of any point in n-dimensional space. They transform linearly and homogeneously, according to certain rules, when a transformation of coordinates is made. Tensors are called covariant, contravariant, or mixed, according to the law of transformation. The number r is called the rank or order of the tensor.

Suppose $(x^1, x^2, \ldots, x^n)$ are the coordinates of a point referred to a given coordinate system and $(\overline{x}^1, \overline{x}^2, \ldots, \overline{x}^n)$ are the coordinates of the same point referred to another coordinate system. Then n quantities $(A^1 A^2, \ldots A^n)$, functions of these coordinates are the contravariant components of a tensor of rank one if they transform as follows:

$$A^i = \frac{\partial \overline{x}^i}{\partial x^r} A^r, i = 1, 2, \ldots, n$$

The summation for the summy index r is understood and the upper suffix is not an exponent but a means of designating the different components. Contravariant tensors of higher rank are defined in a similar way. Thus, for a tensor of rank two,

$$A^{ij} = \frac{\partial \overline{x}^i}{\partial x^r}\frac{\partial \overline{x}^j}{\partial x^s}A^{rs}$$

A tensor of rank zero is a scalar; of rank one, a vector.

The transformation laws for covariant tensors of rank one and two, respectively are

$$A_i = \frac{\partial x^r}{\partial \overline{x}^i}A_r;\ A_{ij} = \frac{\partial x^r}{\partial \overline{x}^i}\frac{\partial x^s}{\partial \overline{x}^j}A_{rs}$$

The transformation law for a mixed tensor of second rank is

$$A^i_j = \frac{\partial \overline{x}^i}{\partial x^r}\frac{\partial x^s}{\partial \overline{x}^j}A^r_s$$

Mixed tensors of higher rank may be defined by analogy. An important mixed tensor is the Kronecker delta,

$$\delta^m_n = 1, \quad m = n$$
$$\delta^m_n = 0, \quad m \neq v$$

If the components of a tensor satisfy the relation $A^{ij} = A^{ji}$, the tensor is symmetric, if $A^{ij} = -A^{ji}$, skew-symmetric. If the components are neither symmetric nor skew-symmetric, they may always be expressed as $A^{ij} = S^{ij} + T^{ij}$, where $S^{ij} = (A^{ij} + A^{ji})/2$, which is symmetric and $T^{ij} = (A^{ij} - A^{ji})/2$, which is skew-symmetric.

For further properties of tensors see also **Christoffel Symbol**; **Field Theory**; **Tensor Contraction**; and **Tensor Differentiation**. See also **Dyadic**.

TENSOR CONTRACTION. Suppose that two indexes in a tensor, one upper and one lower, are identical, A^m_{npm}. Then summation over the repeated index shows that the tensor is actually of lower rank, for its transformation law is

$$A^m_{npm} = \frac{\partial \overline{x}^m}{\partial x^i}\frac{\partial x^j}{\partial \overline{x}^n}\frac{\partial x^k}{\partial \overline{x}^p}\frac{\partial x^h}{\partial \overline{x}^m}A^j_{jkh}$$
$$= \frac{\partial x^j}{\partial \overline{x}^n}\frac{\partial x^j}{\partial \overline{x}^p}\delta^h_i A^i_{jkh} = \frac{\partial x^j}{\partial \overline{x}^n}\frac{\partial x^k}{\partial \overline{x}^p}A^i_{jki}$$

where δ^h_i is a mixed tensor. The result could properly be written A_{jk}, since the tensor transforms like a covariant tensor of rank two. The process of contraction, which can be used for tensors of any rank, thus consists of deleting a repeated upper and lower index. It always reduces the rank of a mixed tensor by two.

An outer product results when A^m is multiplied by B_n to give a mixed tensor. Such a product of any rank or type can be formed. Multiplication, followed by contraction gives an inner product. This process is similar to the scalar product in vector analysis for $A^m B_m$ is a scalar.

These properties, together with addition, show how new tensors can be formed from two or more given tensors. Still another such operation is possible and it also shows the relation between a covariant and a contravariant tensor. Consider a symmetric tensor of the former type, g_{mn} with determinant g and cofactor, G^{mn}. (Note that G^{mn} is not a tensor.) Then, if we define $g^{mn} = G^{mn}/g$, the rule for the expansion of a determinant gives $g_{mn}g^{in} = \delta^i_m$. As suggested by the notation g^{mn} is a contravariant tensor, for if A^n is a vector, then $B_m = g_{mn}A^n$ is also a vector and $g^{mn}B_m = g^{mn}g_{mi}A^i = \delta^n_i A^i = A^n$. Thus, g^{mn} changes a covariant into a contravariant vector. Two vectors related by either g_{mn} or g^{mn} are called associated. In fact, $A^m = g^{mn}A_n$, and $A_m = g_{mn}A^n$ are often regarded as the same vector with covariant components, A_m and contravariant components, A^m.

The quantity g_{mn} is usually called the metric tensor. Consider a rectangular coordinate system, then the square of the line element ds is $ds^2 = dx^2 + dy^2 + dz^2$. In generalized coordinates, $q^{''i}$, one has $ds^2 = g_{mn}dq^m dq^n$ and in still another coordinate system $\overline{q}^i$, $ds^2 = g_{ij}d\overline{q}^i d\overline{q}^j$. (Note that the superscripts on ds, dx, dy, and dz are squares, not tensor indices.)

TENSOR DIFFERENTIATION. Differentiation of a covariant tensor does not yield a tensor for the derivative and does not transform properly. The covariant derivative of a covariant tensor of rank one is then defined as

$$A_{i,j} = \frac{\partial A_\cdot}{\partial x^j} - \{ij, h\}A_h$$

where $\{ij, h\}$ is a Christoffel three-index symbol (not a tensor) and this function transforms like a covariant tensor of rank two. Derivatives of contravariant and mixed tensors of all ranks may be defined in a similar way.

See also **Christoffel Symbol**.

TENSOR FIELD. In each n-dimensional curvilinear coordinate system n^{M+N} functions of position are specified. Using the indicial notation let us denote those defined in the coordinate system x by $t^{j_1 j_2 \cdots j_M}_{k_1 k_2 \cdots k_N}$ and those defined in the coordinate system $\overline{x}$ by $t^{j_1 j_2 \cdots j_M}_{k_1 k_2 \cdots k_N}$. In each case the M superscripts and N subscript take values ranging over $1, 2, \ldots, n$ independently. The functions are related by

$$t^{-j_1 j_2 \cdots j_M}_{k_1 k_2 \cdots k_N}\left|\frac{\partial x}{\partial \overline{x}}\right|^W \frac{\partial \overline{x}^{j_1}}{\partial x^{p_1}}\frac{\partial \overline{x}^{j_2}}{\partial x^{p_2}}$$
$$\cdots \frac{\partial \overline{x}^{j^M}}{\partial x^{p_M}}\frac{\partial x^{q_1}}{\partial \overline{x}^{k_1}}\frac{\partial x^{q_2}}{\partial \overline{x}^{k_2}}\cdots\frac{\partial x^{q_N}}{\partial \overline{x}^{k_N}}t^{p_1 p_2 \cdots p_M}_{q_1 q_2 \cdots q_N}$$

in which the summation convention is employed, $|\partial x/\partial \overline{x}|$ *denotes the Jacobian determinant* $\partial(x^1, x^2, \ldots, x^n)/\partial(\overline{x}^1, \overline{x}^2, \ldots, \overline{x}^n)$, W is an integer (positive or negative) and the summation convention is employed. The aggregate of sets of functions defined in this manner in every curvi-linear coordinate system is called an n-dimensional *tensor field of weight W*. The tensor field is said to be *contravariant* of order M and *covariant* of order N. It is said to have *total order* or *order* $M + N$. If $M = 0$ the tensor field is said to be a *covariant tensor field*. If $N = 0$, it is said to be a *contravariant tensor field*. If neither M nor N is zero, it is said to be a *mixed tensor field*. For summation convention, see also **Tensor**.

The set of functions $t^{j_1 j_2 \cdots j_M}_{k_1 k_2 \cdots k_N}$ are called the *components of the tensor field* in the coordinate system x; similarly the set of functions $\overline{t}^{j_1 j_2 \cdots j_M}_{k_1 k_2 \cdots k_N}$ are called the components of the tensor field in the coordinate system $\overline{x}$. The superscripts are called *contravariant indices* and the subscripts *covariant indices*.

At each point of space at which the tensor field is defined, it determines a set of n^{M+N} quantities in each curvilinear coordinate system. The aggregate of these sets of quantities is called an n-dimensional tensor at the point considered. The set of n^{M+N} quantities determined in the coordinate system x are the components of the tensor in the coordinate system x. The definitions of weight, contravariance, and order of a tensor are analogous to those for a tensor field.

A tensor field is often referred to as a *tensor*, when no confusion is likely to arise.

TENSOR FIELD (Cartesian). In each n-dimensional rectangular Cartesian coordinate system n^M functions of position are specified. Let us denote the functions defined in the rectangular Cartesian coordinate systems x and $\overline{x}$ by $t_{i_1 i_2 \cdots i_M}$ and $\overline{t}_{i_1 i_2 \cdots i_M}$ respectively. In each case the M subscripts $i_1, i_2, \ldots, i_M$ take values ranging over $1, 2, \ldots, M$ independently. The functions are related by

$$\overline{t}_{i_1 i_2 \cdots i_M} = \frac{\partial \overline{x}_{i_1}}{\partial x_{j_1}}\frac{\partial \overline{x}_{i_2}}{\partial x_{j_2}}\cdots\frac{\partial \overline{x}_{i_M}}{\partial x_{j_M}}t_{j_1 i_1 \cdots j_M}$$

where the summation convention is used and the relation is valid for all choices of the rectangular Cartesian coordinate systems x and $\overline{x}$. The aggregate of sets of n^M functions so defined is called an n-dimensional Cartesian tensor field. M is called the *order* of the Cartesian tensor field. The set of functions $t_{i_1 i_2 \cdots i_M}$ are called the components of the Cartesian tensor field in the coordinate system x; similarly the set of functions $\overline{t}_{i_1 i_2 \cdots i_M}$ are called the components of the Cartesian tensor field in the coordinate system $\overline{x}$.

At each point of space at which the Cartesian tensor field is defined, it determines a set of n^M quantities in each rectangular Cartesian coordinate system. The aggregate of these sets of quantities is called an n-dimensional *Cartesian tensor* at the point considered. The set of n^M quantities determined in the coordinate system x are called the *components of the tensor* in the coordinate system x.

A Cartesian tensor field is often referred to as a *Cartesian tensor* and, particularly in applied mathematical contexts, as a *tensor*.

TENTED ICE. See **Pressure Ice**.

TEPHRA. From the Greek word meaning "ash," *tephra* collectively refers to airborne fragments from an erupting volcano. Thus, tephra is a general term for all pyroclastics of a volcano. See also **Pyroclastic**.

TERBIUM. [CAS: 7440-27-9]. Chemical element symbol Tb, at. no. 65, at. wt. 158.92, eighth in the Lanthanide Series in the periodic table, mp 1,356 °C (2,473 °F), bp 3,230 °C (5,846 °F), density 8.230 g/cm^3 20 °C, (68 °F). Elemental terbium has a close-packed hexagonal crystal structure at 25 °C. The pure metallic terbium is silver-gray in color, and is stable in ambient air conditions. When pure, the metal is malleable. There is one natural isotope of terbium ^{159}Tb. The isotope is not radioactive and has a low acute-toxicity rating. 33 radioisotopes have been characterized, with the most stable being ^{158}Tb with a half-life of 180 years, ^{157}Tb with a half-life of 71 years, and ^{160}Tb with a half-life of 72.3 days. All of the remaining radioactive isotopes have half-lifes that are less than 6.907 days, and the majority of these have half lifes that are less than 24 seconds. This element also has 18 meta states, with the most stable being 156 m1-Tb ($t_{1/2}$ 24.4 hours), 154 m2-Tb $t_{1/2}$ 22.7 hours) and 154 m1-Tb ($t_{1/2}$ 9.4 hours). Little is known concerning the characteristics of terbium alloys and intermetallic compounds. Average content of the earth's crust is estimated at 0.9 ppm terbium, making this element the second least abundant of the rare-earth elements. Even at this level, however, terbium is potentially more available than antimony, bismuth, cadmium, or mercury. The element was first identified in 1843 by Swedish chemist Carl Gustaf Mosander, who detected it as an impurity in Yttrium-oxide, Y_2O_3, and named after the village Ytterby in Sweden. It was not isolated in pure form until the recent advent of ion exchange techniques. Electronic configuration of the ground state is mixed:

$$1s^2 2s^2 2p^6 3s^2 3p^6 3d^{10} 4s^2 4p^6 4d^{10} 4f^8 5s^2 5p^6 5d^1 6s^2.$$

Ionic radius Tb^{3+} 0.93 Å, Tb^{4+} 0.76 Å. Metallic radius 1.783 Å. First ionization potential 5.84 eV; second 11.52 eV. Other physical properties of terbium are given under **Rare-Earth Elements and Metals**. See also **Chemical Elements**.

Terbium occurs in apatite and xenotime and is derived from these minerals as a minor coproduct in the processing of yttrium. Processing involves organic ion-exchange or solvent extraction operations. Elemental terbium is produced by calcium reduction of anhydrous TbF_3 in a reactor under an inert atmosphere. Both the oxides and the metal are available at 99.9% purity.

To date, the uses for terbium have been quite limited. Terbium-activated lanthanum oxysulfide Tb:La_2O_2S is a phosphor finding use as an image intensifier for x-ray screens. Terbium-activated indium borate Tb:$InBO_3$ phosphor emits an intense narrow green light (5,450–5,500Å) and has found use in information display systems where there are high ambient-light conditions. Future color television tubes may use terbium-activated yttrium silicate Tb:Y_2SiO_5 or yttrium phosphate Tb:YPO_4 green phosphors. They appear to be highly efficient post-deflection focused phosphors for elimination of the need for a shadow mask in a television tube. Although terbium oxide may be used as a stain for ceramics, the compound does not color glass. In soda-lime glass, a small quantity of terbium provides a strong green-blue fluorescence under ultraviolet radiation. Another important use of terbium is in amorphous Tb-Co(fe) alloys for magnetic recording and information storage.

Terbium is one of the rare chemicals that can be found in houses in equipment such as color televisions, fluorescent lamps, energy-saving lamps and glasses. As with the other lanthanides, terbium compounds are of low to moderate toxicity, although their toxicity has not been investigated in detail. Terbium has no known biological role.

TEREPHTHALIC ACID. [CAS: 100-21-0]. It is also known as 1,4-benzenedicarboxylic acid, and it has the chemical formula $C_6H_4(COOH)_2$ (**1**), formula weight 166.13, crystalline solid sublimes upon heating, sp gr 1.510. The compound is almost insoluble in H_2O, only slightly soluble in warm alcohol, and insoluble in ether. Terephthalic acid (TPA) is a high-tonnage chemical, widely used in the production of synthetic materials, notably polyester fibers (poly-(ethylene terephthalate)) [CAS: 25038-59-9].

(1)

Terephthalic acid came to prominence through the work of Winfield and Dickson in Britain around 1940. Earlier work by Carothers and coworkers in the United States established the feasibility of producing high molecular weight linear polyesters by reacting diacids with diols, but they used aliphatic diacids and diols. These made polyesters which were unsuitable to be spun into fibers. Winfield and Dickson found that symmetrical aromatic diacids yield high-melting, crystalline, and fiber-forming materials; poly(ethylene terephthalate) (PET) has since become the largest volume synthetic fiber.

There are several processes for making terephthalic acid on a large scale: (1) Benzoic acid [CAS: 65-85-0], phthalic acid [CAS: 88-99-3] and other benzene-carboxylic acids in the form of alkali-metal salts, comprise the chargestock. In a first step, the alkali-metal salts (usually potassium) are converted to terephthalates when heated to a temperature exceeding 350 °C (662 °F). The dried potassium salts (of benzoic acid or *o*- or isophthalic acid) are heated in anhydrous form to approximately 420 °C (788 °F) in an inert atmosphere (CO_2) and in the presence of a catalyst (usually cadmium benzoate, phthalate, oxide, or carbonate). The corresponding zinc compounds also have been used as catalysts. In a following step, the reaction products are dissolved in H_2O and the terephthalic acid precipitated out with dilute H_2SO_4. The yield of terephthalic acid ranges from 95 to 98%.

(2) Toluene [CAS: 108-88-3], formaldehyde [CAS: 50-00-0], HCl [CAS: 7647-01-0], calcium hydroxide [CAS: 1305-62-0], and HNO_3 comprise the chargestock. In step 1 of this process, the toluene is reacted with concentrated HCl at about 70 °C (158oF) along with paraformaldehyde [CAS: 30525-89-4]. This accomplishes chloromethylation of approximately 98% of the toluene. In step 2, saponification of the chloromethyltoluene is effected with lime and H_2O under pressure and at about 125 °C (257 °F).

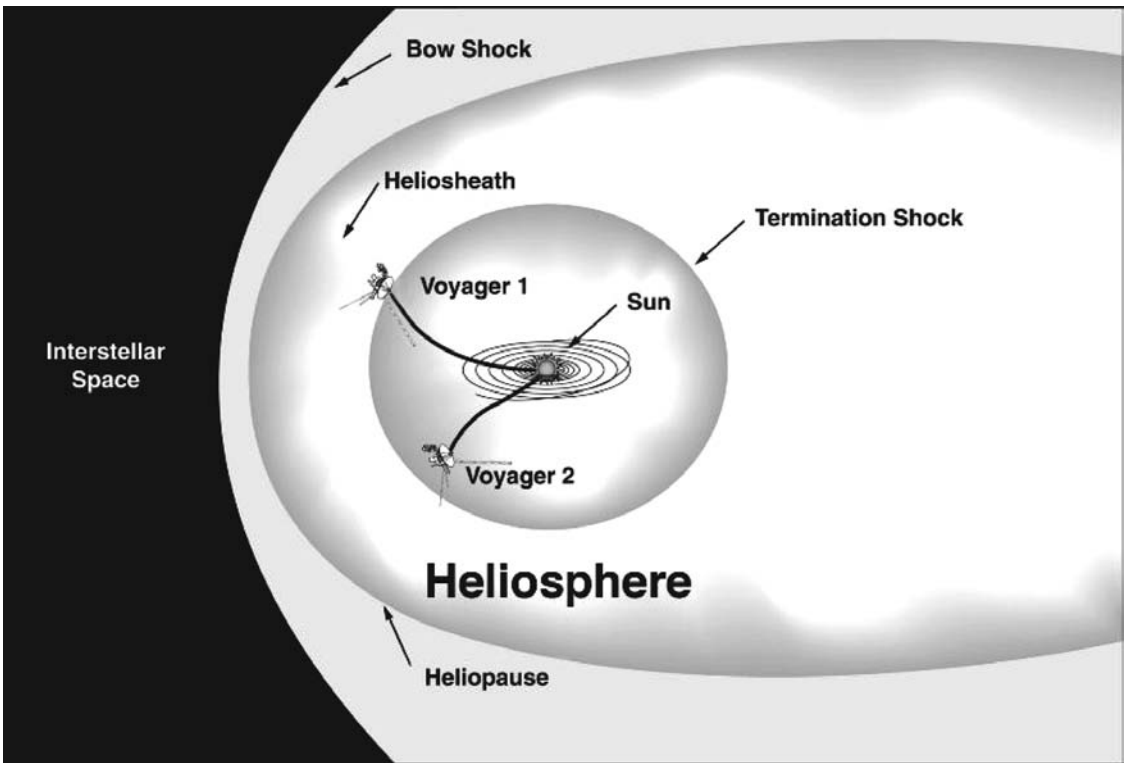

Fig. 1. The location of Voyagers 1 and 2 as of 2005. (*Image courtesy of NASA/Walt Feimer*).

The product is methylbenzyl alcohol. In step 3, the methylbenzyl alcohol is oxidized with HNO_3 (dilute) under a pressure of about 20 atmospheres and at a temperature of about 170 °C (338 °F). The main products are *o*-phthalic acid in HNO_3 solution and insoluble terephthalic acid.

(3) Paraxylene and air comprise the chargestock. These materials, along with a proprietary catalyst and solvent, are fed to a liquid-phase oxidation reactor, operated at moderate pressure and temperature. The reaction is

$$C_6H_4(CH_3)_2 + 3\ O_2 \longrightarrow C_6H_4(COOH)_2 + 2\ H_2O.$$

The design details of these processes are proprietary. There are several other processes which essentially are variations of the foregoing descriptions. See also **Intermediate (Chemical)**; **Phthalic Acid**; and **Phthalic Anhydride**.

TERMINAL MORAINE (or End Moraine). When balance is maintained between the melting of a glacier and its forward advance, the debris carried on (superglacial); within (englacial); and dragged along the bottom (subglacial); is dumped at that point and builds up a heterogeneous mass of the transported material called the terminal moraine. If a glacier is slowly retreating and makes successive halts farther and farther up the valley, a series of terminal moraines are formed which are spoken of as recessional moraines. See also **Drumlin**; and **Glacial Deposits**.

TERMINATION SHOCK. In astronomy, the "termination shock" is the boundary marking one of the outer limits of the sun's influence. It is where the bubble of solar wind particles slows down to below supersonic speed (with respect to the star) due to interactions with the galactic interstellar medium. This causes compression, heating, and a change in the magnetic field. The termination shock is believed to be about 100 astronomical units (AU) from the Sun. The termination shock boundary fluctuates in its distance from the sun as a result of fluctuations in solar flare activity, i.e. changes in the ejections of gas and dust from the sun. See also **Astronomical Unit**; **Solar Flares**; **Solar Wind**; and **Sun (The)**.

The shock arises because solar wind particles are emitted from stars at about 400 km/s (248.5 mi/s), while their speed of sound is about 50 km/s (31 mi/s). (The exact speed depends on the density, which fluctuates considerably.) The interstellar medium, although very low in density, nonetheless has a constant pressure associated with it; the pressure from the solar wind decreases with the square of the distance from the star. As one moves far enough away from the star, the pressure from the interstellar medium becomes sufficient to slow the solar wind down to below its speed of sound; this causes a shock wave. See also **Interplanetary Medium**.

Evidence presented at a meeting of the American Geophysical Union in May 2005 by Dr. Ed Stone suggests that the Voyager 1 spacecraft passed termination shock (Fig. 1) in December 2004 by virtue of the change in magnetic readings taken from the craft. http://www.nasa.gov/vision/universe/solarsystem/voyager_agu.html

TERMITE *(Insecta, Isoptera)*. Also incorrectly known as the white ant, the termite is of large economic importance. Because of their wood-eating habits, termites sometimes do great damage to farm structures and storage buildings used in connection with food production. While highly destructive in this way, the termite is not injurious to crops or livestock. See Fig. 1. See also **Isoptera (Termites)**; and **Termitophile**.

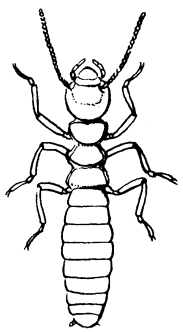

Fig. 1. Termite. (*USDA*.)

In recent years, some entomologists have given increased attention to the biology and physiology of the termite and, in particular, the presence of microorganisms in the termite, the sophisticated chemical defense mechanisms displayed by the termite, and the gaseous byproducts, including carbon dioxide, methane, and molecular hydrogen, generated by termites as a result of their metabolization of large amounts of biomass. These generous amounts of natural atmospheric pollutants are currently estimated to exceed the emissions, particularly of CO_2, from fossil-fired industrial plants.

Over a century ago, entomologists attributed the termite's ability to metabolize cellulose to enzymes synthesized by microorganisms in the insect's gut. This early observation has led to more recent investigations of the microorganisms present and to date at least one hundred species of protozoa and bacteria have been identified in the termite gut. The microscopic ecosystem of the termite has been found to be astonishingly complex. One group of investigators has used the desert termite (*Pterotermes occidentis*) in laboratory studies. This is a rather rare species of termite that lives by consuming the dead interior wood of several species of desert plant, including the saguaro cactus and the palo verde tree. The majority of microorganisms that inhabit the gut of this termite are found in the paunch of the insect (the third segment of its digestive tract). The population density of the protozoa found is between a thousand and a million individuals per milliliter of the gut fluid. In this same fluid are found millions to billions of bacteria that swim around freely in the chamber of the paunch. As yet, it has not been determined if the protozoa, the bacilli, or both participate in generating the termite's wood-digesting enzymes. Many of the microorganisms are anaerobic and cannot live outside the termite gut. It also has been suggested that the anaerobes may depend on bacteria that serve as oxygen scavengers and thus protect them from toxic concentrations. It has been found that several of the microorganisms are sensitive to the pH of the gut fluid.

As pointed out by Prestwich (1983), it is estimated that the insect world has used chemicals both to attract prey and to repel predators for over 100 million years. Insect predators attempt to subdue their prey with toxic venoms or to lure them with seductive perfumes. Some insect prey species take counter actions by ejecting irritating, sticky, hot, or poisonous substances or by themselves becoming inedible. The termite is considered exceptional in terms of its arsenal of chemical defenses. It has been suggested that the termite even outperforms the army ant in this respect. Like the cockroach, the termite has evolved over millions of years from an ancestral stock that is believed to resemble modern roaches. There are over 2000 species of termite in the world today, mostly in tropical regions. Much of this successful survival can be attributed to chemical defenses.

Belgian researchers have suggested three main methods of chemical defense used by the termite: (1) *biting* (introduction of oily or toxic substances into the wound); (2) *daubing* (as with a paintbrush) a predator with contact poison applied to the cuticle — some termite species have an enlarged labrum (upper lip) for this purpose; (3) *glue squirting* — spraying an irritating, viscous entangling agent. Like ants, bees, and many other insects, termite colonies are extremely well organized. For example, so-called solider termites carry over 500 times as much defensive chemicals as do other members of a colony who are devoted to food gathering and mound repair tasks. The most common raiders of termite colonies are ants. In one defense against the ant, the biting and daubing mechanisms are quite successful. When the ant's cuticle is punctured, a hydrocarbon (normally harmless) softens the wound, interfering with the coagulation of the ant's hemolymph and preventing the resclerotization (natural repair) of cuticle damage.

There is considerable variation in the types of chemicals synthesized by various termite species. Predominant, however, are diterpenes, quinones, and modified fatty acids. In research on numerous species of termite, investigators have encountered some surprises, particularly in terms of the concept of parallel evolution. Too detailed for coverage here, an excellent summary is given by Prestwich. An essentially answered question: How do termites protect themselves from the actions of their own toxic chemicals?

As reported by Zimmerman et al. (1982), termites may be a potentially large source of atmospheric methane, carbon dioxide, and molecular hydrogen. Termites occur on about two-thirds of the earth's land surface. They process large amounts of biomass. Their digestion is mainly dependent upon the anaerobic decomposition by symbiotic bacteria (higher termite family, *Termitidae*), and by protozoa (lower termites). Their digestion efficiency (carbon ingested less carbon in feces divided by carbon ingested) is usually greater than 60%. The clearing of tropical forests and conversion of forests to grazing and agriculture tend to increase the density of termites.

Early studies had indicated that termites could contribute more CO_2 to the atmosphere than the combustion of fossil fuels. Follow-up research in the late 1980s revised the estimate downward to a probable 2% contribution of CO_2 to the atmosphere by termites worldwide.

TERMITOPHILE. An insect of another form living in the nest of termites. Both ant and termite colonies are inhabited by other insects, some apparently living as scavengers and profiting by the supply of food and by the protection afforded by the colony while others produce secretions used by their hosts and so live in a commensal relationship. Even in the latter cases the termitophiles may eat the young of the termites, but since they render some return they are not to be regarded as parasitic on the colony. Some, however, are nourished by food supplied by the termites in return for the desired secretion. Insects of such habits are often very strangely formed, differing conspicuously from other members of the orders to which they belong.

Among the known termitophiles are flies, larvae of moths, one species of *Homoptera*, and many beetles.

TERN. See **Waders, Shorebirds, and Gulls**.

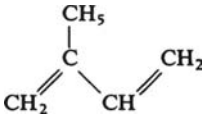
TERNE. See **Tin**.

TERPENE ALCOHOL. A generic name for an alcohol related to or derived from a terpene hydrocarbon, such as terpineol or borneol.

See also **Terpenes and Terpenoids**.

TERPENELESS OIL. An essential oil from which the terpene components have been removed by extraction and fractionation, either alone or in combination. The optical activity of the oil is thus reduced. The terpeneless grades are much more highly concentrated than the original oil (15–30 times). Removal of terpenes is necessary to inhibit spoilage, particularly of oils derived from citrus sources. On atmospheric oxidation the specific terpenes form compounds that impair the value of the oil; for example, *d*-limonene oxidazes to carvone and γ-terpinene to *p*-cymene. Terpeneless grades of citrus oils are commercially available. See also **Terpenes and Terpenoids**.

TERPENES AND TERPENOIDS. [CAS: 68956-56-9]. The class of organic compounds known as terpenes is characterized by the presence of the repeating carbon skeleton of isoprene:



These compounds are widely distributed in nature. The name *terpene* used properly refers to the hydrocarbons which are exact multiples of the skeletal isoprene unit. However the name "terpene," sometimes used loosely, includes not only hydrocarbons but also other functional types of naturally occurring organic compounds which contain the reoccurring isoprene skeleton. In the strictest sense, the names *terpenoid* or *isoprenoid* should be used instead of the more loosely applied usage of terpene.

Terpenoids are divided into subclasses as follows:

Subclass name	No. of carbon atoms	No. of isoprene skeletal units
Hemiterpenoids	C_5	1
Monoterpenoids	C_{10}	2
Sesquiterpenoids	C_{15}	3
Diterpenoids	C_{20}	4
Sesterterpenoids	C_{25}	5
Triterpenoids	C_{30}	6
Tetraterpenoids	C_{40}	8
Polyterpenoids	$(C_5)^n$	n

Together they possess a wide variety of functional groups and structures. Nearly every common functional group is represented. Acyclic, monocyclic and polycyclic structures are observed. The greatest structural variation within a single subclass is to be found among sesquiterpenoids.

The combination of skeletal isoprene units in a regular fashion was exemplified early in the study of terpenoids by nearly all of these compounds. On the basis of this regularity the *regular isoprene rule* was formulated and was taken to mean that terpenoids would possess structures built from a regular "head-to-tail" arrangement of isoprene units. However, as structures of more terpenoids were elucidated, departures from the regular rule were observed. In time "irregular" structures were also accommodated through postulated rearrangement of a regular isoprenoid chain to the "irregular" isoprene skeleton. Rearrangements could occur subsequent to or concommitant with natural cyclization. Thus, the adaptation of the *regular isoprene rule* now finds expression in the *biogenetic isoprene rule*, a rule which is supported experimentally. Particularly significant examples of naturally occurring compounds conforming to the biogenetic isoprene rule are lanosterol, a triterpenoid alcohol associated with cholesterol in wool fat, and gibberelic acid, an important plant-growth regulating substance which is the product of a diterpenoid precursor.

The various terpenoid subclasses are not equally distributed in nature. Representatives of the low-molecular weight end of the terpenoid spectrum are seldom encountered as stable isolable natural products. Isoprene itself has not been detected in plants or animals, but the existence of two highly reactive hemiterpenoid substances in living cells is well established. These are the isomeric γ, γ-dimethylallyl pyrophosphate and isopentenyl pyrophosphate, the two being ubiquitous in living organisms and represent the fundamental isoprene building block in terpenoid biogenesis. One source of evidence for the existence of these hemiterpenoids is the presence of the γ, γ-dimethylallyl unit as a substituent of other classes of natural products, often phenols. The origin of these truly vital hemiterpenoids has been found to be mevalonic acid (3,5-dihydroxy-3-methylpentonoic acid), a six-carbon acid produced by the coenzyme A-assisted condensation of three moles of acetic acid. Decarboxylation and dehydration of mevalonic acid pyrophosphate are known to give the five-carbon unit of isopentenyl pyrophosphate. Isopentenyl pyrophosphate and γ, γ-dimethylallyl pyrophosphate are not only the links between the various subclasses of terpenoids but also biogenetically connect seemingly unrelated plant constituents such as steroids and some types of phenolics and alkaloids.

Monoterpenoids and to a lesser extent sesquiterpenoids are the chief components of the volatile oils readily obtained by the distillation of leaves, wood, and blossoms of a broad array of plants. Sesquiterpenoids are among the most universally distributed natural products. Iridolactone, a monoterpenoid, occurs as a defensive secretion of an ant species belonging to the genus *Iridomyrmex*. The iridoids, which is the general name given to the structural type exemplified by iridolactone, make up an important group of monoterpenoids. Another representative of this group is loganin which along with the amino acid tryptophan provides the carbon atoms of a group of indole alkaloids. Medically important quinine and reserpine are members of this group of alkaloids. The "resin acids" are a group of diterpenoid carboxylic acids which form the major nonvolatile part of natural resins often obtained from conifers. Examples are abietic, pimaric and isopimaric acids. Sesterterpenoids, the most recently discovered terpenoid subclass, are produced by insects and fungi. The tricyclic cereoplasteric acid has been isolated from the waxy coating secreted by the insect *Cereoplastes albolineatus*. The fungus responsible for the leaf spot disease in corn produces the acyclic geranylnerolidol and the tricyclic ophiobola-7, 18-dien-3α-ol. Triterpenoids are found mainly in plants where they occur in resins and plant sap as free triterpenoids, esters or glycosides. A few are observed in animal sources, for example, the acyclic squalene and the tricyclic lanosterol. The connection between squalene and lanosterol is a vitally important one since these two triterpenoids, along with the hemiterpenoid isopentenyl pyrophosphate, are intermediates in the mevalonic acid based biogenesis of steroids. Tetraterpenoids are frequently referred to as *carotenoids*. These constitute a group of natural pigments containing long systems of conjugated carbon-carbon double bonds which are responsible for their color. β-Carotene is the principal pigment of the carrot but this pigment has been isolated from other plant sources also. See also **Carotenoids**. Finally the presence of polyisoprenoids (natural rubber and gutta-percha) in nature shows that the isoprene unit, like the simple sugar and amino acids, has been used to form linear macromolecules.

The use of terpenoids, usually as mixtures prepared from plants, dates from antiquity. The several "essential oils" produced by distillation of plant parts contained the plant "essences." These oils have been employed in the preparation of perfumes, flavorings, and medicinals. Examples are: oils of clove (local anesthetic in toothache), lemon (flavoring), lavender (perfume), and juniper (diuretic). Usually essential oil production depends on a simple technology which often involves steam distillation of plant material. The perfume industry of Southern France uses somewhat more sophisticated procedures in the isolation of natural flower oils since these oils are heat sensitive. The separation of oils from citrus fruit residues in California and Florida is done by machine.

The oleoresinous exudate or "pitch" of many conifers, but mainly pines, is the raw material for the major products of the naval stores industry. The oleoresin is produced in the epithelial cells which surround the resin canals. When the tree is wounded the resin canals are cut. The pressure of the epithelial cells forces the oleoresin to the surface of the wound where it is collected. The oleoresin is separated into two fractions by steam distillation. The volatile fraction is called "gum turpentine" and contains chiefly a mixture of monoterpenes but a smaller amount of sesquiterpenes is present also. The nonvolatile "gum rosin" consists mainly of the diterpenoid resin acids and smaller amounts of esters, alcohols and steroids. "Wood turpentine," "wood rosin" and a fraction of intermediate volatility, "pine oil" are obtained together by gasoline extraction of the chipped wood of old pine stumps. "Pine oil" is largely a mixture of the monoterpenoids terpineol, borneol and fenchyl alcohol. "Sulfate turpentine" and its nonvolatile counterpart, "tall oil," are isolated as by-products of the kraft pulping process. "Tall oil" consists of nearly equal amounts of saponified fatty acid esters and resin acids.

Turpentine is used in syntheses by the chemical and pharmaceutical industries. It also is used as a paint thinner and as a component of polishes and cleaning compounds. Pine oil finds application as a penetrant, wetting agent and preservative, especially by the textile and paper industries, and as an inexpensive deodorant and disinfectant in specialty products. The resin acids are used in the production of ester gum, "Glyptal" resins and are indispensable in paper sizing.

A few individual terpenoids, as well as less expensive mixtures of these compounds, find practical applications. Some examples are: the diterpenoid Vitamin A, the sesquiterpenoid santonin (as an anthelmintic), and the pyrethrins, pyretholone esters of the monoterpenoid chrysanthemic acid (used as an insecticide). A number of sesquiterpenoid lactones of the germacranolide, guaianolide and elemanolide types have shown promise as tumor inhibitors.

The different terpenoid content of plants has served as a finger printing method helpful in botanical identification, especially in cases where differentiation by morphological characteristics has failed. The striking difference in the chemotaxonomy of Jeffery and ponderosa pines serves as an example. The turpentine from the former species consists almost entirely of the paraffinic hydrocarbon *n*-heptane. Turpentine from ponderosa pine consists largely of the monoterpenes β-pinene and Δ^3-carene.

Besides being of considerable biochemical and botanical interest and of importance in the industrial arts, the food, perfumary, and pharmaceutical trades, the terpenoids have been also a continuing challenge to the organic chemist. The earliest work on the volatile oils was very difficult since the oils were usually complex mixtures and as a consequence individual compounds were isolated as liquids of uncertain purity. Physical constants such as molecular refraction and melting points of solid derivatives, especially those from which the compound could be regenerated were of importance in structural investigations. Organic chemistry relied heavily on oxidative degradation techniques. Dehydrogenation of cyclic terpenoids to aromatic systems and the synthesis of these aromatics played an important role in structure determination. In recent times much of the previous difficulty of obtaining pure samples of terpenoids has been overcome through the use of various chromatographic techniques. Gas-liquid phase chromatography has been used to good advantage in separating both microgram quantities and much larger amounts of the more volatile monoterpenoids and sesquiterpenoids. Much of the type of information formerly obtained only be degradative procedures and dehydrogenations can now be obtained through mass spectrometry. Through nuclear magnetic resonance, infrared and ultraviolet spectrometry, structural information can be obtained in a small fraction of the time that was formerly needed to gain the same amount of information.

Acid-promoted cyclization of acylic terpenoids is common. Geraniol, or more readily its trans isomer nerol, can be cyclized with acids to *p*-menthane derivatives. More importantly, citral, 2,6-dimethyl-2-octen-8-al, when condensed with acetone gives pseudoionone. The latter when cyclized with acid gives a mixture of α- and β-isomers which in turn are used in the preparation of perfumes, as an intermediate in a number of industrial syntheses of Vitamin A, and also in a commercial synthesis of the plant hormone abscisic acid. Polyclic terpenoids are prone to rearrangement of the carbon skeleton. The acid catalyzed rearrangement of the monoterpene camphene to derivatives of isobornyl alcohol are well known and have been the subject of extensive theoretical studies. Diterpenoids and triterpenoids undergo "backbone" rearrangement through the migration of hydride and methyl groups. Frequently these migrations are stereospecific and are acid promoted.

Studies of terpenoid chemistry have also involved syntheses. Several of the complex sesquiterpenoid structures have been confirmed or, in some cases, correctly established through synthesis. Many elegant new general synthetic methods have been developed as a result of attempts to synthesize terpenoids. The chemistry of terpenoids present a continually growing area of chemical research, perhaps the equal of any in complexity, subtlety, and variety.

TERRAPIN *(Reptilia, Chelonia)*. Certain of the pond and land turtles, especially those of the genera *Malaclemmys* and *Pseudemys*. The related genus *Terrapene* includes the box turtles, and the common painted turtles are also closely connected forms. Sale of painted turtles in the United States has been outlawed for reasons of health — the turtles being considered as carriers of dangerous microorganisms. The species whose flesh is so highly esteemed is the diamond-back terrapin or salt-marsh turtle found in salt marshes along the Atlantic coast from Massachusetts to Florida. This and a related species of the Gulf coast make up the genus *Malaclemmys*. The species of *Pseudemys* are commonly called sliders or cooters, one species bearing the name red-bellied terrapin. They are edible but are less highly valued than the diamond-back. Terrapins are widely distributed in the northern hemisphere. Elsewhere they are limited to a few species in Central and South America.

TERRA SATELLITE (EOS AM-1). Earth's 4.5 billion year history is a study in change. Natural geological forces have been rearranging the surface features and climatic conditions of our planet since its beginning. Today, there is compelling scientific evidence that human activities have attained the magnitude of a geological force and are speeding up the rates of global changes. For example, carbon dioxide levels have risen 30 percent since the industrial revolution and about 40 percent of the world's land surface has been transformed by humans.

Scientists do not understand the cause-and-effect relationships among Earth's lands, oceans, and atmosphere well enough to predict what, if any, impacts these rapid changes will have on future climate conditions. Scientists need to make many measurements all over the world, over a long period of time, in order to assemble the information needed to construct accurate computer models that will enable them to forecast the causes and effects of climate change. The only feasible way to collect this information is through the use of space-based Earth "remote sensors" (instruments that can measure things like temperature from a distance). Consequently, NASA's Earth Science Enterprise has begun an international study of planet Earth that is comprised of three main components: 1) an Earth Observing System (EOS), consisting of a fleet of satellites specially designed to study the complexities of global change; 2) an advanced computer network for processing, storing, and distributing data (called EOSDIS); and 3) teams of scientists all over the world who will study the data. See also **Earth Observing System (EOS)**.

Terra is a multi-national NASA scientific research satellite in a sun-synchronous orbit around the Earth. It is the flagship of the Earth Observing System (EOS). The name "Terra" comes from the Latin word for earth. The satellite was launched from Vandenberg Air Force Base, California on December 18, 1999 aboard an Atlas IIAS launch vehicle. On February 24, 2000, Terra began collecting a new 18-year global data set on which to base future scientific investigations about our complex home planet.

EOS Terra Spacecraft

Physically, the EOS Terra spacecraft is roughly the size of a small school bus. It carries a payload of five state-of-the-art sensors that will study the interactions among the Earth's atmosphere, lands, oceans, and radiant energy (heat and light). Each sensor has unique design features that will enable EOS scientists to meet a wide range of science objectives.

EOS Terra will orbit the Earth from pole to pole, descending across the equator in the morning when cloud cover is minimal and its view of the surface is least obstructed. See also http://earthobservatory.nasa.gov/Library/AM1/Anim/am_godview.mov. The satellite's orbit will be perpendicular to the direction of Earth's spin, so that the viewing swaths from each overpass can be compiled into whole global images. See also http://earthobservatory.nasa.gov/Library/AM1/Anim/spacewindow.mov. Over time, these global images will enable scientists to show and tell the stories of the causes and effects of global climate change.

The sensors on EOS Terra will not actively scan the surface (such as with laser beams or microwave pulses). Rather, the sensors work much like a camera. Sunlight that is reflected by Earth, and heat that is emitted from Earth, will pass through the apertures of Terra sensors. See also http://earthobservatory.nasa.gov/Library/AM1/Anim/am_reflect2.mov. This radiant energy will then be focused onto specially designed detectors

that are sensitive to selected regions of the electromagnetic spectrum, ranging from visible light to heat. The information produced by these detectors will then be transmitted back to Earth and processed by computers into images that one can interpret.

The five Terra onboard sensors are: **ASTER**, or Advanced Spaceborne Thermal Emission and Reflection Radiometer; **CERES**, or Clouds and Earth's Radiant Energy System; **MISR**, or Multi-angle Imaging Spectroradiometer; **MODIS**, or Moderate-resolution Imaging Spectroradiometer; and **MOPITT**, or Measurements of Pollution in the Troposphere.

The life expectancy of the EOS Terra mission is six years. It will be followed in later years by other EOS spacecraft that take advantage of new developments in remote sensing technologies.

Terra Instruments

Aster. The Advanced Spaceborne Thermal Emission and Reflection Radiometer obtains high-resolution (15 to 90 square meters per pixel (162 to 969 square feet per pixel) images of the Earth in 14 different wavelengths of the electromagnetic spectrum, ranging from visible to thermal infrared light. Scientists use ASTER data to create detailed maps of land surface temperature, emissivity, reflectance, and elevation.

ASTER is the only high spatial resolution instrument on the Terra platform. ASTER's ability to serve as a 'zoom' lens for the other Terra instruments is particularly important for change detection, calibration/validation and land surface studies. Unlike the other instruments aboard Terra, ASTER will not collect data continuously; rather, it will collect an average of 8 minutes of data per orbit. All three ASTER telescopes (VNIR, SWIR, and TIR) are pointable in the crosstrack direction. Given its high resolution and its ability to change viewing angles, ASTER will produce stereoscopic images and detailed terrain height models.

The ASTER instrument was built in Japan for the Ministry of Economy, Trade and Industry (METI). A joint United States/Japan Science Team is responsible for instrument design, calibration, and data validation.

CERES (Clouds and the Earth's Radiant Energy System). There are two identical CERES instruments aboard Terra that measure the Earth's total radiation budget and provide cloud property estimates that enable scientists to assess clouds' roles in radiative fluxes from the surface to the top of the atmosphere. One CERES instrument will operate in a cross-track scan mode and the other in a biaxial scan mode. The cross-track mode will essentially continue the measurements of the Earth Radiation Budget Experiment (ERBE) mission as well as the Tropical Rainfall Measuring Mission (TRMM), while the biaxial scan mode will provide new angular flux information that will improve the accuracy of angular models used to derive the Earth's radiation balance.

Each CERES instrument has three channels — a short-wave channel for measuring reflected sunlight, a longwave channel for measuring Earth-emitted thermal radiation in the 8-12 μm "window" region, and a total channel for total radiation. Onboard calibration hardware includes a solar diffuser, a tungsten lamp system with a stability monitor, and a pair of blackbody sources. Cold space and internal calibration looks are performed during each normal Earth scan.

CERES is a Principal Investigator instrument provided by NASA and managed by NASA's Langley Research Center (LaRC) in Hampton, Virginia. The instrument was built by TRW in Redondo Beach, California.

MISR or (Multi-Angle Imaging Spectro-Radiometer). No instrument like MISR has flown in space before. Viewing the sunlit Earth simultaneously at nine widely spaced angles, MISR provides ongoing global coverage with high spatial detail. Its imagery is carefully calibrated to provide accurate measures of the brightness, contrast, and color of reflected sunlight.

Most satellite instruments look only straight down, or toward the edge of the planet. To fully understand Earth's climate, and to determine how it may be changing, it is necessary to know the amount of sunlight that is scattered in different directions under natural conditions. MISR is a new type of instrument designed to address this need — it will view the Earth with cameras pointed at nine different angles. One camera points toward nadir, and the others provide forward and aftward view angles, at the Earth's surface, of 26.1°, 45.6°, 60.0°, and 70.5°. As the instrument flies overhead, each region of the Earth's surface is successively imaged by all nine cameras in each of four wavelengths (blue, green, red, and near-infrared). See Fig. 1.

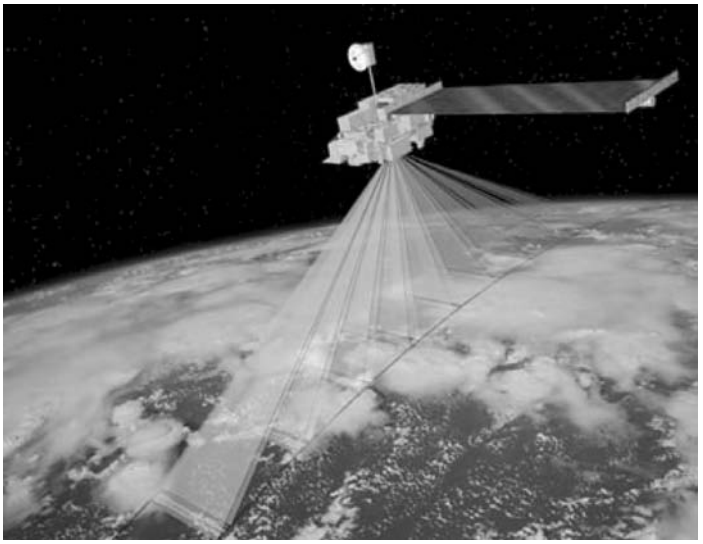

Fig. 1. This computer-generated image shows the Terra spacecraft, with the MISR instrument on board, orbiting Earth. Direction of flight is toward the lower left. The actual locations imaged by the 9 cameras, each with 4 color bands, along Earth's surface are illustrated here with translucent surfaces. (Image courtesy of Shigeru Suzuki and Eric M. De Jong, Solar System Visualization Project.JPL image P-49081)

MISR provides new types of information for scientists studying Earth's climate, such as the partitioning of energy and carbon between the land surface and the atmosphere, and the regional and global impacts of different types of atmospheric particles and clouds on climate. The change in reflection at different view angles affords the means to distinguish different types of atmospheric particles (aerosols), cloud forms, and land surface covers. Combined with stereoscopic techniques, this enables construction of 3-D models and estimation of the total amount of sunlight reflected by Earth's diverse environments.

MODIS (Moderate-Resolution Imaging Spectroradiometer). With its sweeping 2,330-kilometer-wide (1,448 mile) viewing swath, MODIS sees every point on the world every 1-2 days in 36 discrete spectral bands. Consequently, MODIS greatly improves upon the heritage of the NOAA Advanced Very High Resolution Radiometer (AVHRR) and tracks a wider array of the earth's vital signs than any other Terra sensor. See Fig. 2. For instance, the sensor measures the percent of the planet's surface that is covered by clouds almost every day. This wide spatial coverage will enable MODIS, together with MISR and CERES, to determine the impact of clouds and aerosols on the Earth's energy budget. The sensor has an unprecedented channel (centered at 1.375 microns) for detection of wispy cirrus clouds — believed to contribute to global warming by trapping heat emitted from the surface. Conversely, cumulus clouds and aerosols are thought to have a cooling effect on the Earth's surface by reflecting and absorbing incoming sunlight. Which effect on climate will prove greater in the long run? MODIS, together with MISR and CERES, will help answer that question.

Note: The scene was made by combining three of the visible bands of the MODIS Land Surface Reflectance product. (Image courtesy of MODIS instrument team, NASA Goddard Space Flight Center.)

MODIS is ideal for monitoring large-scale changes in the biosphere that will yield new insights into the workings of the global carbon cycle. While no current satellite sensor can directly measure carbon dioxide concentrations in the atmosphere, MODIS can measure the

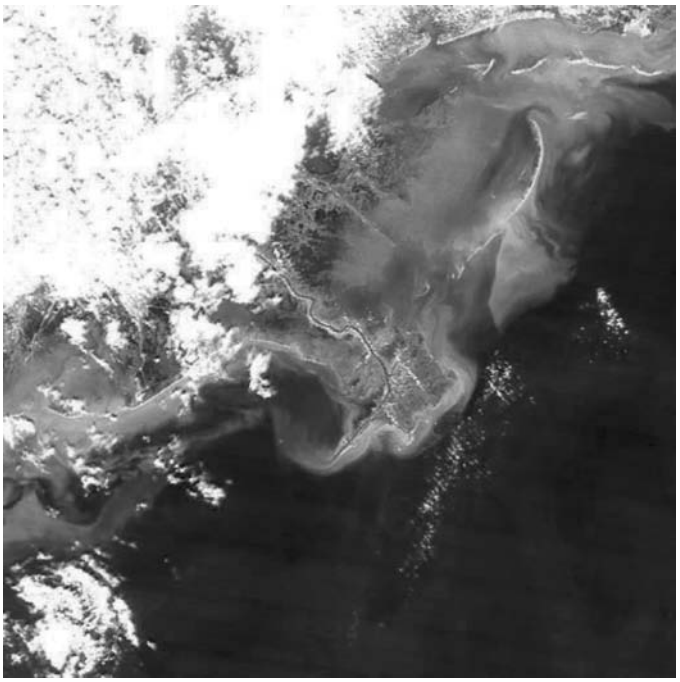

Fig. 2. This image of the Mississippi Delta was acquired on February 24, 2000 and is one of the first scenes acquired by the Moderate resolution Imaging Spectroradiometer (MODIS) on the EOS-Terra Spacecraft. It covers an area of 100km by 100km (62 by 62 miles) over New Orleans, Louisiana and the Gulf of Mexico. Some features clearly visible on the image are: the classic bird's foot shape of the Mississippi River's channels in the delta; sediment plumes around the delta and between the barrier islands north of it; and differences in ocean color between the shallow bays behind the barrier islands and the open waters of the Gulf of Mexico

photosynthetic activity of land and marine plants (phytoplankton) to yield better estimates of how much of the greenhouse gas is being absorbed and used in plant productivity. Coupled with the sensor's surface temperature measurements, MODIS' measurements of the biosphere are helping scientists track the sources and sinks of carbon dioxide in response to climate changes.

Almost every day over the entire globe, the sensor monitors changes on the land surface, thereby building upon and extending the heritage begun by Landsat. MODIS maps the areal extent of snow and ice brought by winter storms and frigid temperatures. The sensor observes the "green wave" that sweeps across continents as winter gives way to spring and vegetation blooms in response. It sees where and when disasters strike — such as volcanic eruptions, floods, severe storms, droughts, and wildfires — and will hopefully help people get out of harm's way. MODIS' bands are particularly sensitive to fires; they can distinguish flaming from smoldering burns and provide better estimates of the amounts of aerosols and gases fires release into the atmosphere.

MODIS sees changes in the Pacific phytoplankton populations that may signal the onset of the famous El Niño/La Niña climatic siblings well ahead of their arrival. In turn, by coupling its sea surface temperature and ocean color measurements, MODIS will observe the impacts El Niño and La Niña have on the microscopic marine plant. While these measurements extend and build upon the heritage of the Coastal Zone Color Scanner and, MODIS also has a unique new channel for measuring chlorophyll fluorescence. All plants bombarded with light begin to glow, or fluoresce, but in wavelengths that our eyes cannot see. The more plants fluoresce, the less energy they are using for photosynthesis. Thus, MODIS not only maps the distribution of phytoplankton, it also helps us gauge its health.

MOPITT (Measurement of Pollution in the Troposphere). MOPITT is an instrument designed to enhance our knowledge of the lower atmosphere and to particularly observe how it interacts with the land and ocean biospheres. Its specific focus is on the distribution, transport, sources, and sinks of carbon monoxide and methane in the troposphere. Methane is a greenhouse gas with nearly 30 times the heat-trapping capacity of carbon dioxide; it is known to leak from swamps, livestock herds, and biomass burning, but the total output from these individual sources is unknown. Carbon monoxide, which is expelled from factories, cars, and forest fires, hinders the atmosphere's natural ability to rid itself of harmful pollutants.

MOPITT is the first satellite sensor to use gas correlation spectroscopy. The sensor measures emitted and reflected radiance from the Earth in three spectral bands. As this light enters the sensor, it passes along two different paths through onboard containers of carbon monoxide and methane. The different paths absorb different amounts of energy, leading to small differences in the resulting signals that correlate with the presence of these gases in the atmosphere.

MOPITT's spatial resolution is 22 kilometers (13.7 miles) at nadir and it 'sees' the Earth in swaths that are 640 kilometers (398 miles) wide. Moreover, it can measure the concentrations of carbon monoxide in 5-kilometer (3 mile) layers down a vertical column of atmosphere, to help scientists track the gas back to its sources.

TERRESTRIAL SCINTILLATION. Generic term for scintillation phenomena observed in light that reaches the eye from sources lying within the Earth's atmosphere; to be differentiated from astronomical scintillation, which is observed in light from extraterrestrial sources such as stars. Also called *atmospheric boil*, *atmospheric shimmer*, *shimmer*, or *optical haze*. Terrestrial scintillation is produced by irregular refraction effects due to passage, across the line of sight, of air parcels (schlieren) whose densities differ slightly from that of their surroundings. Density irregularities with dimensions of the order of centimeters, or at most decimeters, are responsible for most such scintillatory effects.

TERTIARY. The first period of the Cenozoic era (after the Cretaceous of the Mesozoic era and before the Quaternary), believed to have covered the span of time between 65 million and 3 to 2 million years ago. The Tertiary is divided into five epochs; the Paleocene, Eocene, Oligocene, Miocene, and Pliocene. The name was originally assigned as an era rather than a period designation. In this latter sense, it may be considered to have either four periods (Eocene, Oligocene, Miocene, Pliocene), or two (Paleogene and Neogene), with the Pleistocene and Holocene included in the Neogene.

TESLA COIL. Essentially an air-core transformer used in connection with a spark gap and capacitor to produce a high voltage at a high frequency.

TESTING (Blood). See **Blood**.

TESTING (Chemical). Identification of a substance by means of reagents, chromatography, spectroscopy, melting and boiling point determination, etc.

See also **Analysis (Chemical)**.

TESTING (Fuels). See **Calorimetry**; **Coal**; and **Petroleum**.

TESTING (Impact). See **Impact Testing**.

TESTING (Physical). Application of any procedure whose object is to determine the physical properties of a material. There are four major categories of tests: (1) Those that are direct measurements of a property, e.g., tensile strength. (2) Those that subject the material to actual service conditions; these often require a long period of time, e.g., shelf life of foods and corrosion of metals. (3) Accelerated tests, which require specially designed equipment that simulates service conditions on an exaggerated scale; in these, only a few hours are necessary to duplicate years of service life, e.g., oxygen bomb aging of elastomers. (4) Nondestructive testing by N-ray of radiography. Elaborate standard testing procedures are established by the American Society for Testing and Materials: http://www.astm.org.

The more common types of tests are as follows:

- Abrasion (elastomers, textiles).
- Adhesion (glues, resins).
- Aging (elastomers, plastics, leather, food products).
- Color stability (pigments, organic dyes) (exposure).
- Corrosion (metals, alloys) (exposure).
- Dielectric (electrical tapes, plastics, glass).
- Flammability (textiles, fibers, paper, plastics).
- Flash point of combustible liquids (Tag closed cup TCC, Cleveland open cup COC, open cup OC.
- Hardness (metals, elastomers, plastics) (Brinell, Rockwell, Shore penetration).
- High temperature (elastomers, adhesives).
- Impact strength (composites, glass cement).
- Sun-cracking (paints, varnishes, elastomers) (exposure).
- Tear (paper, rubber, textiles).
- Tensile strength (fibers, elastomers, paper, textiles, metals).
- Viscosity (lubricants) (Saybolt, Engler).

See also **Nondestructive Testing (NDT)**.

TESTING (Physiological). Determination of the toxicity of a substance or product by administering it to laboratory animals in controlled dosages, by mouth, skin application, or injection. Materials commonly subjected to such evaluation are pharmaceuticals, pesticides, and foods. Extensive testing programs are required before such products are approved for human use.

TESTOSTERONE. See **Gonads**; **Hormones**; and **Steroids**.

TEST PATTERN. In television, a special chart on which lines and other detail are arranged to indicate certain characteristics of the system through which the television signal obtained from this chart passes.

TESTUDINATA. The turtle and tortoises, constituting an order of the class *Reptilia*, also known as the order *Chelonia*. These animals have a short broad body enclosed in a shell composed, in most species, of closely joined bony plates covered with thin plates of horn or tortoise shell. The bony plates are flattened ribs and vertebrae, with supplementary dermal plates. The upper part of the shell is the carapace and the plate below the body is the plastron; the two are firmly united along the sides in most species. The skin is covered with scales and the jaws are without teeth, forming a horn-sheathed cutting beak.

Most species of the order are partially aquatic but some are strictly terrestrial. The marine turtles are the most thoroughly aquatic species, but even they come to shore to lay their eggs. These species have all four limbs developed as paddlelike flippers while the other members of the group merely have webbed toes.

TETANUS. A serious, often life-threatening disease caused by neurotoxin (*tetanospasmin*) generated by the anaerobic, Gram-negative bacillus *Clostridium tetani* which occurs in soil and in the intestines of domestic animals. Spores of the organism can also be recovered from clothing, house dust, and even the air of occupied buildings, such as hospitals. These and/or the *Clostridia* are introduced into the human body by way of penetrating wounds in which deep layers of tissue are punctured and exposed. When the spores multiply and spread, they generate two toxins, *tetanospasmin* and *tetanolysin*. Only the former has clinical effects, reaching the spinal cord and brain by blood spread and retrograde axon transport along peripheral nerves. The toxin interferes with the normal control of reflexes and muscle spasms result. These spasms vary in accordance with the relative strengths of opposing muscles. Thus, a spasm may produce an extension of hips and knees, flexion of the biceps, and/or *trismus* (lockjaw). Early symptoms of the disease are pain associated with muscle spasms, restlessness, stiffness (back, neck, thighs, abdomen), difficulty in opening the mouth (this being the first symptom in over half of cases). There also may be difficulty in swallowing. The early phase of the disease, with all or some of the foregoing symptoms, has a duration of about 72 hours, after which a phase known as general tetanus takes place. In persons who recover from the disease, this general phase will persist for about one week, during which time there are violent muscular spasms, although the patient retains consciousness. A sneering facial expression (*risus sardonicus*) may develop. Usually any sudden stimulus (bright light, loud noise) will stimulate what is known as a *tonic seizure*. The fever may rise to 101–102 °F (38.3–38.9 °C). Laryngeal spasm is the most dramatic and perhaps the most dangerous event in tetanus. Airway obstruction compromises gaseous exchange or renders it impossible; cyanosis occurs and death follows if the spasm does not pass off or is relieved by treatment. After a peaking of the general tetanus phase, several weeks are required for full recovery, during which time respiratory assistance is usually needed for 2 to 4 weeks. The patient usually is hospitalized for a total of 5–8 weeks.

Diagnosis of tetanus is usually not difficult because of the rapid progress of the disease and its specific early symptoms. Acute strychnine poisoning is the only disease with very similar symptoms. Trismus alone, however, is not fully confirmative of tetanus because this also occurs in encephalitis. There is an immediate differentiation observed, however, in that the person with tetanus usually remains conscious even during violent spasms, whereas in encephalitic trismus, most patients will be comatose. Trismus also can be produced by certain drugs, to which some individuals are particularly sensitive. These include phenothiazine. Trismus in such instances is called the *grimacing syndrome*.

Respiratory and cardiovascular complications may arise during the course of the disease and fractures may occur through frequency and severity of muscular spasms.

In the treatment of tetanus, the physician has three major objectives: (1) the prevention of further violent muscle spasms and the dangerous consequences which these pose, particularly as regards breathing; (2) the prevention of respiratory complications and preparing to handle such when they arise (tracheotomy, for example); and (3) slowing the source of the toxin. Muscle relaxants are used in conjunction with sedatives to control spasms and tonic seizures. The usual drug of choice is diazepam (Valium®) because of its rapid action. When spasms do not respond fully to this therapy, very strong neuromuscular blocking agents, such as *d*-Turbocurarine or pancuronium, may be required. This procedure of inducing muscle relaxation and of inducing, depending upon dosage, partial, temporary paralysis, is referred to as *curarization* (curare = *a* toxic mixture of about 40 alkaloids occurring in several species of South American trees with powerful action on the nervous system). Where facilities are available, the total paralysis regimen is now the method of choice for treating patients with severe tetanus. Hypertension, tachycardia, and profuse sweating brought on by overactivity induced by the disease are sometimes treated with a beta-adrenergic blocking drug, such as propranolol. Rarely is the intravenous use of morphine required. To provide an adequate airway, nasotracheal intubation will be used. In some cases, tracheostomy is required. Morbid anatomical lesions do not explain all deaths in tetanus, but the respiratory system is involved

in most cases treated conservatively. Overwhelming tetanus intoxication of the brainstem is another important factor. Although antibiotics have not been proved to assist in the treatment of tetanus in a direct way, they are sometimes administered to reduce possible infection by other microorganisms as the result of tissue damaged by the *C. tetant* toxins. Although tetanus antitoxin apparently does not neutralize toxin already present in the nervous system of the patient, antitoxin can reduce the quantity of circulating toxin. Available in the United States and some other countries is human tetanus immune globulin, which is better tolerated than equine antiserum and has a longer effective life. Active immunization with toxoid is the surest way of preventing tetanus. If proof is required, the high death rate from tetanus in World War I when active immunization was not practiced should be compared with the virtual absence of the disease in World War II when immunization with toxoid was routine. After undertaking emergency medical treatment in the early phase of the disease, the physician will, of course, take prompt action in debriding and prophylaxis of the wound.

TETANY. See **Parathyroid Glands**.

TETHERED BALLOON. A positively buoyant unmanned balloon attached to a cable that is used to raise and lower the balloon. Instrument packages are suspended from the balloon to measure characteristics such as air temperature, winds, humidity, refractive index, trace gases, and aerosols as functions of time (by keeping the height constant) or height (by raising and lowering the balloon). They have been used for measuring both mean values and turbulent fluctuations. Balloon heights of over a kilometer have been reached, and instrument packages are sometimes deployed at more than one height below the balloon. Tethered balloons have been deployed from fixed locations over land and from ships.

TETHERED SATELLITE SYSTEM (TSS) MISSION. See **Space Science Missions: Sun**.

TETRACHORIC CORRELATION. If a bivariate normal distribution is dichotomized according to each variable, the value of ρ, the correlation coefficient, is uniquely determined by the proportions falling into the four resulting categories. If an observed 2×2 contingency table is regarded as having arisen in this way, an estimate of ρ can be obtained, using Tables of the bivariate normal distribution. Such an estimate is called a *tetrachoric correlation*.

TETRADIC. A dyadic converts a vector into another vector and a tetradic converts a dyadic into another dyadic. Thus, if ϕ and ψ are dyadics, the tetradic with 81 components can be represented by the Hebrew character (gimel) and $\psi =: \phi$. The components of the tetradic require four subscripts, while only two are needed for the dyadics. The relation between various components is

$$\psi_{ij} = \sum_{k,l} G_{ijkl}\phi_{kl}$$

An indemfactor, a unit tetradic, a conjugate, etc., can be defined as for a dyadic. These operators can be applied to the study of stress and strain in nonisotropic solids. See also **Dyadic**.

TETRADYMITE. A mineral, bismuth tellurium sulfide, corresponding to the formula Bi_2Te_2S. It is rhombohedral. Tetradymite occurs usually in gold quartz veins. It is found in Norway, Sweden, England, Bolivia, British Columbia; and in the United States, in Virginia, North Carolina, Georgia, Montana, Colorado, and elsewhere. It derives its name from the Greek word meaning fourfold, in reference to the double twin crystals occasionally developed.

TETRAHEDRITE. A mineral of the composition, $(Cu, Fe)_{12}As_4S_{13}$, isomorphous with tennantite. The color ranges from steel-gray to iron-black. The mineral frequently contains cobalt, lead, mercury, nickel, silver, or zinc in replacement of the copper. Tetrahedrite usually occurs in tetrahedral crystals associated with copper ores. The mineral is considered an important copper ore and sometimes is a valuable ore for silver. The mineral sometimes is referred to as *fahlore, gray copper ore*, and *stylotypite*.

TETRAHEDRON. See **Polyhedron**.

TEXT FILES. See **File Types**.

THALAMUS. See **Central and Peripheral Nervous Systems**.

THALLIUM. [CAS: 7440-28-0]. Chemical element symbol Tl, at. no. 81, at. wt. 204.38, periodic table group 3, mp 303.5 °C (578 °F), bp 1447–1467 °C (2637-2672 °F), density 11.85 g/cm^3 (20 °C (68 °F). Elemental thallium has a hexagonal close-packed crystal structure normally, but also exhibits a face-centered cubic crystal structure.

Thallium metal is bluish-gray upon fresh exposure, changing to dark gray on standing, this oxidation increased with temperature above 25 °C (77 °F); soft, and may be easily cut with a knife. It is malleable but of low tenacity, so that it must be extruded to form wire; HNO_3 is the best solvent; forms alloys with many metals, e.g., mercury, cadmium, zinc, silver, copper, magnesium.

Thallium (Greek *thallos* meaning "a green shoot or twig") was first identified by Sir William Crookes in 1861 in England while he was making spectroscopic determinations for tellurium on residues from a sulfuric acid plant. The name comes from Thallium's bright green spectral emission lines. In 1862 Crookes and Claude-Auguste Lamy isolated the metal independent of each other. Thallium occurs naturally as ^{203}Tl and ^{205}Tl. Eleven radioactive isotopes have been identified ^{198}Tl through ^{202}Tl, ^{204}Tl, and ^{206}Tl through ^{210}Tl. With exception of ^{204}Tl which has a half-life of 4.07 years, the other isotopes have relatively short half-lives expressed in minutes, hours, and days. See also **Radioactivity**. Thallium is not considered an abundant element, estimates of occurrence in the earth's crust ranging from 0.3 to 3.0 ppm. In a list of 65 chemicals found in seawater, thallium does not appear. First ionization potential 6.106 eV; second, 20.32 eV; third, 29.7 eV. Oxidation potentials $Tl \rightarrow Tl^+ e^-$, 0.336 V; $Tl^+ \rightarrow Tl^{3+} + 2e^-$, −1.25 V; $Tl + OH^- \rightarrow TlOH + e^-$, 0.3445 V; $TlOH + 2OH^- \rightarrow Tl(OH)_3 + 2e^-$, 0.05 V. Electron configuration $1s^2 2s^2 2p^6 3s^2 3p^6 3d^{10} 4s^2 4p^6 4d^{10} 4f^{14} 5d^2 5p^6 5d^{10} 6s^2 6p^1$. Other important physical properties of thallium are given under **Chemical Elements**.

Thallium occurs in small amounts in pyrite [CAS: 1309-36-0], zinc blende, and hematite [CAS: 1317-60-8] of certain localities, and in a few rare minerals in Sweden and Macedonia. For the recovery of thallium from the flue dust of pyrite burners, the dust is boiled with H_2O, allowed to stand some time, filtered, and HCl added to the filtrate, whereupon crude thallous chloride is precipitated. This is purified by further treatment, and thallium metal obtained (1) by electrolysis of the sulfate solution or (2) by fusion of

the chloride with sodium cyanide [CAS: 143-33-9] and carbonate [CAS: 3812-32-6].

Uses. Thallium compounds have limited use in industrial applications. The use of thallous sulfate in rodenticides and insecticides has been replaced by other compounds less harmful to animals Thallium sulfide has been used in photoelectric cells. A thallium bromide–thallium iodide mixture is used to transmit infrared radiation for signal systems. Thallous oxide is used in the manufacture of glass that has a high coefficient of refraction. Thallium formate–malonate aqueous solutions (Clerici's solution) have been used in mineral separations. Many thallium compounds have been used as reagents in organic synthesis in research laboratories.

Toxicity. The relative toxicities of thallium compounds depend on their solubilities and valence states. Soluble univalent thallium compounds, eg, thallous sulfate, acetate, and carbonate, are especially toxic. They are rapidly and completely absorbed from the gastrointestinal tract, skin peritoneal cavity, and sites of subcutaneous and intramuscular injection. Thallium is also rapidly absorbed from the mucous membranes of the respiratory tract, mouth, and lungs following inhalation of soluble thallium salts. Insoluble compounds, eg, thallous sulfide and iodide, are poorly absorbed by any route and are less toxic.

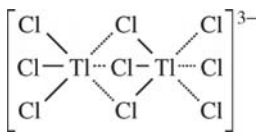
Thallium, which does not occur naturally in normal tissue, is not essential to mammals but does accumulate in the human body. Levels as low as 0.5 mg/100 g of tissue suggest thallium intoxication. Based on industrial experience, 0.10 mg/m^3 of thallium in air is considered safe for a 40-h work week. The lethal dose for humans is not definitely known, but 1 g of absorbed thallium is considered sufficient to kill an adult and 10 mg/kg body weight has been fatal to children. In severe cases of poisoning, death does not occur earlier than 8–10 d but most frequently in 10–12 d. Thallium excretion is slow and prolonged. For example, thallium is present in the feces 35 d after exposure and persists in the urine for up to three months.

The usual symptoms in human thallotoxicosis resulting from acute, subacute, or chronic intoxication are generally the same. Common symptoms include nausea, vomiting, abdominal colic, pain in legs, nervousness and irritability, chest pain, gingivitis or stomatitis, and anorexia. Alopecia (hair loss) does not always occur, especially in cases of mass intake of thallium and low resistance where the patient may die before the occurrence of hair loss. Thallium intoxication during the first trimester of pregnancy can cause skeletal deformities, alopecia, rash, low birth weight, and premature birth.

A variety of therapies for thallium poisoning have been suggested by neutralizing thallium in the intestinal tract, hastening excretion after resorption, or decreasing absorption. Berlin-Blue (ferrihexacyanate) and sodium iodide in a 1 wt % solution have been recommended. Forced diuresis hemoperfusion and hemodialysis in combination results in the elimination of up to 40% of the resorbed thallous sulfate.

Chemistry and Compounds. Oxidation states: thallous, Tl^+; thallic, Tl^{3+}. Because of low oxidation potential of thallium to form Tl^+, thallium is quite reactive, dissolving slowly in most dilute mineral acids to form thallium(I) solutions. The thallium(I) halides are insoluble in water, but thallium trihalides are soluble; the latter are formed by treatment of the thallium(I) halide in solution with the corresponding halogen. Thallium(III) iodide, however, does not exist, TlI_3 being $[Tl^+][I_3^-]$.

Thallium(III) compounds are readily reduced to the thallium(I) state (see difference in oxidation potentials above) and are thus fairly strong oxidizing agents. Thallium(I) compounds resemble those of the alkali metals in many respects, including a soluble, strong basic hydroxide (TlOH) ($K_B = 0.14$), a soluble carbonate (Tl_2CO_3), the formation of well crystallized salts, including those with complex anions, the formation of polysulfides (Tl_2S_5), and polyiodides (thus TlI_3 contains the monovalent metal ion, like rubidium iodide, RbI_3 and cesium iodide, CsI_3). Thallium(I) ion resembles silver in forming insoluble halides, sulfide and chromate. The thallium(I) ion forms only weak complexes (probably because of its larger size and low charge) but the thallium(III) ion forms strong ones. There are four complex chloro ions $[TlCl_4]^-$, $[TlCl_5]^{2-}$, $[TlCl_6]^{3-}$, and $[Tl_2Cl_9]^{3-}$, the last having the six-coordinated structure



The complex compounds include the chelates, such as the oxine chelate, and also such compounds as $Tl(TlCl_4)$, $Tl_3(TlBr_6)$, $TlCl_3 \cdot 3NH_3$, $14Rb_3TlBr_6 \cdot 16H_2O$ (here the presence of the ion $[Tl(H_2O)_8]^+$ has been shown), oxalates, such as $H[Tl(C_2O_4)_2]$ (dioxalatothallic acid), $K2[Tl(C_2O_4)_2(NO_2)_2] \cdot H_2O$ and a number of complex hydrides, as well as the unstable binary hydride TlH_3.

The most readily prepared organometallic compounds are the dialkyl ones of the type R_2TlX, where X is an acid radical accompanying the ion $[R_2Tl]^+$. The trialkyl compounds of the type TlR_3 are immediately decomposed by H_2O, giving RH and R_2TlOH, in which the thallium atom is isoelectronic with the mercury atom in R_2Hg, and which is a strong base: $(C_2H_5)_2TlOH$, $K_B = 0.90$.

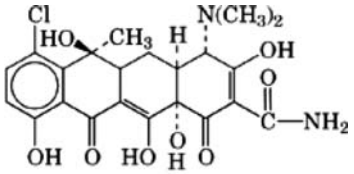
THEILERIASIS. Theileriasis (theileriosis) is a tick-transmitted protozoan disease of cattle seen primarily in central and eastern Africa. The disease not only affects domesticated cattle, but also ox, zebu, water buffalo, and African buffalo. The most significant form of the disease is caused by the protozoan *Theileria parva* (*Piroplasma kochi*, *Piroplasma parvum*, *Theileria kochi*, *Theileria lawrencei*) and is known as African Coast fever, East Coast fever, bovine theileriasis, or Corridor disease. The most important vector of the disease is the tick, *Rhipicephalus appendiculatus*, which harbors the protozoan through one molt. About 90–100% adult cattle infected with *T. parva* die, but calves seem to be less susceptible. After receiving a bite from an infected tick, there is an incubation period of 8–25 days before the appearance of the disease. In the acute form, the animals have a fever, cease to eat, may have a nasal discharge and lachrymate, have general weakness, and diarrhea. Rapid and labored breathing precede death.

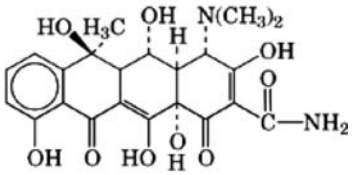
There are other milder forms of theileriasis that resemble the disease caused by *T. parva* infection. They also primarily affect cattle and are transmitted by ticks. Causative organisms include *Theileria annulata*, responsible for tropical thieleriasis, tropical piroplasmosis, Egyptian fever, and Mediterranean Coast fever. These affect ox, zebu, and water buffalo. Endemic areas include northern Africa, southeastern Europe, the southern part of the former USSR, and Asia. *Theileria mutans* is the cause of benign bovine thieleriasis, Marico calf disease, and mild gall sickness. It affects ox and zebu in Africa, Asia, southern Europe, England, the former USSR, Australia, and North America.

There are no fully effective therapeutic agents for the treatment of theileriasis. Chlorotetracycline (**1** [CAS: 57-62-5] $C_{22}H_{23}ClN_2O_8$) and

oxytetracycline (2, [CAS: 79-57-2] $C_{22}H_{24}N_2O_9$) have therapeutic activity during the incubation period.



(1)



(2)

Pamaquine (3, [CAS: 491-92-9] $C_{19}H_{29}N_3O$) was reported to have a specific effect on the erythrocyctic forms. Other drugs with limited efficacy are imidocarb (4, [CAS: 27885-92-3] $C_{19}H_{20}N_6O$) on *T. annulata*, halofuginone (5, [CAS: 55837-20-2] $C_{16}H_{17}BrClN_3O_3$) on both *T. annulata* and *T. parva*, and the naphthoquinones menoctone (6, [CAS: 14561-42-3] $C_{24}H_{32}O_3$), parvaquone (7, [CAS: 4042-30-2] $C_{16}H_{16}O_3$), and buparvaquone (8, [CAS: 88426-33-9] $C_{21}H_{26}O_3$) on *T. parva*. Methotrexate (9, [CAS: 59-05-2] $C_{20}H_{22}N_8O_5$) has been found to be active *in vitro*.

DANIEL L. KLAYMAN, Walter Reed Army Institute of Research

THEILER, MAX (1899–1972). Theiler was a South African born research physician whose work culminated in the development of the yellow fever 17D vaccine, still the preferred method of immunization today.

Max Theiler was born to Swiss parents in Pretoria, where at the time his father, Sir Arnold Theiler (1867–1936), was official veterinarian to Transvaal during serious outbreaks of rinderpest. His medical education was cosmopolitan; he attended the Universities of Basle and of Cape Town, and in London St Thomas' Hospital Medical School and the London School of Tropical Medicine. He then joined the Department of Tropical Medicine at Harvard University Medical School. His one year there set him on the road to the research on yellow fever which would eventually produce the effective vaccine that is still in use, and which earned him a Nobel Prize in 1951. Soon after his arrival at Harvard he suffered an attack of the debilitating pain and discomfort that had dogged his life and work since his early schooldays in South Africa, but which had defeated diagnosis by local doctors. Now he was in better hands. His colleagues at Harvard asked the right questions, drew the right conclusions, and prescribed the right treatment: Max Theiler now made a full recovery from the schistosomiasis (bilharzia) he had acquired when, breaking family rules as a child in South Africa, he had waded in a nearby river, home to water snails carrying schistosomes, in search of aquatic wildlife. See also **Yellow Fever**.

From Harvard he moved in 1930 to the Rockefeller Foundation International Health Division's yellow fever laboratories at the Rockefeller Institute. It was here that he and his team, over a period of years in the 1930s, developed the effective, attenuated, yellow fever 17D vaccine. The search for a vaccine had been on since 1927, when Adrian Stokes, Johannes Bauer and N. Paul Hudson (Stokes died of accidentally acquired yellow fever before their paper was published in 1928) of the Rockefeller Yellow Fever Commission in West Africa demonstrated the susceptibility of the rhesus monkey to the virus, and Andrew Watson Sellards and Jean Laigret isolated the French strain at Dakar. Edward Hindle and G. Marshall Findlay were working in the Wellcome Laboratories in London on the French strain, courtesy of Sellards, in monkey experiments. Theiler searched for a less expensive and more readily available animal and soon found the white mouse susceptible to the virus injected by the intracerebral route. After years of setbacks — at one stage the mouse-adapted virus, although

attenuated for monkeys, was found to have acquired marked neurotropic affinities–and advances through extensive cultures and subcultures of the 17D strain of the Asibi yellow fever virus, Theiler's 17D yellow fever vaccine was tested in Brazil over three years between 1937 and 1940. It has taken its place as one of the safest and most effective live viral vaccines. Production has ceased of an earlier French neurotropic vaccine.

After the award of the Nobel Prize for Physiology or Medicine in 1951 Theiler was made Director of the Division of Medicine and Public Health of the Rockefeller Foundation, and continued to work there until his death in August, 1972.

LISE WILKINSON, Wellcome Institute for the History of Medicine UCL, London, UK

THEODOLITE. An optical instrument that consists of a sighting telescope so mounted that it is free to rotate around horizontal and vertical axes. The instrument incorporates graduated scales so that angles of rotation may be measured. Theodolites normally are calibrated for (1) collimation value, i.e., the centering of the cross hair to the telescope, (2) trunnion error, i.e., the truth of rotation of the telescope in a true vertical plane, and (3) the centering of the axis of rotation. Accuracy of the circle, position of the plate bubble, and accuracy of the micrometers also are measurable and correctable features. Values usually may be read in fractions of a second of arc.

Theodolites are used for alignment of large jigs and fixtures in manufacturing operations. Through triangulation, the instruments also can be used for length measurements. With addition of an autocollimation system, the theodolite can be used to establish incremental spacing of divided circles or any similar object, such as the tooth spacing of a large gear. A theodolite with a two-sided reading system eliminates errors of centering of circles and, therefore, when using the instrument with an autocollimating eyepiece, it is not necessary that the theodolite be precisely centered to the part under measurement. Since the instrument is rotatable in both the horizontal and vertical axis, the device essentially combines for the metrologist the value of two optical dividing units.

In meteorology, the theodolite is used to observe the motion of a pilot balloon. The telescope is usually fitted with a right-angle prism so that the observer continues to look horizontally into the eyepiece whatever the variation of the elevation.

THEORA. See **Data Compression**.

THEOREM. An assertion of which there is a proof. With few exceptions, notably Fermat's last theorem, any assertion referred to as a theorem has been rigorously proved. Examples from algebra are the Fundamental Theorem of Algebra, the Remainder Theorem, and the Factor Theorem.

THEORETICAL PLATE. Any contacting device in a fractionating column, such as packing, grids, or screens, that effects the same degree of separation of vapor from liquid as one simple distillation. A column that gives the same separation as 10 successive simple distillations is considered to have 10 theoretical plates. The effectiveness of a fractionating column is measured in terms of theoretical plates. As many as 100 theoretical plates are used in laboratory and industrial operation. The total column height divided by the number of theoretical plates is known as HETP (height equivalent to a theoretical plate). This concept is also used in chromatographic techniques.

THEORY OF EQUATIONS. The branch of mathematics concerned with determining the solvability of algebraic equations and with developing methods for solving them. An equation of the form

$$a_0x^n + a_1x^{n-1} + \cdots + a_n = 0$$

where n is a positive integer and $a_0, a_1, \ldots, a_n$ are constants contained in the field of complex numbers of which $a_0 \neq 0$, is called an integral rational equation of the nth degree in x. (See also **Algebraic Equations**.) The left hand member is called a polynomial of the nth degree in x.

The remainder theorem states that the remainder obtained in dividing a polynomial $f(x)$ by a monomial $x - c$ is equal to $f(c)$. The factor theorem states that if r is a zero of a polynomial $f(x)$, then $(x - r)$ is a factor of $f(x)$. This indicates that if r is a root of an integral rational equation $f(x) = 0$, then $(x - r)$ is a factor of $f(x)$. The fundamental theorem of algebra states that every integral rational equation in a single variable x has at least one root and a corollary states that every polynomial $f(x)$ of degree n can be decomposed into exactly n linear factors. A repeated factor indicates a multiple root of the equation $f(x) = 0$. If a factor $x - r$ occurs k times with $k > 1$, r is called a root of multiplicity k. Every integral rational equation of degree n has exactly n roots, where a root of multiplicity k is counted as k roots. If the coefficients of the polynomial $(a_0, a_1, \ldots, a_n)$ are limited to the real number field, or any other field contained in the complex number field, the above theorems still hold; however, complete factorization will, in general, require complex roots.

By expressing a general polynomial $f(x)$ as a product of n linear factors and equating coefficients of like powers of x one can determine relationships between the coefficients of an integral rational equation

$$a_0x^n + a_1x^{n-1} + \cdots + a_n = 0$$

and its n roots $r_1, r_2, \ldots, r_n$. The relationships between $a_0, a_1, \ldots, a_n$ and $r_1, r_2, \ldots, r_n$ are

$$\begin{aligned}
\frac{a_1}{a_0} &= -(r_1 + r_2 + \cdots + r_n),\\
\frac{a_2}{a_0} &= (r_1r_2 + r_1r_3 + \cdots r_1r_n + \cdots + r_{n-1}r_n),\\
\frac{a_3}{a_0} &= -(r_1r_2r_3 + r_1r_2r_4 + \cdots + r_1r_2r_n + \cdots + r_{n-2}r_{n-1}r_n),\\
&\cdots\cdots\cdots\cdots\cdots\cdots\cdots\cdots\cdots\\
\frac{a_n}{a_0} &= (-1)^n(r_1r_2r_3r_4\cdots r_n).
\end{aligned}$$

For an equation with real coefficients, it is known that if $a + ib$ is a root where a and b are real then $a - ib$ is also a root. For an equation with rational coefficients, if $a + \sqrt{b}$, where a and b are rational but $\sqrt{b}$ is not, is a root, then $a - \sqrt{b}$ is also a root. For an equation with integral coefficients, all rational roots may be found by determining whether the fractions whose numerators are factors of the constant term, and whose denominators are factors of the coefficient of the highest power of x, satisfy the equation.

Various methods can be used for determining bounds for the real roots of an equation. For an equation with real coefficients, it can be shown that the equation cannot have a real root greater than $|a_k/a_0| + 1$ or less than $-|a_k/a_0| - 1$, where a_0 is the coefficient of the highest power of x and a_k is the coefficient of greatest numerical value. Also, it can be shown that there are no positive roots less than $|a_n|(|a_n| + |a_k|)$, where a_k is the coefficient of greatest numerical value as before and a_n is the constant term.

An equation is said to be solved in terms of radicals if the roots can be expressed in terms of the coefficients using only the operations of addition, subtraction, multiplication, division, and extraction of roots. By the middle of the sixteenth century, general equations through degree 4 had been solved in terms of radicals. See also **Quadratic Equation** ($n = 2$), **Cubic Equation** ($n = 3$), and **Biquadratic Equation** ($n = 4$). Attempts to solve higher degree equations led nowhere for over 200 years. Ruffini and Abel are credited with proving that equations of degree higher than 4 cannot be solved by radicals. Those who credit Ruffini admit that his proof was incomplete. Those who credit Abel mention that Ruffini's proof was earlier but incomplete. Other authorities state that Abel's proof contained two oversights and credit Galois with the first definitive proof. Galois's theory proves the impossibility of solving equations of degree higher than 4 by establishing a correspondence between the permutations of roots

of equations with rational coefficients in the algebraic relations holding among the roots and groups. If the permutation of roots preserves the validity of all the algebraic relations among the coefficients it is called a permissible permutation. The set of permissible permutations is called the Galois group of the equation. A theorem states that an algebraic equation is solvable if and only if its Galois group is solvable. It has been shown that the group of all permutations on n symbols is not solvable when $n \geq 5$, and that there exist equations with rational coefficients which have these groups as Galois groups. Therefore, it follows that solution by radicals is impossible for $n > 4$. Hermite succeeded in solving the general equation of degree 5 in terms of elliptic functions. Recent work in this direction solves the general equation of degree n in terms of Fuchsian functions.

For equations of degree higher than 2, it is usually more practical to determine the roots by an approximate method. The first step is to isolate the roots, that is, identify intervals which contain only one (possibly a multiple) root. See also **Rolle Theorem**; and **Budan Theorem**.

Once the roots have been isolated the roots can be obtained to the desired degree of accuracy using Horner's method of Newton's method for real roots. The Graeffe method can be used for real or complex roots. Newton's method is not limited to algebraic functions. Let $f(x)$ be a function with a root in the interval $a \leq x \leq b$. Let $f'(x)$ denote the derivative of $f(x)$. Newton's method consists of evaluating $f(x)$ and $f'(x)$ for a value $x = x_0$ where $a \leq x_0 \leq b$ and solving the equation

$$f(x_0) + f'(x_0)(x_1 - x_0) = 0$$

for x_1. The solution for x_1 is then used as a new value for x_0 and the process is repeated until the desired accuracy is achieved. As with any method which may diverge or oscillate some care must be taken during its use.

A set of simultaneous equations in several variables can be reduced to a set of equations each of which contains only one variable. This is easily accomplished for linear equations by the use of determinants. See also **Determinant**. For higher degree equations, it may be useful to calculate the resultant. Let

$$f(x) = a_0x^n + a_1x^{n-1} + \cdots + a_n = 0,$$
$$g(x) = b_0x^m + b_1x^{m-1} + \cdots + b_m = 0$$

be two equations whose coefficients may involve another unknown y. Suppose $a_0 \neq 0$ and let $\alpha_1, \alpha_2, \ldots, \alpha_n$ denote the roots of $f(x) = 0$. If one of these is also a root of $g(x) = 0$ then $a_0^m g(\alpha_1)g(\alpha_2)\cdots g(\alpha_n) = 0$. The left hand side of this equation is a homogeneous polynomial of dimension m in the coefficients $a_0, a_1, \ldots, a_n$, and a homogeneous polynomial of dimension n in the coefficients $b_0, b_1, \ldots, b_m$. This polynomial is called the resultant of $f(x)$ and $g(x)$ and is denoted by $R(f, g)$. The vanishing of the resultant is a necessary and sufficient condition for the two equations $f(x) = 0$ and $g(x) = 0$ to have a common root, provide $a_0 \neq 0$. If $b_0 \neq 0$, a necessary and sufficient condition is $R(g, f) = 0$.

It can be shown that

$$R(g, f) = (-1)^{mn}R(f, g).$$

For the two polynomials

$$f(x) = a_0x^n + a_1x^{n-1} + \cdots + a_n \text{ and}$$
$$g(x) = b_0x^m + b_1x^{m-1} + \cdots + b_m,$$

the determinant $D(f, g)$ given by

$$D(f,g) = \begin{vmatrix} a_0 & a_1 & a_2 \cdots a_n & & \\ & a_0 & a_1 \cdots a_n & & \\ & \cdots\cdots & & & \\ & & a_0 & a_1 \cdots a_n & \\ b_0 & b_1 \cdots b_m & & & \\ & b_0 & b_1 \cdots b_m & & \\ & \cdots\cdots & & & \\ & & b_0 & b_1 \cdots b_m & \end{vmatrix} \begin{matrix} \\ \\ \\ \left.\begin{matrix}\\ \\ \\ \end{matrix}\right\} m \text{ rows} \\ \\ \\ \left.\begin{matrix}\\ \\ \\ \end{matrix}\right\} m \text{ rows} \end{matrix}$$

is known as Sylvester's determinant. The vanishing of Sylvester's determinant is a necessary and sufficient condition that f and g have a common divisor of degree > 0, provided that $a_0 \neq 0$. It can be shown that Sylvester's determinant and the resultant are identical polynomials in the coefficients of f and g. Therefore, the resultant can be calculated by using Sylvester's determinant.

Let $f(x)$ represent nth degree polynomial as before. Let D represent the discriminant. See also **Discriminant**. The discriminant vanishes if and only if the equation $f(x) = 0$ has equal roots. Let $f^1(x)$ be the derivative of $f(x)$. It can be shown that the discriminant is related to the resultant of f and f^1 as

$$(-1)^{n(n-1)/2}a_0D = R(f, f^1).$$

DONALD R. HODGE, The BDM Corporation, Vienna, VA

THEORY OF SAMPLING. See **Sampling**.

THERMAL. 1. Pertaining to temperature or heat.

2. A discrete buoyant element in which the buoyancy is confined to a limited volume of fluid.

3. A relatively small-scale, rising current of air produced when the atmosphere is heated enough locally by the earth's surface to produce absolute instability in its lowest layers. The use of this term is usually reserved to denote those currents either too small and/or too dry to produce convective clouds; thus, thermals are a common source of low-level clear-air turbulence. It is generally believed that the term originated in glider flying, and it is still very commonly used in this reference.

THERMAL CONDUCTIVITY. An important property of materials that determines the rate at which thermal energy may flow through the material. Materials are selected for various purposes based upon their ability to conduct heat well (as in heat exchangers) or upon their resistance to conduct heat (as in insulation products).

In engineering terms, thermal conductivity is the time rate of transfer of heat by conduction through a unit thickness across a unit area for a unit difference of temperature. The units usually used are *calories per second* per *square centimeter* for a thickness of 1 centimeter and for a *temperature difference* of 1 °C.

THERMAL CONTROL SYSTEM. See **Space Technology 8 (ST8) Mission**.

THERMAL CONVECTION. See **Convection**.

THERMAL DIFFUSION. See **Diffusion**.

THERMAL DIFFUSIVITY. The quantity $K\rho/C_v$, where K is the thermal conductivity, ρ is the density, and C_v is the specific heat per unit mass. The magnitude of this quantity determines the rate at which a body with a nonuniform temperature approaches equilibrium.

THERMAL EFFICIENCY. Thermal efficiency is output, in heat units, divided by the heat supplied or chargeable. Thermal efficiency may partially define the operating condition of both a machine or a static piece of equipment. In the case of static equipment, if it is well insulated it may have very high thermal efficiencies. A machine which converts heat supplied into work output (the steam engine, Diesel engine, etc.) is always characterized by low thermal efficiencies because the conversion of the low-grade type of heat energy into high-grade energy of mechanical work is accomplished with considerable difficulty. The thermal efficiencies of the best prime movers today rarely exceed 35%, and are not found higher than 40% even when optimum conditions of loading, maintenance, and

fuel employed are present. Thermal efficiency of a prime mover may be based on the output at the shaft per unit of heat supplied, or upon the electrical output in the case of a generator drive. It may also be based on cylinder horsepower in piston and cylinder prime movers. Heat supplied and chargeable to internal combustion engines is the heat in the fuel. Heat supplied to steam prime movers is the heat in the steam at the throttle; the heat chargeable is the heat supplied after deducting the heat of condensate in the exhaust.

THERMAL EQUATOR. The belt of maximum temperature surrounding the earth, which moves north and south with (but lagging) the sun's motion. It is also spoken of as the center of the area bounded by the yearly mean isotherms of 80 °F (26.7 °C). See also **Climate**.

THERMAL EXPANSION COEFFICIENT. The change in volume per unit volume per degree change in temperature (cubical coefficient). For isotropic solids the expansion is equal in all directions, and the cubical coefficient is about three times the linear coefficient of expansion. These coefficients vary with temperature, but for gases at constant pressure the coefficient of volume expansion is nearly constant and equals 0.00367 for each degree Celsius at any temperature.

THERMAL GRADIENT (or Geothermal Gradient). 1. According to Smithsonian Physical Tables, the rate of variation of temperature in soil and rock from the surface of the earth down to depths of the order of kilometers. The thermal gradient varies greatly from place to place, depending on the geological history of the region, the radioactivity of the underlying rocks, and the conductivity of the upper rocks. An average figure is about +10 °C per kilometer.

2. In the atmosphere, the maximum rate of decrease of temperature with distance. Temperature gradients directed vertically are known as lapse rates.

THERMAL INSTABILITY. See **Atmosphere (Earth)**.

THERMAL JET ENGINE. A jet engine, that utilizes heat to expand gases for rearward ejection. This is the usual form of aircraft jet engine.

THERMAL NOISE. See **Noise**.

THERMAL PRESERVATION TECHNOLOGY. See **Food Processing**.

THERMAL RADIATION. All bodies that are not at absolute zero emit radiation excited by the thermal agitation of their molecules or atoms, whether there are other causes of excitation or not. This thermal radiation ranges in wavelength from the longest infrared to the shortest ultraviolet rays, its spectral energy distribution, however, depending upon the nature of the body and upon its temperature. The total emissive power of a surface at any temperature is the rate at which it emits energy of all wavelengths and in all directions, per unit area of radiating surface. The flux density (per unit solid angle) in various directions obeys the cosine emission law approximately; but strictly only in the case of a black body. See also **Wien Laws**.

THERMAL STABILITY. A phase must satisfy certain conditions if it is to be stable (or metastable). For systems consisting of a single component the necessary and sufficient conditions are the conditions of thermal stability and of mechanical stability. The condition of thermal stability is

$$C_v > 0$$

The heat capacity at constant volume of all stable (or metastable) phases is positive.

THERMAL WIND. See **Winds and Air Movement**.

THERMIONIC CONVERSION. The process whereby electrons released by thermionic emission are collected and utilized as electric current. The simplest example of this is provided by a vacuum tube, in which the electrons released from a heated anode are collected at the cathode or plate. Used as a method of producing electrical power for spacecraft.

THERMIONIC EMISSION. Direct ejection of electrons as the result of heating and material, which raises electron energy beyond the binding energy that holds the electron in the material.

THERMISTOR. The name "thermistor" is derived from *therm*ally sensitive res*istor*, since the resistance of a thermistor varies as a function of temperature. Although semiconductors have been known as a class of materials for many years, only since the 1950s have sufficient theory and manufacturing techniques been developed to spur their use as primary temperature elements.

A thermistor is an electrical device made of a solid semiconductor with a high-temperature coefficient of resistivity, which exhibits a linear voltage-current characteristic when its temperature is held constant. When a thermistor is used as a temperature-sensing element, the relationship between resistance and temperature is of primary concern. The approximate relationship applying to most thermistors is:

$$R_T = R_0 \exp B \left(\frac{1}{T} - \frac{1}{T_0} \right) \tag{1}$$

where R_0 = resistance value at reference temperature T_0 °K, ohms.
R_T = resistance at temperature T °K, ohms.
B = constant over temperature range, dependent upon manufacturing process and construction characteristics (specified by supplier)

$$B \cong \frac{E}{K} \tag{2}$$

where E = electron volt energy level
K = Boltzmann's constant (8.625×10^{-5} eV/°K)

A second form of the approximate resistance-temperature relationship is written in the form

$$R_T = R_\infty e^{B/T} \tag{3}$$

where R_∞ = thermistor resistance as temperature approaches infinity, ohms.

Both equations (1) and (2) are only best approximations and, therefore, are of limited use in making highly accurate temperature measurements. However, they do serve to compare thermistor characteristics and thermistor types. The temperature coefficient usually is expressed as a percentage change in resistance per degree of temperature change and is approximately related to B by

$$a = \frac{dR}{dT} \left(\frac{1}{R} \right) = \frac{-B}{T_0^2} \tag{4}$$

where T_0 is in degrees Kelvin. It should be noted that the resistance of the thermometer is solely a function of its absolute temperature. Furthermore, it is apparent that the thermistor's resistance-temperature function has a characteristic high negative coefficient as well as a high degree of nonlinearity. The value of the coefficient for a common commercial thermistor is on the order of 2–6% per °K at room temperature. This

value is approximately ten times that of metals used in the manufacture of resistance thermometers.

Resultant considerations due to the high coefficient characteristic of thermistors include inherent high sensitivity and high level of output, eliminating the need for extremely sensitive readout devices and leadwire matching techniques. However, limitations on interchangeability (particularly over wide temperature ranges), calibration, and stability — also inherent to thermistors — are quite restrictive. The high degree of nonlinearity in the resistance-temperature function usually limits the range of the readout instrumentation. In many applications, special prelinearization circuits must be used before interfacing with related system instrumentation. The negative temperature coefficient also may require an inversion (to positive form) when interfacing with some analog and/or digital instrumentation.

A number of metal oxides and their mixtures, including the oxides of cobalt, copper, iron, magnesium, manganese, nickel, tin, titanium, uranium, and zinc are among the most common semiconducting materials used in the construction of thermistors. Usually compressed into the desired shape from specially formulated powder, the oxides are then recrystallized by heat treatment, resulting in a dense ceramic body. The leadwires are then attached while electric contact is maintained, and the finished thermistor is then encapsulated. Some common configurations of thermistors are shown in Fig. 1. A comparison of the resistance-temperature characteristics of thermistors with platinum metal used in resistance thermometers is given in Fig. 2.

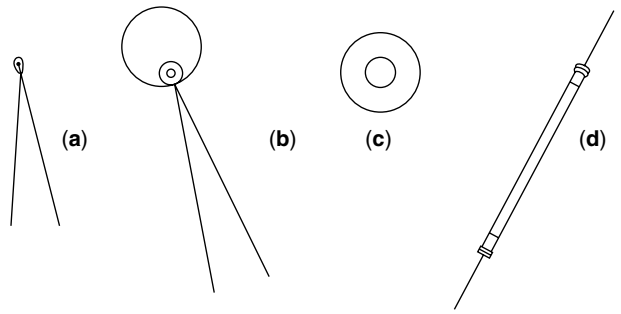

Fig. 1. Thermistor configurations: (**a**) bead, (**b**) disc, (**c**) washer, (**d**) rod.

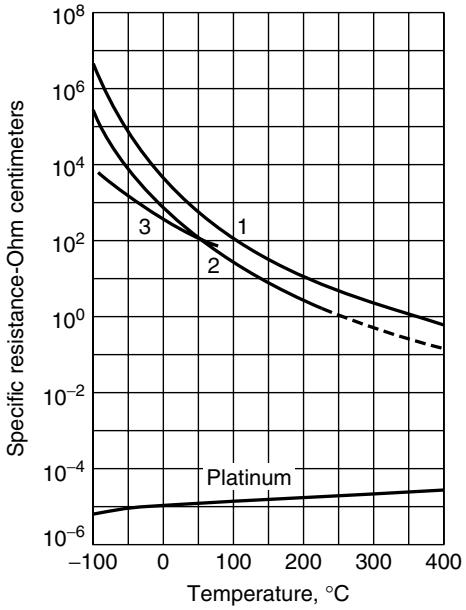

Fig. 2. Resistance-temperature characteristics of thermistors as compared with platinum metal used in resistance thermometers.

THERMITE. A mixture of ferric oxide [CAS: 1309-37-1] and powdered aluminum [CAS: 7429-90-5], usually enclosed in a metal cylinder and used as an incendiary bomb, invented by the German chemist Hans Goldschmidt around 1900. On ignition by a ribbon of magnesium, the reaction produces a temperature of 2200 °C, which is sufficient to soften steel. This is typical of some oxide/metal reactions that provide their own oxygen supply and thus are very difficult to stop.

THERMOCHEMISTRY. That aspect of chemistry which deals with the heat changes which accompany chemical reactions and processes, the heat produced by them, and the influence of temperature and other thermal quantities upon them. It is closely related to chemical thermodynamics. The heat of formation of a compound is the heat absorbed when it is formed from its elements in their standard states. An exothermic reaction evolves heat; and endothermic reaction requires heat for initiation.

THERMOCLINE. That layer of water in the oceans situated between the relatively warm surface water and the much colder main mass of water at the bottom. The temperature falls rather sharply in this layer, or zone, in contrast to the others that are relatively uniform. See also **Ocean**; and **Solar Energy**.

THERMOCOUPLE. In 1821, Seebeck discovered that an electric current flows in a continuous circuit of two metals if the two junctions are at different temperatures, as shown in Fig. 1. A and B are two metals, T_1 and T_2 are the temperatures of the junctions. I is the thermoelectric current. A is thermoelectrically positive to B if T_1 is the colder junction. In 1834, Peltier found that current flowing across a junction of dissimilar metals causes heat to be absorbed or liberated. The direction of heat flow reverses if current flow is reversed. Rate of heat flow is proportional to current but depends upon both temperature and the materials at the junction. Heat transfer rate is given by PI, where P is the Peltier coefficient in watts per ampere, or the Peltier emf in volts. Many studies of the characteristics of thermocouples have led to the formulation of three fundamental laws:

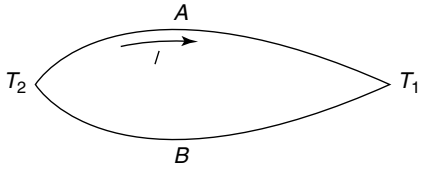

Fig. 1. Simple thermocouple circuit.

1. *Law of the homogeneous circuit*. An electric current cannot be sustained in a circuit of a single homogeneous metal; however it may vary in section, by the application of heat alone.

2. *Law of intermediate metals*. If in any circuit of solid conductors the temperature is uniform from any point P through all the conducting matter to a point Q, the algebraic sum of the thermoelectromotive forces in the entire circuit is totally independent of this intermediate matter and is the same as if P and Q were put in contact.

3. *Law of successive or intermediate temperatures*. The thermal emf developed by any thermocouple of homogeneous metals with its junctions at any two temperatures T_1 and T_3 is the algebraic sum of the emf of the thermocouple with one junction at T_1 and the other at any other temperature T_2 and the emf of the same thermocouple with its junctions at T_2 and T_3. See Fig. 2.

Common thermocouple wire combinations used in industry are listed in Table 1. A choice of different metals is needed to fulfill a broad range of temperatures as well as for oxidizing or reducing conditions in use. The temperature-thermal emf curves for common types of thermocouples are

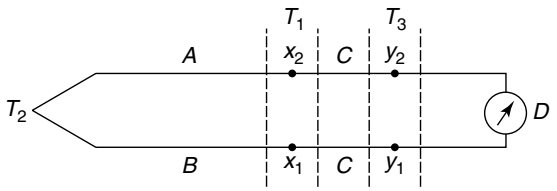

Fig. 2. Law of Intermediate Metals makes it possible to use "foreign" wires to connect thermocouple to measuring instrument. Thermocouple materials A and B can be connected to the instrument by use of connecting materials C and D. If the temperatures at X_1 and X_2 are both at T_1 and if temperatures at Y_1 and Y_2 are both at T_3, the emf of the circuit will be independent of materials C and D.

TABLE 1. COMMONLY USED THERMOCOUPLES AND TEMPERATURE RANGES

ANSI Type	Positive Element	Negative Element	Normal Temperature Range °F	Normal Temperature Range °C
B	Platinum 20% Rhodium	Platinum 6% Rhodium	1,600–3,100	870–1,700
E	Chromel	Constantan	32–1,600	0–870
J	Iron	Constantan	32–1,400	0–760
K	Chromel	Alumel	32–2,300	0–1,260
R	Platinum 13% Rhodium	Platinum	32–2,700	0–1,480
S	Platinum 10% Rhodium	Platinum	32–2,700	0–1,480
T	Copper	Constantan	−300–+700	−180–+370

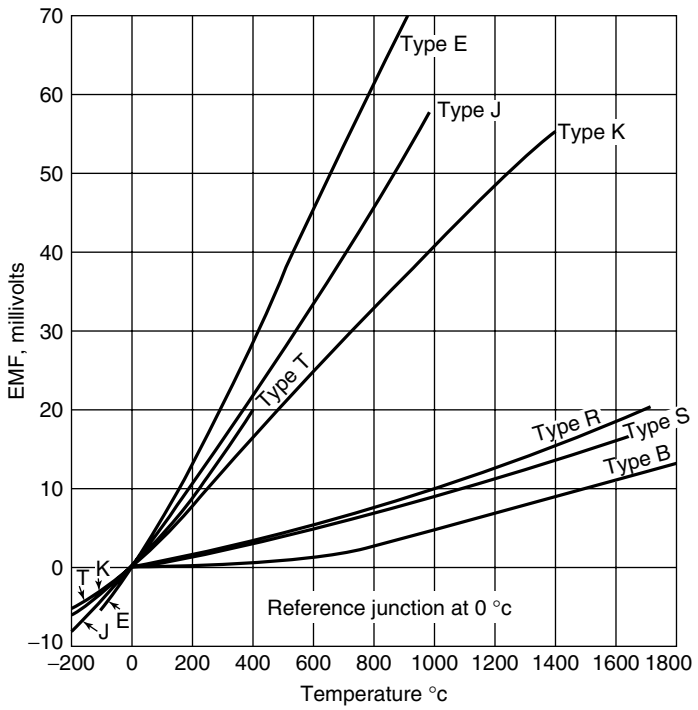

Fig. 3. Temperature-thermal emf curves for common types of thermocouples. (*Honeywell*.)

given in Fig. 3. The hot junction of a thermocouple may be joined by any means that will ensure good electrical continuity when in use. Commonly, the two wires are twisted together and either welded or silver-soldered. Simple clamping of wires together provides adequate connection for short-term use in clean atmospheres at lower temperatures. For industrial

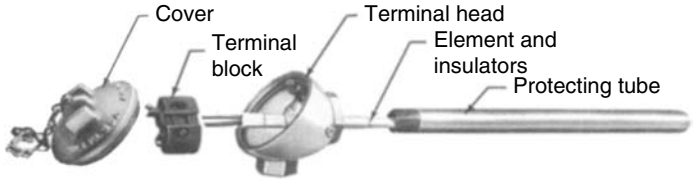

Fig. 4. Assembly of industrial thermocouple, terminal block, and protecting tube. (*Honeywell*.)

applications, the thermocouple is usually placed within a protecting tube. A typical assembly is shown in Fig. 4. For lower temperatures, carbon steel may be used. As the temperature goes up, wrought iron, stainless steel, nickel, nickel-chromium-iron, fused silica, silica-alumina, silicon carbide, alumina, and beryllia may be used. Beryllia protecting tubes will withstand operating temperatures of up to 4,000 °F (~2,200 °C). For some applications, disposable-tip thermocouples have been developed. These are particularly effective for high-temperature molten-metal temperature measurements.

The emf developed by a thermocouple depends upon the temperature of both the measuring and reference junctions. Thus, to determine temperature, the following data must be known: (1) the calibration data for the particular thermocouple; (2) the measured emf; and (3) the temperature of the reference junction. In laboratory cases, the reference junction can be maintained at the freezing temperature of water. However, in most modern instruments, the ambient temperature of the reference junction is sensed, and the correction is incorporated in the measurement circuitry.

Multiple thermocouples may be used in parallel and connected to a single instrument. A typical application is a fire-warning system. Multiple thermocouples also may be connected in series. This is a means for obtaining the average temperature of an object. Also two or more thermocouples may be connected in series so that the emf outputs of the couples are additive. In application installations, thermopiles sometimes are used to detect the presence or absence of the pilot flame and cause a relay to turn off the main gas supply valve.

THERMODYNAMIC DIAGRAM. Any chart or graph representing values of pressure, density, temperature, water vapor, or functions thereof, such that the equation of state, the Clapeyron–Clausius equation, and the first law of thermodynamics for adiabatic and saturation or pseudoadiabatic processes are satisfied. Sometimes called *adiabatic chart*, *adiabatic diagram*.

A very large number of individual diagrams fall under this general description. These common diagrams are mathematical transformations of each other. They display (reading counterclockwise about a point) isobars (approximately horizontal), isotherms, vapor lines, saturation or pseudoadiabats, and dry adiabats. When an air parcel undergoes a reversible process, the succession of states is represented on the thermodynamic diagram by a curve. A cyclic process is represented by a closed curve. On some charts the area so enclosed is directly proportional to the work done in the process, and some authors prefer to restrict the use of "thermodynamic diagram" to such charts Table 1.

TABLE 1. THERMODYNAMIC CHART

Chart	X (x-axis)	Y (y-axis)	Equation for T = const	Equation for θ = const	Thermodynamic work by system	Remarks
Aerogram or **Refsdal diagram**	$\ln T$	$-T \ln p$	$X = \ln T$	$Y = \frac{c_p}{R}(\ln \theta - X) + \text{const}$	$-R\int Y dX$	Only isotherms are straight lines.
Clapeyron $(\alpha, -p)$	α	$-p$	$Y = -\frac{RT}{X}$	$Y = \text{const}\left(\frac{\theta}{X}\right)^{c_p/c_v}$	$-\int Y dX$	Classic physics diagram; isentropes curved and nearly parallel to isotherms.
Emagram or **Neuhoff diagram**	T	$-\ln p$	$X = T$	$Y = \text{const} - \frac{c_p}{R}\ln\left(\frac{X}{\theta}\right)$	$-R\int Y dX$	Isentropes slightly curved.
Pastagram	T_0	$T_0\left[1 - \left(\frac{p}{p_0}\right)^{R\gamma/g}\right]$	$Y = X - T$	$Y = X\left[1 - \left(\frac{\theta}{X}\right)^{1/(1 - g/c_p\gamma)}\right]$	Not relevant	T_0, p_0 are surface values, γ = 6.5 K km^{-1}; used mainly for hydrostatic calculations.
Stüve or Pseudo-adiabatic	T	$-p^{R/c_p}$	$X = T$	$Y = \text{const}(X/\theta)$	$c_p\int \ln(-Y) dX$	Isentropes are straight, inclined lines; proportionality of area and work sacrificed.
Skew T–log p or Skewed emagram	$T - c \ln p$	$-\ln p$	$Y = \frac{X - T}{c}$	$\frac{R}{c_p}Y + \ln(X - cY) = \ln \theta + \text{const}$	$-R\int Y dX$	Isotherms straight, but tilted according to $T = X - cY$; isentropes curved.
Tephigram	T	$\ln \theta$	$X = T$	$Y = \ln \theta + \text{const}$	$-c_p\int Y dX$	Isobars are curved, inclined lines.
Thetagram	T	$-p$	$X = T$	$Y = X \ln(-Y) + \text{const}$	$-R\int (X/Y) dY$	Isentropes curved; area not proportional to work.

THERMODYNAMIC EQUILIBRIUM. See **Equilibrium**.

THERMODYNAMICS. Classical thermodynamics is a theory which on the basis of four main laws and some ancillary assumptions deals with general limitations exhibited by the behavior of macroscopic systems. Phenomenologically it takes no cognizance of the atomic constitution of matter. All *mechanical* concepts such as kinetic energy or work are presupposed. Thermodynamics is motivated by the existence of dissipative mechanical systems. A *thermodynamic system* K may be thought of as a collection of bodies in bulk; when its condition is found to be unchanging in time (on a reasonable time scale) it is *in equilibrium*. It is then characterized by the values of a finite set of, say, n physical quantities, it being supposed that none of these is redundant. Such a set of quantities constitutes the *coordinates* of K, denoted by $x(= x_1, \ldots, x_n)$. Any set of values of these is a *state* $\mathfrak{S}$ of K. In virtue of these definitions, K is in a state only when it is in equilibrium. The passage of K from a state $\mathfrak{S}$ 1 to a state $\mathfrak{S}'$ is a *transition* of K. A transition is *quasi-static* if in its course it goes through a continuous sequence of states, and if the forces that do work on the system are just those which hold it in equilibrium. A transition is *reversible* if there exists a second transition that restores the initial state, the final condition of the surroundings of K being the same as the initial condition. Reversible transitions are assumed to be quasi-static.

An enclosure, such that the equilibrium of a system contained within it can only be disturbed by mechanical means, is *adiabatic*, otherwise it is *diathermic*. For instance, stirring, or the passage of an electric current, constitute "mechanical means." A system K_0 in an adiabatic enclosure is *adiabatically isolated*, but this does not preclude mechanical interactions with the surroundings. Its transitions are then called adiabatic.

For the time being, the masses of all substances present will be supposed fixed, and to achieve simplicity it will be given that (1) there are no substances present whose properties depend on their previous histories, and (2) capillary forces as well as long-range interactions are absent. Further, it will be supposed that of the n coordinates of K, just $n - 1$ have geometrical character (*deformation coordinates*, e.g., volumes of enclosures), so that the work done by K in a quasi-state transition is

$$\int dW = \int \sum_{k=1}^{n-1} P_k(x)\, dx_k \tag{1}$$

Such a system will be called a *standard system* ($n - 1$ enclosures in diathermic contact, each containing a simple fluid, may serve as example, x_n being any one of the pressures).

The Zeroth Law. Suppose two systems $K_A(x)$ and $K_B(y)$ to be in mutual diathermic contact. Experience shows that the states $\mathfrak{S}_A$ and $\mathfrak{S}_B$ cannot be assigned arbitrarily, but that there exists a necessary relation of the form

$$f(x; y) \equiv f(x_1, \ldots, x_n; y_1, \ldots, y_m) = 0 \tag{2}$$

between them. If K_C is a third system, its diathermic equilibrium with K_B on the one hand, or with K_A on the other, is governed by conditions

$$g(y; z) = 0 \tag{3}$$

and

$$h(z; x) = 0 \tag{4}$$

respectively. That these three functions are not independent is expressed by the *Zeroth Law: If each of two systems is in equilibrium with a* third *system then they are in equilibrium with each other*. It follows that any two of Equations (2) through (4) imply the third, i.e., they must be equivalent to equations of the form

$$\xi(x) = \eta(y) = \zeta(z) \tag{5}$$

Thus, with each system there is now associated a function, its *empirical temperature function*, such that two systems can be in equilibrium if and only if their *empirical temperatures* (i.e., the values of their empirical temperature functions) are equal. Write $t = \xi(x)$; so that one has the *equation of state* of K_A. Also, t may be introduced in place of any one of the x_k. Note that the empirical temperature is not uniquely determined since $t_A = t_B$ may be replaced by $\phi(t_A) = \phi(t_B)$ where the function ϕ is monotonic but otherwise arbitrary: one has a choice of *temperature scales*. For a system not in equilibrium, temperature is not defined.

The First Law. It is obvious that one can do mechanical work upon a system (say by stirring) while its initial and final states are the same. (Nothing is being said about the surroundings!) In this sense mechanical energy is not conserved. One might, however, hope that it is conserved at least in a restricted class of transitions. That this is so is asserted by the *First Law: The work W_0 done by a system K_0 in an adiabatic transition depends on the terminal states alone*. Thus, if $\mathfrak{S}'(x')$, $\mathfrak{S}''(x'')$ are the terminal states

$$W_0 = F(x'; x'')$$

If $\mathfrak{S}'''(x''')$ is a third state, and the previous transition proceeds via $\mathfrak{S}'''$, W_0 must not depend on x''', i.e.,

$$F(x'; x''') + F(x'''; x'') \equiv F(x'; x'')$$

It follows that there must exist a function $U(x)$, defined to within an arbitrary additive constant, such that

$$F(x'; x'') = U(x') - U(x'')(= -\Delta U, \text{ say})$$

$U(x)$ is the *internal energy function* of K. (To make sure that U is in fact defined for all states, one assumes that *some* adiabatic transition always exists between any pair of given states.) The energy of a compound standard system is the sum of the energies of its constituent standard systems. Further, U must be a monotonic function of t, and it is convenient to choose the scale of t such that $\partial U/\partial t > 0$.

When the transition from $\mathfrak{S}'$ to $\mathfrak{S}''$ is adiabatic, $W_0 + \Delta U$ vanishes by definition of U. If the transition is not adiabatic and W is the work done by K, the quantity

$$\Delta U + W(= Q, \text{ say}) \tag{6}$$

will in general fail to vanish. Q is then called the *heat absorbed* by K. Every element of a quasistatic adiabatic transition is subject to $dQ = 0$, i.e., by Equations (1) and (6), to the differential equation

$$\sum_{k=1}^{n-1} \left(P_k(x) + \frac{\partial U(x)}{\partial x_k} \right) dx_k + \frac{\partial U}{\partial t}\, dt = 0 \tag{7}$$

The Second Law. Experiment shows that if $\mathfrak{S}'$ and $\mathfrak{S}''$ are arbitrarily prescribed states, then it may be that no adiabatic transition from $\mathfrak{S}'$ to $\mathfrak{S}''$ exists. When this is the case one says that $\mathfrak{S}''$ is *inaccessible* from $\mathfrak{S}'$, but $\mathfrak{S}'$ is then accessible from $\mathfrak{S}''$, as has been already assumed. The states may of course happen to be mutually accessible. The existence of states adiabatically inaccessible from a given state is asserted precisely by the *Second Law: In every neighborhood of any state $\mathfrak{S}$ of an adiabatically isolated system there are states inaccessible from $\mathfrak{S}$*. (This formulation of the Second Law is known as the *Principle of Carathéodory*.) *A fortiori* this law applies to quasistatic transitions, i.e., those which satisfy Equation (7). It asserts there are states $\mathfrak{S}''$ near $\mathfrak{S}'$ such that no functions $x_k(t)$ exist which satisfy Equation (7) and whose values when $t = t''$ are just x_k'', $(k = 1, \ldots, n-1)$. It is merely a mathematical problem (the Theorem of Carathéodory) to prove that this is the case if and only if there exist functions $\lambda(x)$ and $s(x)$, $(x_n \equiv t)$ such that the left-hand member is identically equal to λds, where ds is the total differential of s. Thus, the Second Law entails that

$$dQ = dU + dW = \lambda\, ds \tag{8}$$

(dQ is of course not a total differential), s is called the *empirical entropy function of* K. It is not uniquely determined, since it may be replaced by any monotonic function of s. If two standard systems K_A and K_B in diathermic contact make up a compound system K_C; $dQ_C = dQ_A + dQ_B$, i.e., because of Equation (8),

$$\lambda_A ds_A + \lambda_B ds_B = \lambda_C ds_C$$

By including s_A, s_B and the common empirical temperature t among the coordinates of K_C, one infers that

$$\lambda_A = T(t)\theta_A(s_A), \quad \lambda_B = T(t)\theta_B(s_B),$$
$$\lambda_C = T(t)\theta(s_A, s_B)$$

The common function $T(t)$ is called the *absolute temperature function*, while

$$S_A(s_A) = \int \theta_A(s_A)\, ds_A$$

is the *metrical entropy* of K_A. The "element of heat" dQ of any standard system thus splits up into the product of a universal function of the empirical entropy and the total differential $dS(x)$ of the metrical entropy function:

$$T\, dS = dU + dW \tag{9}$$

By multiplying T by a constant and dividing S by the same constant, T can be arranged to be positive.

If one now chooses $x_n = S$ and recalls that the $x_k (k < n)$ are freely adjustable, the Second Law would be violated if S were also adjustable at will (by means of non-static adiabatic transitions). Taking continuity requirements into account, it follows that S can either never decrease or never increase. The single example of the sudden expansion of a real gas shows that it can never decrease. One has the *Principle of Increase of Entropy: The entropy of an adiabatically isolated system can never decrease*.

The Third Law. It is known from experiment that for given values of the deformation coordinates, the energy function has a lower bound U_0. The question rises whether the entropy S has an analogous property. It is found in practice that the specific heats $\partial U/\partial T$ of all substances appear to go to zero at least linearly with T as $T \to 0$. This ensures that the function S goes to a finite limit S_0 as $T \to 0$. Experiment shows, however, further that as $T \to 0$, the derivatives of S with respect to the deformation coordinates also go to zero. In contrast with U_0, S_0 has therefore the remarkable property that it is independent of the deformation coordinates. One thus arrives at the *Third Law: The entropy of any given system attains the same finite least value for every state of least energy*. One immediate consequence of this is that the so-called *classical ideal gas* (the product of whose volume V and pressure P is proportional to T, and whose energy is a function of T only) cannot exist in nature. Further, no system can have its absolute temperature reduced to zero. The Third Law is therefore a statement about the properties of functions, not of systems, at $T = 0$.

The practical applications of the theory just outlined divide themselves into two broad classes: (1) Those which are based on the existence and properties of the functions U and S and some others related to them — all "thermodynamic identities" being merely the integrability condition for the total differentials of these functions; and (2) those which are based on the Principle of Increase of Entropy: the entropy of the actual state of an adiabatically enclosed system being greater than that of any neighboring "virtual" state.

The most important of the auxiliary functions just mentioned are the *Helmholtz Function*:

$$F = U - TS \tag{10}$$

the *Gibbs Functions*:

$$G = U - TS + \sum_{k=1}^{n-1} P_k x_k \tag{11}$$

the *Enthalpy*:

$$H = U + \sum_{k=1}^{n-1} P_k x_k \tag{12}$$

sometimes called *thermodynamic potentials*. Then, e.g.,

$$dF = -S\,dT - dW$$

F therefore contains all available quantitative information about K, since

$$S = -\frac{\partial F}{\partial G}, \quad \text{and} \quad P_k = -\frac{\partial F}{\partial x_k} \tag{13}$$

The same is true of G for instance, since

$$S = -\frac{\partial G}{\partial T}, \quad \text{and} \quad x_k = -\frac{\partial G}{\partial P_k}$$

F and G are naturally taken as functions of $x_1, \ldots, x_{n-1}, T$ and of $P_1, \ldots, P_{n-1}, T$, respectively. At times one speaks of F as the "Helmholtz free energy" and of G as the "Gibbs free energy." In an *isothermal* reversible transition, the amount W of work done by a system is equal not to the decrease of its energy U but to the decrease $-\Delta F$ of its (Helmholtz) free energy. In the presence of internal sources of irreversibility

$$W < -\Delta F$$

In considering physicochemical equilibria, that is to say, if one is interested in the internal constitution of a system in equilibrium when changes of phase and chemical reactions are admitted, one introduces the *constitutive coordinates* n_i^α; this being the number of moles of the ith constituent C_i in the αth phase. The definitions of Equations (10) through (12) remain unaltered, for the n_i^α do not enter into the description of the interaction of the system with its surroundings. Let an amount dn_i^α of C_i be introduced quasistatically into the αth phase of the system. The work done on K shall be $\mu_i^\alpha\,dn_i$. The quantity μ_i^α so defined is the *chemical potential* of C_i in the αth phase. It is in general a function of all the coordinates of K. Then, identically.

$$dG = \sum_{k=1}^{n-1} x_k\,dP_k - S\,dT + \sum_i \sum_a \mu_i^\alpha\,dn_i^\alpha$$

Integrability conditions such as

$$\partial \mu_i^\alpha / \partial T = -\partial S / \partial n_i^\alpha$$

are applications of the first kind. On the other hand, the minimal property of G, derived from the maximal property of S, requires that

$$\sum_i \sum_a \mu_i^\alpha\,dn_i^\alpha = 0$$

when all virtual states differ only in the values of the constitutive coordinates. If the system is chemically inert, the dn_i^α are subject only to the requirements of the conservation of matter. One then concludes that if there are c constituents and p phases, i.e., $n + pc$ coordinates in all, then the number f of these to which arbitrary values may be assigned is

$$f = c - p + n$$

This typical application of the second kind is the Gibbs Phase Rule (for inert systems). This rule is often stated merely for systems with only two external coordinates ($n = 2$, e.g., $x_i = P$, $x_2 = T$). There must then be no internal partitions within the system, nor may it, for instance, contain magnetic substances in the presence of external magnetic fields.

The beauty and power of phenomenological thermodynamics lies just in the generality and paucity of its basic laws which hold independently of any assumptions concerning the microscopic structure of the systems which they govern. Its quantitative content is limited to conditions of equilibrium. Its conceptual framework is too narrow to permit the description of the temporal behavior of systems, except to the extent that it makes it possible to decide which, of any pair of states of an adiabatically enclosed system, must have been the earlier state.

Statistical thermodynamics seeks to remedy these deficiencies by making specific assumptions about the microscopic structure of the system K, and relating its macroscopic behavior to that of its atomic constituents. K is then to be regarded as an *assembly* of a very large number of particles, which, on a non-quantal level, is a mechanical system with, say, N degrees of freedom. A *microstate* of K is a set of values of its N coordinates and its N conjugate momenta. It is out of the question to measure all these at a given time. One therefore constructs a *representative ensemble* $\mathcal{E}_K$ of K, which is an abstract collection of a very large number of identical copies of K. At any time t, the members of $\mathcal{E}_K$ will be in different microstates. Let the fractional number of members of the ensemble whose microstates lie in the range dp, dq about p, be $\phi\,dp\,dq$. Then ϕ is the *probability-in-phase*, and with $d\Gamma = dp\,dq$

$$\int \phi\,d\Gamma = 1 \tag{14}$$

The reason for this terminology is implicit in the *Postulate: The probability that a given assembly K will, at time t, be in a microstate lying in the range $d\Gamma$ about p,q, is equal to the probability $\phi\,d\Gamma$ that the microstate of a member of $\mathcal{E}_k$, selected at random at time t, lies in the same range.*

The mean value $\langle f \rangle$ of a dynamical quantity f is defined to be

$$\langle f \rangle = \int f \phi\,d\Gamma$$

If N is sufficiently large, fluctuations about the mean will usually be negligible.

When K is in equilibrium, ϕ must be constant in time, and this will be the case if it is a function of the (time-independent) Hamiltonian H of K. Ensemble averages are now assumed to coincide with temporal averages. When, in particular, K is in diathermic equilibrium with its surroundings one can show that ϕ must have the form

$$\phi = \exp[(\phi - H)/\phi] \tag{15}$$

where ϕ and θ are independent of p,q. Then

$$\theta \langle \ln \theta \rangle = \phi - \langle H \rangle \tag{16}$$

and, because of Equation (14)

$$d \int \exp[(\phi - H)/\theta]\,d\Gamma = 0 \langle d[(\phi - H)/\theta]$$

where d refers to a variation of the macroscopic coordinates of K. Using Equation (16) and its variation, the relation

$$-\theta d \langle \ln \phi \rangle = d\langle H \rangle - \langle dH \rangle \tag{17}$$

follows. Now $\langle H \rangle$ ($= \overline{U}$, say) is the total energy of the assembly, while $\langle dH \rangle$ is the average of the change of the potential energy, i.e., the work

$-dW$ done by the external forces on K. If one writes

$$\overline{S} = -k\langle \ln \phi \rangle$$

where k is a constant, Equation (17) becomes

$$k^{-1}\theta\, d\overline{S} = d\overline{U} + dW$$

This is identical with the phenomenological relation of Equation (9) if one formally identifies S with $\overline{S}$, U with $\overline{U}$ and θ with kT. In this way, contact with the phenomenological theory has been established, and the quantities characteristic of the one theory have been *correlated* with that of the other. With this correlation, or interpretation, ϕ becomes F. However, because of Equations (14) and (15)

$$F = -kT \ln \int \exp(-H/kT)\, d\Gamma$$

so that if only H is known, the integral on the right (the *partition function*), and thus F, can be calculated. The equation of state of a real gas can thus in principle be obtained from a knowledge of the forces operating within the assembly. This illustrates how the additional information put into the theory yields a correspondingly greater output. Phenomenologically, such an equation of state might be written as

$$PV = \sum_{n=1}^{\infty} B_n(T) V^{1-n}$$

but here each of the *virial coefficients* $B_1, B_2, \ldots$ must be measured separately.

THERMOELECTRIC COOLING. Like conventional refrigeration systems, thermoelectric systems obey the same basic laws of thermodynamics. Both in principle and result, thermoelectric cooling has much in common with conventional refrigeration methods. In a conventional refrigeration system, the main working parts are the freezer, condenser, and compressor. The freezer surface is where the liquid refrigerant boils, changes to vapor, and absorbs heat energy. The compressor circulates the refrigerant above ambient level. The condenser helps to discharge the absorbed heat into surrounding ambient. In thermoelectric refrigeration, the refrigerant in both liquid and vapor forms is replaced by two dissimilar conductors. The freezer surface becomes cold through absorption of energy by electrons as they pass from one semiconductor to another, instead of energy absorption by the refrigerant as it changes from liquid to vapor. The compressor is replaced by a direct current power source which pumps the electrons from one semiconductor to another. A heat sink replaces the conventional condenser fins, discharging the accumulated heat energy from the system.

The components of a thermoelectric cooler are indicated by the cross section of a typical unit shown in Fig. 1. Thermoelectric coolers such as this are actually small *heat pumps* that operate on the physical principles well established over a century ago. Semiconductor materials

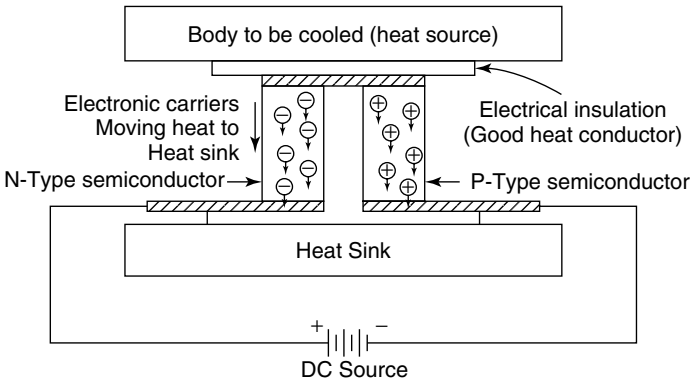

Fig. 1. Cross section of thermoelectric cooler.

with dissimilar characteristics are connected electrically in series and thermally in parallel, so that two junctions are created. The semiconductor materials are n- and p-type and are so named because either they have more electrons than necessary to complete a perfect molecular lattice structure (n-type), or not enough electrons to complete a lattice structure (p-type). The extra electrons in the n-type material and the holes left in the p-type material are called *carriers* and they are the agents that move the heat energy from the cold to the hot junction.

Heat absorbed at the cold junction is pumped to the hot junction at a rate proportional to carrier current passing through the circuit and the number of couples. Good thermoelectric semiconductor materials, such as bismuth telluride, greatly impede conventional heat conduction from hot to cold areas, yet provide an easy flow for the carriers. In addition, these materials have carriers with a capacity for carrying more heat. Only since the refinement of semiconductor materials in the early 1950s has thermoelectric refrigeration been considered practical for many applications.

In practical use, couples are combined in a module where they are connected in series electrically and in parallel thermally. See Fig. 2. Normally, a module is the smallest component available. The user can tailor quantity, size, or capacity of the module to fit exact requirements without procuring more total capacity than is actually required. Modules are available in a variety of sizes, shapes, operating currents, operating voltages, number of couples, and ranges of heat-pumping levels. The present trend is toward a larger number of couples operating at a low current.

Thermoelectric coolers find three basic categories of applications. (1) Use in electronic components; (2) in temperature control units; and (3) in medical and laboratory instruments.

Modules normally contain from 2 to 71 couples with ceramic-metal laminate plates. If modules are to be used in cooling chambers of large components, a total surface area of virtually any size can be made by placing the appropriate number of modules side by side.

The interfaces at the cold junction and the hot junction must be constructed to transfer heat in and out of the module with little difference in temperature. This is accomplished with metal-ceramic laminate plates

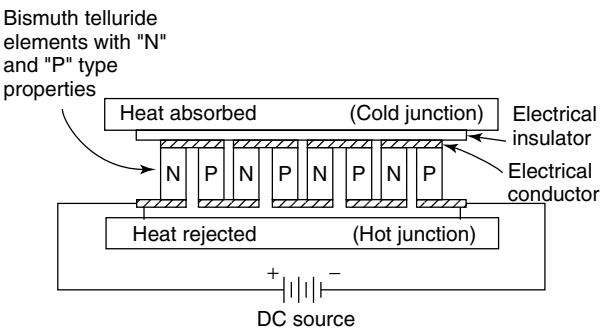

Fig. 2. Thermoelectric module assembly. Elements are electrically in series, thermally in parallel.

that give strength and permit good thermal bonding between the two interfaces. The outer plate surface is usually tinned to facilitate soldering to heat sinks. Where soldering is not practical, as in the case of thermal expansion differences, heat transfer grease is recommended. Epoxy bonding agents are available where a more permanent solderless bond is required.

The single-stage module is capable of pumping heat where the difference in temperature of the cold junction and hot junction is 70°C or less; however, in those applications requiring higher delta T_s, the modules can be cascaded. Cascading is a mechanical stacking of the modules so that the cold junction of one module becomes the heat sink for a smaller module placed on top. In addition to the heat pumped by any given stage, the next lower stage must also pump the heat resulting from the input power to that upper stage. Consequently, each succeeding stage must be larger and larger from the top of the cascade downward.

With any given set of heat sink and cold spot temperatures, there exists an optimum heat-pumping capacity or "size" ratio between each adjacent pair of stages. The optimum size ratio increases as the overall delta T increases, but decreases as the number of stages increases. It is not necessarily a constant from stage to stage, even with delta T and number of stages fixed. True optimization of a cascade design requires accurate temperature-dependent data on the thermoelectric materials in combination with a computerized numerical design theory.

Applications requiring low-temperature thermoelectric coolers usually have strict limitations on available power. Therefore, it is not practical to fabricate and stock numerous different cascades that can be optimized for only one set of conditions. On the other hand, fully optimized prototypes involve engineering and manufacturing costs that may prove uneconomical for some applications. Therefore, a low-cost alternative approach has been developed for responding to such requirements. Standard cascades are fabricated by assembling *partials* of standard modules. The number of different standard cascades is virtually unlimited due to "free" variables, such as number of stages, couple distribution, and the basic building block module. In order to determine the best standard cascade for a given application, the desired hot-side temperature, cold-side temperature, and thermal load are entered into a computer system. The result is a list of numerous standard coolers, which meet these specifications with various combinations of input power and cost. Generally, the lowest input power devices are of higher cost and vice versa.

The heat sink design is very important. The heat sink must carry heat away with minimum rise of temperature. It should be stressed that all the thermoelectric cooler does is to move energy from the load to the heat sink where it must be dissipated to another medium, the latter required to be cooler than the hot junction.

Power supply capabilities for thermoelectric coolers range from the simple open-loop direct current supply with a switch to sophisticated feedback systems with close temperature regulation and fast response. The only limitation on the supply is that ripple be maintained at a point lower than 10 to 15%. Open-loop systems will generally contain a transformer, rectifiers, choke, and chassis with heat sink for the rectifiers. In feedback systems, a thermistor is used to sense temperature at the cold junction. This signal is compared with the desired temperature setting to obtain an error signal.

THERMOELECTRIC ENERGY CONVERSION. Thermoelectric energy conversion is the science of the interchange of thermal and electrical energy in simple solid-state devices, generally heavily doped semiconductors. Figure 1 shows two thermocouples connected in series. If thermal energy is applied at the top of the device from some heat source, and removed at the bottom by a heat sink, an electrical potential appears across the device as indicated by the polarity signs. The size of the ΔT and the basic material properties determine the voltage across the couple. Potential per couple is usually on the order of tenths of a volt. Practical working voltages are obtained by connecting a large number of these thermocouples in series. The amount of current is dependent on the cross-sectional area and length of the legs.

If an electric current were to be passed through the device from an outside source, heat would be absorbed at one junction and released at the other. The device then operates as a solid-state heat pump.

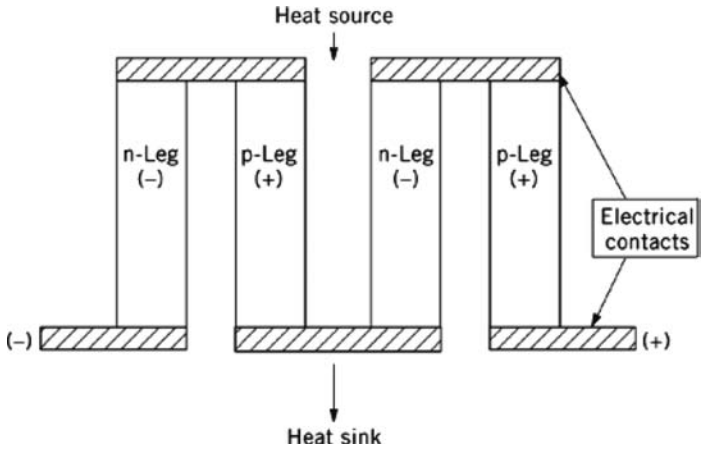

Fig. 1. Schematic of a simple thermoelectric device having two thermocouples in series.

Thermoelectric devices can be used to generate electrical power, to refrigerate, or to transfer large amounts of heat without the use of freons or compressors or any rotating machinery. However, the overall efficiency of these devices is somewhat lower than other systems, and the initial cost is often higher. Mass production, improved design and manufacturing techniques, and an extremely long (decades or more) operating life for many of these solid-state devices should both decrease initial cost and serve to aid in the recovery of the costs over time.

Segmenting of legs to take advantage of the higher performance of certain materials in a given temperature range has been used to increase conversion efficiency. However, this technique is limited because all of the thermal and electrical currents must flow through each segment. Every material has its own optimum current-to-charge (I/q) ratio. Thus in a given segmented couple it is normally impossible to have each segment operating at its own optimum efficiency unless the couple is used at precisely the design hot-and-cold junction temperatures.

In thermoelectric cooling applications, extensive use has been made of cascaded systems to attain very low temperatures, but because the final stage is so small compared to the others, the thermal flux is limited. The relative sizes of the stages are adjusted to obtain the maximum ΔT. Thus, for higher cooling capacity, the size of each stage is increased while the area ratios are maintained.

A number of good references have been published on thermoelectric energy conversion, the first in 1957. The most current materials research and device design work is presented annually in two conferences: the International Conference on Thermoelectrics, sponsored by the International Thermoelectric Society, www.its.org/ and the Intersociety Energy Conversion Engineering Conference (IECEC), which is hosted on a rotating basis by seven cooperating technical societies: American Chemical Society (ACS), www.acs.org/, American Institute of Aeronautics and Astronautics (AIAA) www.aiaa.org/, American Institute of Chemical Engineers (AIChE), www.aiche.org/ American Nuclear Society (ANS), www.ans.org/, American Society of Mechanical Engineers (ASME), www.asme.org/, Institute of Electrical and Electronics Engineers (IEEE), www.ieee.org/, and Society of Automotive Engineers (SAE) www.sae.org/.

The basic ideas of thermoelectricity have been known for nearly two centuries, but until well after the Second World War the primary use was for temperature measurement using metallic wires. Then, upon improvements in semiconductor technology, thermoelectric power generation and refrigeration came under serious consideration.

In 1822 Seebeck began to study the magnetic polarization of metals and ores produced by a temperature difference. His goal was to prove that the earth's magnetic field arose from temperature differences between the equator and the poles. The extensive data collected laid the foundation for later development, even though Seebeck himself had steadfastly refused to believe that the magnetic fields observed in the experiments came from the electric current flowing as a result of the electrical potentials generated by the temperature differences in the circuits of dissimilar materials.

The second principal thermoelectric effect was discovered by Peltier in 1834, who reported the production or absorption of heat at the interface of two dissimilar conductors when an electric current was passed through them. The significance of this discovery was misinterpreted, however. Peltier thought that Joule heating (I^2R) only occurred with strong electrical currents. It was not until 1838 that Lentz finally gave the correct interpretation of the Peltier effect. He provided a phenomenological demonstration by placing a drop of water at the junction of bismuth and antimony rods and caused it to freeze or melt, depending on which direction an electrical current was made to flow through the rods.

In 1857, Thomson (Lord Kelvin) placed the whole field on firmer footing by using the newly developing field of thermodynamics to clarify the relationship between the Seebeck and the Peltier effects. He also discovered what is subsequently known as the Thomson effect, a much weaker thermoelectric phenomenon that causes the generation or absorption of heat, other than Joule heat, along a current-carrying conductor in a temperature gradient.

In 1919, electrical power generators using these effects were attempted. Metallic components were used, which caused the efficiencies to fall well below one percent. These generators were not economically justifiable. However, the rapid growth of semiconductor theory brought a renewed interest in these devices. Practical power generators having from 6 to 11% efficiency were developed, which were especially useful for remote terrestrial and space applications. Indeed, radioisotope thermoelectric generators proved to be an enabling technology for deep-space exploration programs to the outer planets and beyond.

THERMOELECTRICITY. Electricity produced directly by applying a temperature difference to various parts of electrically conducting or semiconducting materials. Usually two dissimilar materials are used, and the points of contact are kept at different temperatures (Peltier effect). Many temperature-measuring devices (thermocouples, thermopiles) work on this principle, since the voltage is proportional to the temperature difference. Metallic conductors are usually used for these (thermometers," which produce a rather small current. A newer use for the effect is as a source of electrical energy, i.e., a means of direct conversion of heat into electricity (or vice versa) without the use of a generator (or motor). The materials used for these thermoelectric couples are semiconductors (e.g., tellurium, zinc antimonide; lead, bismuth, and germanium tellurides; samarium sulfide) or thermoelectric alloys, all of which produce relatively large currents. Several of these "cells" are then hooked in series much like the cells of a battery.

THERMOFOR PROCESS. A moving-bed catalytic cracking process in which petroleum vapor is passed up through a reactor countercurrent to a flow of small beads or catalyst. The deactivated catalyst then passes through a regenerator and is recirculated.

THERMOGRAPH. A self-recording thermometer. The thermometric element is most commonly either a bimetal strip or a Bourdon tube filled with a liquid. In the first case the bimetal element has the form of a helical coil with one end rigidly fastened to the instrument and the other to the recording pen. In the second case the tube is made with an elliptical cross section so that an expression of the liquid caused by a temperature increase will cause the radius or curvature of the bend to increase, thus moving the instrument pen, which is fastened to the tip of the tube. A resistance thermometer and a thermoelectric thermometer may be converted into thermographs if provision is made to record their output.

THERMOGRAPHY. Thermography or thermal imaging is the technique of detecting spatial and time variations of radiated heat energy and transforming them to a visible display. The equipment, called the sensor, consists of an (IR) camera connected to a television and video tape recorder. The heart of the ir camera is an array of infrared detectors sensitive from visible to at least 5 μm and preferably to 14 μm wavelength. The detector array and a set of optics provide for two-dimensional spatial resolution of the thermal scene. The high speed response of the sensor results in "real time" television displays. Since thermal radiation is a function of emissivity and temperature a calibrated thermographic sensor can remotely measure the surface temperature of objects. When the camera is coupled to a spectrometer or narrow band filters the sensor is capable of spectral discrimination. Thus thermography can become both spatial radiometry and spectral imaging. The major trades-off in sensor design are typically among spatial resolution, spectral resolution, field of view, frame time and scene-temperature sensitivity.

The development of thermography began in the 1950s using either uncooled but low sensitivity bolometers or InSb photodiodes cooled to 77 K. These sensors had single detector elements, two axes scanning, large scanning mirrors, approximately 0.2 K sensitivity and a frame time exceeding 2 minutes. Adaptation to medical diagnosis was difficult because the patient was not allowed to move during the long frame time. During the 1960s linear arrays of mercury-doped germanium detectors (240 elements cooled to 35 K) were used for higher sensitivity and frame times of less than 0.1 seconds. With smaller optics, one axis scanning and a television-like display these machines were the first thermal imaging cameras. The military versions were called "forward looking infrared" or flir because heretofore military infrared with a single detector was primarily aerial reconnaissance with the airplane's motion providing one dimension of the scan. The linear array eliminated the need to move the entire airborne sensor to get a picture. During the 1970s linear detector arrays made from HgCdTe provided good sensitivity with only 77 K cooling and led to the military "Common Module" concept for lower cost, smaller size and television-like display.

From the early 1980s to present, infrared sensitive two dimensional arrays were mated to integrated circuits for signal processing and sensitivity to better than 0.03 K. These focal plane arrays of some 500 by 500 elements eliminate the need for scanning and provide good spatial resolution. Some versions have no special cooling requirements. The development trend is to increase the number of pixels to improve resolution, increase the field of view and keep the size and cost of the optics within acceptable bounds.

With reduced sensor cost the range of applications now includes thermal vision industrial processing, industrial security, police work, maritime safety, airline safety and vision enhancement for night driving and flying and weather satellites. For these applications, the thermal sensor typically uses a broad spectral band to achieve highest sensitivity.

The infrared lens is often coated silicon, germanium, or an infrared glass. The ir window may also be an interference filter made of materials similar to the lens. The detector array is an integral part of the silicon integrated circuit read-out chip and contains circuits which buffer (impedance match), and switch to sequentially output the detector signals. Signal processing on the focal plane is limited to buffering, switching (multiplexing), and amplification. Typically, the focal plane signal is an analog of the photon intensity variations. The analog signals are converted to a digital format (A/D conversion) for signal processing which may consist of gain and offset corrections (for uniformity), contrast enhancement, resolution vs sensitivity tradeoff, frame addition, freeze frame (snap-shot or frame-grabbing), dithering for reduction of aliased signals, data compression for transmission, false color renditioning, and many other processing techniques. The digital signal level is typically near one volt and as such is not readily corrupted by electromagnetic interference. Although it is desirable to put the A/D converter on the focal plane for maximum noise immunity the power needed to convert at high data rates would overheat the focal plane.

In situations where sufficient thermal radiation is available the spectral band can be narrowed (by filters or spectrometer) with only a proportional reduction in sensitivity. When the spectral band is narrowed to a particular absorption band of a given chemical substance the spatial distribution and temporal variation of that substance may be measured as was done in the visible by astronomers (scanning slit spectrographs) for many years. Infrared focal plane array technology is making possible spectrographic imaging in the infrared portion of the electromagnetic spectrum which is rich in molecular absorption lines. This will have a major impact on industrial processing where control of the chemistry is essential for cost reduction and safety. The potential applications are detection and source location of toxic gases, monitoring chemical manufacturing processes on a real-time basis, remote temperature profile sensing, automobile exhaust gas monitoring and measuring the location and degree of chemical leaks in production or storage. Spectral thermography will help detect and control toxic atmospheric gases such as CO, N_xO, SO_x, NH_4 and ozone. A thermographic sensor with an integral gas sampling tube is a spot sensor and that with a remote heat source or retro-mirrors performs remote sensing.

The various types of detectors available for measuring infrared radiation are described in entry on **Infrared Radiation**.

Applications

Thermography as a night vision tool in the nonmilitary sector is being used by law enforcement agencies to detect the movement of suspects in the complete dark. In fact contraband discarded by suspects in flight have been detected and recovered using their latent heat signature acquired by body contact. Sensors are finding use by rescue services looking for survivors floating in the water at night. Since the average adult body even at rest has the energy consumption of a 100 W light bulb and emits 30% of its radiation in the 8 to 12 μm spectral band, the lightly clothed human is a bright thermographic source. All mammals are easy to detect in relatively clear weather making it easier to count livestock at night than in daylight.

Thermal imaging is under development as nighttime vision enhancement for drivers of trucks and automobiles. When perfected the driver will have a display projected on the windshield (heads-up display) showing the forward view as seen by the infrared camera. Distant vision will be similar to daylight viewing. Humans and animals approaching the roadway will be readily seen and there will be no glare from street light or even oncoming headlights. Thermal vision in rain and fog will be better than unaided, but infrared absorption and scattering by water droplets will still greatly reduce penetration. Although thermal imaging is common in military aircraft, commercial airlines have been slow to introduce it because of the high cost of the airborne version. It is being used by a few airlines to help with collision avoidance and landing in light fog.

Efforts have been made to evaluate human trauma caused by disease and injury using thermal imaging. Investigations continue by medical schools to make thermography an early screening tool for the detection of kidney disease and breast cancer. A cancer in its early stages grows quickly creating a small amount of excess heat which appears as a bright spot on a thermograph display. Since only one breast is likely to be affected at the early stage, the radiologist looks for thermal pattern asymmetry in comparison of one breast to the other. However complications caused by blood vessels near the skin and weak response to deep lesions, have led to unacceptably high false-positive and false-negative detection as determined by the medical community.

Industrial use of thermal imaging typically is the detection of thermal anomalies such as leaking pipes and valves, overheating boilers, transformers and power lines, and friction generated heat in bearings. These are simple heat detection applications but the imaging process quickly locates the problem in the three-dimensional industrial environment. The ir camera is scanned like a TV camera and the output signal is digitized for evaluation by a programmed computer than compares the output of each frame with a calibrated reference frame. An alarm declares when a thermal anomaly is detected. Defects in materials and circuit boards can be detected by the associated discontinuities in thermal conduction.

Spectral identification of gases in industrial processing and atmospheric contamination is becoming an important tool for process control and monitoring of air quality. The present optical method uses the ftir (Fourier transform infrared) interference spectrometer having high resolution ($<1\ cm^{-1}$) capability and excellent sensitivity (few ppb) with the use of cooled MCT (mercury–cadmium–telluride) detectors.

Spectral monitoring for chemical process control has been demonstrated for semiconductor integrated circuit manufacture and detection of contamination of processing gases and liquids. Open path or remote ir sensing is used to monitor workplace gas and vapor exposures, emissions from hazardous waste sites and to track emissions along fence lines. Aerosol analysis by infrared spectroscopy are used to set mass detection limits and spectral quality. The removal of NO_x has been monitored by analysis of the by-products of the process using ir spectroscopy. Ir spectroscopy will be an important process control technique when the system cost is significantly reduced.

THERMOGRAVIMETRIC ANALYSIS. This analytical technique (TGA), also sometimes referred to as thermogravimetry, is a method whereby the weight and temperature of a sample under test are continuously recorded as the sample is heated at a constant and linear rate. The heating, usually within the range from ambient up to 1,100 or 1,500 °C, is achieved by a furnace, which surrounds, but does not touch, the sample. Thus, the sample remains freely suspended from the balancing mechanism, which is actuated as the sample mass alters in response to chemical reactions produced as its temperature is progressively increased. Weight-loss curves are preferably produced by means of an X-Y recorder. Of course, the term *weight-loss* must be used with reservation because in some atmospheres a sample may gain weight. Indirectly, TGA information can be applied to studies of rates of reaction and energies of activation for the reaction, sublimation, or vaporization of chemical compounds and minerals. Weight gains are caused by the adsorption and absorption of gases by solid samples, direct reaction as in oxidation, corrosion, recarbonation, and hydration, or the reaction of gases to produce solids. Conversely, weight losses are produced by the desorption of gases, dehydration, vaporization, sublimation, gaseous desolvation, and gas-liberating reactions of both organic and inorganic substances. Specific fields that have widely used TGA include: studies involving the thermal stability of minerals and mineral mixtures; the pyrolysis of coals, petroleum, and cellulose; the analysis of soils; roasting and calcining; thermochemical reactions of ceramics and cements; dehydration hygroscopicity studies; solid-state reactions; effect of radiation on various materials; corrosion studies; and the detection of short-lived unstable intermediate compounds.

THERMOGRAVITATIONAL COLUMN. See **Diffusion**.

THERMOHALINE CIRCULATION. The thermohaline circulation is a term for the global density-driven circulation of the oceans. Derivation is from *thermo-* for heat and *-haline* for salt, which together determine the density of sea water. It is driven by the fluxes of heat and freshwater at the ocean surface. The freshwater flux affects salinity, and both temperature and salinity changes cause density changes that drive the thermohaline circulation. The present-day forcing consists of cooling and net precipitation in high latitudes, warming and evaporation in subtropical latitudes; note the opposing effects on density. The present-day thermohaline circulation consists of 1) sinking of strongly cooled, moderately saline water in relatively small regions located in areas of relatively strong winter cooling; 2) deep flow throughout the global ocean

basins; and 3) slow upwelling toward the surface. Its transport is small compared to wind-driven transport, but it is believed that the thermohaline circulation is responsible for much of the heat transported by the ocean. See also **Gradient Current**; and **Upwelling**.

THERMOMETER. An instrument that measures temperature. A thermometer may take advantage of one of several physical properties of materials that change when they are subjected to a change in temperature. Liquids, gases, and solids expand with increasing temperature; decrease in volume with decreasing temperature. Thus, there are liquid-in-glass thermometers, which depend upon the volumetric relation of mercury or other liquids with temperature. The difference in the energy radiating from materials at various temperatures is the basis of optical and radiation pyrometers. Bimetallic thermometers depend upon the differing expansiveness of different metals. Changes in electrical resistance with temperature are utilized in resistance thermometers and thermistors. Thermocouples depend upon the Seebeck, Peltier, and Thomson effects, wherein the emf in an electrical circuit comprising dissimilar metals bears a relationship to the temperature difference between a cold junction and the temperature being measured.

Several kinds of thermometers are described in this volume. See alphabetical index.

THERMOMETER (Filled-System). A representative filled-system thermometer is shown in Fig. 1. The temperature-sensing element (bulb) contains a fluid that changes its volume or pressure with temperature. The pressure-sensitive element (bourdon) responds to these changes by delivering a motion or force to a device that transduces the signal to a usable form. This is commonly a mechanical linkage which drives a pointer or pen, but may be a pneumatic or electric device which transmits the temperature signal over long distances. These signals frequently are used for process control purposes.

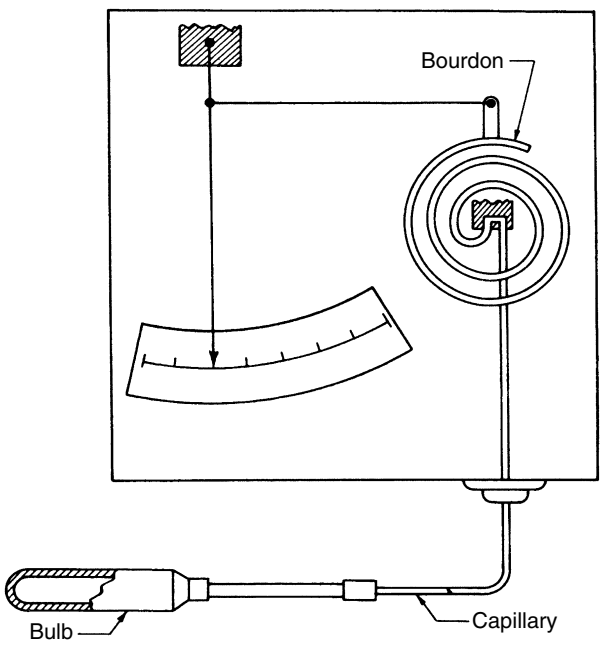

Fig. 1. Filled-system thermometer.

Filled-system thermometers may be placed into one of two fundamental categories: (1) Those in which the bourdon responds to a volume change; and (2) those in which the bourdon responds to a *pressure change*. Those that respond to volume changes are completely filled with a liquid. The variation in liquid expansiveness with temperature is greater than that of the bulb metal, the net volume change being communicated to the bourdon. In this design, an internal-system pressure change is not of primary importance. In those systems that respond to pressure changes, the bulb is either filled with a gas, or partially filled with a volatile liquid. Changes in gas or vapor pressure with changes in bulb temperature are communicated to the bourdon. The bourdon will increase in volume with increase in pressure, but in this design, this effect is not of primary importance.

In liquid-filled thermal systems, mercury or various organic fills are used. In vapor-filled systems, a number of hydrocarbons, including ethane, ethyl chloride, ethyl ether, chlorobenzene, and propane, among others, are used. Nitrogen or other fully-dried and purified gases may be used in a gas thermometer.

THERMONEUTRAL ZONE. See **Meteorology**.

THERMOPHONE. An electroacoustic transducer in which sound waves of calculable magnitude result from the expansion and contraction of the air adjacent to a conductor whose temperature varies in response to a current input. When used for the calibration of pressure microphones, a thermophone is generally used in a cavity, the dimensions of which are small compared to a wavelength.

THERMOPILE. A transducer for converting thermal energy directly into electrical energy. It is composed of pairs of thermocouples that are connected either in series or in parallel. The output voltage of N pairs of series-connected thermocouples is N times the voltage developed by a single pair, while the current developed by N pairs of parallel connected thermocouples is N times the current developed by a single pair. Thermopiles are used in thermoelectric radiation instruments when the output of a single pair of thermocouples is not large enough. See also **Thermocouple**.

THERMOPLASTIC. A high polymer that softens when exposed to heat and returns to its original condition when cooled to room temperature. Natural substances that exhibit this behavior are crude rubber and a number of waxes; however, the term is usually applied to synthetics such as polyvinyl chloride, nylons, fluorocarbons, linear polyethylene, polyurethane prepolymer, polystyrene, polypropylene, and cellulosic and acrylic resins.

See also **Plastics**.

THERMOSET. A high polymer that solidifies or "sets" irreversibly when heated. This property is usually associated with a cross-linking reaction of the molecular constituents induced by heat or radiation, as with proteins, and in the baking of dough. In many cases, it is necessary to add "curing" agents such as organic peroxides or (in the case of rubber) sulfur. For example, linear polyethylene can be cross-linked to a thermosetting material by either radiation or chemical reaction. Phenolics, alkyds, amino resins, polyesters, epoxides, and silicones are usually considered to be thermosetting, but the term also applies to materials in which additive-induced cross-linking is possible, e.g., natural-rubber.

THERMOSPHERE. The atmospheric shell extending from the top of the mesosphere to outer space. It is a region of more or less steadily increasing temperature with height, starting at roughly 100 kilometers (62 miles). The thermosphere includes, therefore, the exosphere and most of the ionosphere. See also **Atmosphere (Earth)**.

THERMOSTATIC BIMETAL. See **Bimetal Thermometer**.

THERMOTROPIC ATMOSPHERE. See **Atmosphere (Earth)**.

THERMOTROPIC MODEL. See **Meteorology**.

THETA FUNCTION. Four functions of infinite series, written in terms of $q = e^{\pi/\tau}$, where τ is a complex number having its imaginary part positive. A representative theta function is

$$\theta(z, q) = 1 + 2\sum_{n=1}^{\infty} qn^2 \cos 2nz$$

They are related to elliptic functions and are especially useful in making numerical calculations with such functions. See also **Elliptic Integral**; **Jacobi Elliptic Function**; and **Weierstrass Function**.

THETA PINCH. See **Nuclear Reactor**.

THEVENIN THEOREM. The current in any terminating impedance Z_T connected to any network is the same as if Z_T were connected to a generator whose voltage is the open circuit voltage of the network, and whose internal impedance Z_R is the impedance looking back from the terminals of Z_T, with all generators replaced by impedance equal to the internal impedance of these generators.

THICKENER (Food). See **Additives (Food)**.

THICKENER (Process). See **Classifying (Process)**.

THICKENERS. Thickeners are widely used, particularly in the mineral processing industry and in wastewater treatment. Typical applications include thickening of alumina red mud, alumina hydrate, coal tailings, copper middlings and concentrate, magnesium hydroxide, china clay (kaolin), phosphate slimes, potash slimes, pulp-mill wastes, and gas-washing effluents. In hydrometallurgical installations, thickeners are employed for the separation of dissolved components from leached residues in countercurrent washing configurations, e.g., in copper, uranium, alumina, and precious metals production.

The most widely used conventional thickeners in metallurgical and mineral processing applications give solids fluxes (mass flow rate of solids per unit area) in the range of 0.011–0.022 kg/($m^2 \cdot s$). The conventional thickeners are constructed of steel (~25-m diameter(~82-ft) or concrete (<200-m diameter (<656-ft). The floor is usually sloped toward the underflow discharge in the center. Large thickeners have earth bottoms. Raking mechanisms turning slowly around the center column consolidate the solids in the compression layer and facilitate the discharge of solids. Smaller basins can be covered for conservation of heat or to prevent freezing.

The center-drive mechanism and feed launder are usually supported by a walkway that extends across one-half or the whole diameter of the basin. Devices having drive mechanisms and rakes supported by a truss across the diameter of the thickener are referred to as bridge machines. The bridge thickeners usually do not exceed 25–45 m (82–148 ft) in diameter. In thickeners with larger diameters, the drive mechanism is supported by a central column or pier and the rates are driven and supported by a drive cage. The sediment is discharged into an annular trench around the bottom of the column.

In even larger caisson thickeners, the central column is sufficiently large to accommodate a discharge pump at the bottom. The discharge passes through the column and along the access walkway above the basin. Caisson thickeners can be built having diameters of up to 200 m (656 ft). These often have an earth bottom.

The rake arms are driven by fixed connections or dragged by cables or chains suspended from a drive arm that is rigidly connected to the drive mechanism. The rake arms are connected to the bottom of the central column by a special arm hinge that allows both horizontal and vertical movements. This arrangement lifts the rakes automatically if the torque becomes excessive. The drive arm can be attached below the suspension level or, if scaling is a problem, above the basin.

The traction thickener includes a traction mechanism where the movement of the rake is supplied by a single long arm pivoted around the center column and driven by a trolley that moves on a peripheral rail around the basin. Such units have diameters of 60–130 m (197–427 ft).

The most common thickener is the circular basin type. After treatment with flocculant, the feed stream enters the central feed well that dissipates the stream's kinetic energy and disperses it gently into the thickener. See also **Flocculating Agents**. The feed finds its height in the basin, where its density matches the density of the inside suspension and spreads out at that level. Solids concentration increases downward in an operating thickener giving stability to the process. The settling solids and some liquid move downward. The amount of the latter depends on the underflow withdrawal rate. Most of the liquid moves upward and into the overflow that is collected in a trough around the periphery of the basin.

A typical thickener has three operating layers: clarification, zone-settling, and compression. Frequently, the feed is contained in the zone-settling layer that theoretically eliminates the need for the clarification zone because the particles would not escape through the interface. In practice, however, the clarification zone provides a buffer for fluctuations in the feed and the sludge levels.

The most important design dimensions of a thickener are pool area and depth. The pool area is chosen to be the largest of the three layer requirements. In most cases, only the zone-settling and compression layer requirements need to be considered. However, if the clarity of the overflow is critical, the clarification zone may need the largest area. As to the pool depth, only the compression layer has a depth requirement because the concentration of the solids in the underflow is largely determined by the time detention and sometimes by the static pressure. Thickness of the other two layers is governed only by practical considerations.

Improved application of flocculating agents has resulted in several other high capacity thickeners capable of handling fluxes up to 0.19–0.38 kg/($m^2 \cdot s$). A good example is the deep-cone thickener developed by the National Coal Board (NCB, U.K.) http://www.staffspasttrack./org.uk/exhibit/coal/default.htm. It is based on the deep-cone vessel used for the processing of coal and metallurgical ores since the turn of this century. The vessel is equipped with a slow-turning stirring mechanism (2 rpm) that enhances flocculation in the upper part and acts as a rake in the lower section. The unit is used for densification of froth-flotation tailings at overflow rates from 6.5 to 10 m/h; the final discharge contains 25–35 wt % moisture. Other commercial deep-cone thickeners are of particular advantage, as is the NCB unit, where the final underflow density is increased by the large weight of solids above the discharge point, e.g., with flocculated clays.

An unraked version of the deep-cone thickener was developed for the thickening of red mud, the insoluble residue from caustic digestion of bauxite in the Bayer process, in a countercurrent decantation system. The deep-cone units are the last two in a nine-stage system. Whereas these are smaller in diameter for the same solids throughput, they are able to produce thicker underflows than the remaining seven conventional, raked thickeners. This greater thickening translates into fewer stages needed for the same washing, and thus represents a further space saving.

There are two U.S. thickeners based on feeding the slurry under the settling–solids interface (sludge blanket) in a way similar to the sludge-blanket clarifiers described. These also offer other features designed to accelerate flocculation and thus increase the capacity. In the Eimco Hi-Capacity thickener, the feed is introduced from the top through a hollow shaft that incorporates flocculant addition and a mixing device. The feed is then directed into the established sludge blanket under the sludge line

that partially submerges a set of inclined settling plates. The settled solids are moved by a conventional raking mechanism at the bottom of the basin.

In the Enviro-Clear thickener, the flocculated feed enters vertically from the bottom and is directed horizontally at a controlled velocity into the sludge blanket by an impingement plate. A number of other arrangements are also available. The feed can, eg, enter from the top through a center well surrounding the rake driveshaft. A glass window allows visual observation of the sludge line. Available unit sizes range from 4 to 18 m (13 to 59 ft) with typical overflow rates from 2.4 to 14.4 m/h (8 to 47 ft/h). The applications include sugar and paper production, and mineral processing.

Stacking of sedimentation units in vertical arrangements increases the capacity per unit area. Multiple compartment or tray thickeners consist of two or more conventional thickener compartments up to 35 m (115 ft) in diameter stacked vertically. Each compartment has a set of raking arms operating from a rotating central shaft common to the whole stack. The compartments are used either in series or parallel.

Another development in this category is the Swedish Lamella thickener, which consists of a number of inclined plates (flat or corrugated) stacked closely together. The flocculated feed enters the stack from the side feed box. The flow moves upward between the plates while the solids settle onto the plate surfaces and slide down into the sludge hopper underneath, where they are further consolidated by vibration or raking. Even distribution of the flow through the plates is assisted by flow-distribution orifices placed in the overflow exit. In theory, the effective settling area is the sum of the horizontal projected areas of all plates. In practice, only ∼50% of the area is utilized. When treating sticky sludges, the whole Lamella pack can be vibrated intermittently or continuously to assist the sliding motion of the solids down the plates. In some instances, the plates are corrugated instead of flat or they are replaced by tube bundles in the tube settler; these tubes are square and have a cross-section of $\sim 50 \times 50$ mm^2 ($\sim 2 \times 2$ in^2) and are 950 mm (37 inches) long. The Lamella thickener and the tube settler are used in the treatment of coal, gas-scrubber effluents, fly ash, leach solutions, and many other applications. In coal concentration, the typical overflow rates range from 1.7 to 2.9 m/h (5.6 to 9.5 ft/h).

The Lamella principle has also been extensively used in immiscible liquid–liquid separation, where such units are better known as tilted plate separators. The plates, which can again be either flat or corrugated (with the corrugations running down the sloping surface), also provide surfaces where coalescence of the dispersed phase can take place. The actual configuration of such units has to be somewhat different from those for solid–liquid separation, in order to accommodate the necessary collection–skimming of the light component, such as in oil from water applications.

An interesting variation on the theme of the Lamella principle in oil–water separation is the Vertical Gravity Separator VGS from Axsia Mozley company of the NATCO Group. Instead of a pack of flat parallel plates, it uses a conical spiral plate pack in a vertical cylindrical vessel. In parallel plate units for solid–liquid separation, another development reported is in making the plates into electrodes so that the settlement rates are enhanced by electrophoretic mobility of the particles. Finally, the overflow rates of the Lamella and tilted plate settlers can also be increased by installing, within the same unit, a deep bed filter in series with the plate pack.

THICKNESS CHART. See **Meteorology**.

THICKNESS MEASUREMENT AND GAGING SYSTEMS. The requirement to measure and control material thickness appears in numerous industries, particularly those situations involving sheets, webbed materials, and precisely made parts. Thickness and related dimensions may be measured in several ways, including: (1) pneumatic gaging, (2) electric and electronic gaging, (3) nuclear-radiation gaging, (4) ultrasonic thickness gaging, and (5) x-ray thickness gaging, among others.

Pneumatic Gaging. A pneumatic gaging system consists essentially of components that provide a constant-pressure air supply, an indicating means, and a metering orifice. The principle of operation is based on the effects of varying the flow of air from the metering orifice. See also **Pneumatic Controller**; and **Transmission (Pneumatic).** For example, as flow from the orifice is obstructed, pressure in the system will build up to the regulated valve, and flow through the system will drop. Over a significant range of values in such a gaging system, there exists a linear relationship between flow or pressure and the size of the escapement orifice. In many gaging applications, the linear relationship is equated to the clearance that separates a sized metering orifice and an obstruction. The indicating component shows the change in flow or pressure in terms of a linear measurement. The orifice obstruction can be either the workpiece being gaged or an integral part of the gage spindle. An example of the first is found in the gaging of a bore by inserting a gaging spindle containing two diametrically opposed orifices through which air is flowing. Here, there is no contact between the gaging spindle and the part being measured; the closeness of fit serves as the obstruction. In the second kind of gage, the gage spindle includes a component that mechanically contacts the work being measured. Movement of this component relative to a sized orifice affects air flow and establishes the basis for measurement. The kinds of measurements that can be made by different orifice arrangements are illustrated in Fig. 1.

Electric and Electronic Gaging. The use of air jets in pneumatic systems has many advantages because, to some degree, the concept does approach universality of application, not being severely affected by temperature, vibration, and other ambient conditions. In one widely used electrical system, the gage head contains two coils with a sintered iron core centered between them. This core is attached to the gage spindle and moves axially, as shown in Fig. 2. Its position relative to the coils affects the impedance of the coils. The coils and a symmetrical transformer in the oscillator form a bridge. When the core rests equally between the two coils, the bridge is balanced and the output signal from the gage head is zero. When the core is displaced, the impedance of the coils is changed. The impedance of one coil is reduced while that of the other is increased, which generates a signal in proportion to the amount of displacement of the core. The signal then is amplified, rectified, and indicated on a direct current meter, which is calibrated in units of length. Typical applications include checking roundness, concentricity, parallelism, thickness, cam contours, tapers, flatness, and squareness — without requiring precision fixturing.

Nuclear-Radiation Thickness Gaging. Noncontact gaging techniques are required for several applications — for example, thickness control of paper and plastic sheeting. As shown by Fig. 3, the basic single-head gage holds a beta radioisotope source beneath the sheet to be measured and a detector cell above. The gage can measure a single point or scan the sheet automatically. Transmitted radiation is converted into an electric current

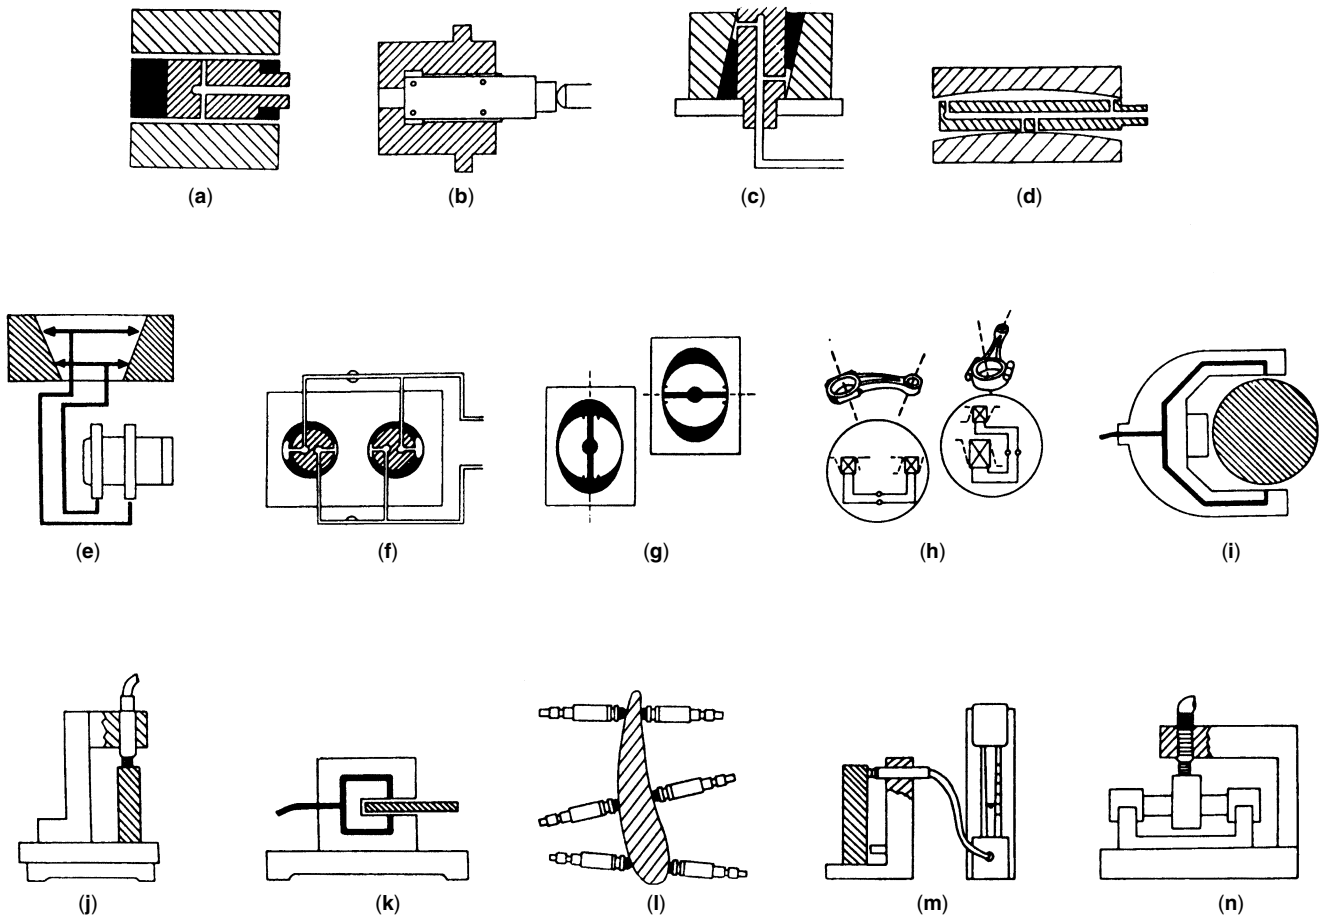

Fig. 1. Basic applications of pneumatic gages: (**a**) two diametrically opposed open jets check true diameter of holes having tolerances of 0.005-inch (< 0.1 millimeter or less); (**b**) contact-type gaging head for measuring diameters of interrupted bores and bores with keyways; (**c**) spindle with opposed open orifices spaced longitudinally to check squareness of a bore axis with a face; (**d**) camber or straightness of hole is checked by rotating through 180⟩ a spindle having four jets; (**e**) taper is indicated as any spindle is passed through a bore; (**f**) center distance between holes is checked by a fixture with two spindles, each having two opposed jets; (**g**) out-of-round is indicated when any spindle is rotated through 90⟩; (**h**) parallelism of holes is indicated by combining two spindles of type used in squareness checking; (**i**) outside diameter is checked by two opposed standard jets; tolerance usually 0.002 inch (0.05 millimeter) or less; (**j**) height, width, or depth can be measured by a suitably fixtured contact-type gaging head; (**k**) thickness gage for thin parts and items having close tolerance incorporates two opposing standard jets; (**l**) multiple-contact-type gage heads mounted in a suitable fixture for checking contour; (**m**) squareness of surfaces for close-tolerance parts having good surface finish can be checked by a fixtured spindle; and (**n**) concentricity can be indicated by one or more contact-type spindles mounted in a suitable gage fixture.

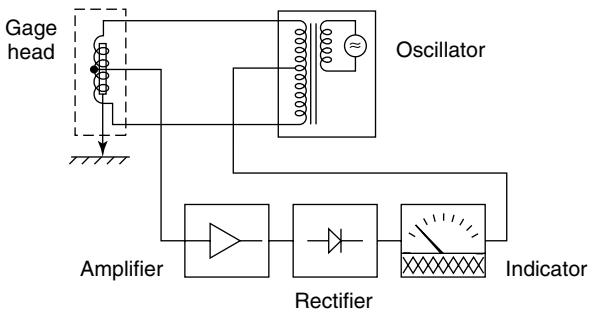

Fig. 2. Impedance-type gaging system.

and amplified for readout or automatic control. Calibration is usually in terms of basis weight (weight per unit area).

Nuclear fluorescence is also used. This system measures only coating weight regardless of base material hardness or thickness.

Ultrasonic Thickness Gaging. These gages find extensive application in the measurement of wall thickness and are useful in measuring most structural materials that will transmit sound. Almost all metals, plastics, and ceramics, and various composite materials can be measured this way.

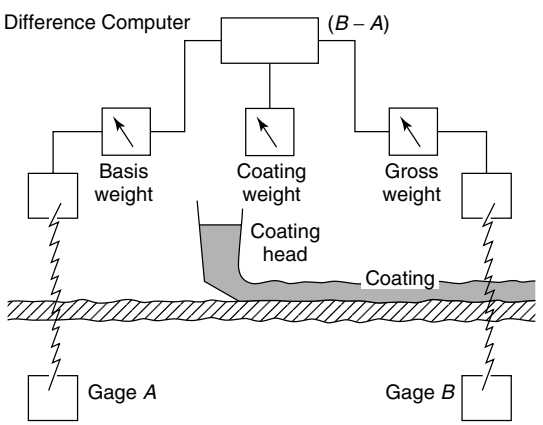

Fig. 3. Double-gage beta-radiation system for control of coatings on paper, textiles, and plastics. (*Ohmart*.)

Measurements are instantaneous and can be made from one side of the part. Suitable transducer configurations also permit readings at elevated temperatures for determination of corrosion losses in chemical equipment while "on stream."

Ultrasonic gages utilize ultrasonic vibrations, most commonly in the portion of the frequency spectrum between 1 MHz and 15 MHz. Sound waves in these frequencies have certain characteristics which make them suitable for making measurements and finding defects. The sound beam can readily pass through most structural materials. It will reflect from acoustic boundaries, either internal flaws or geometric boundaries, such as the back surface of the part. Sound travels at characteristic velocity in the material, and this permits timing of the wave propagation through the material.

The basic element of an ultrasonic gaging system consists of a *generator* to produce the high-frequency electronic vibrations that, in turn, activate the crystal *transducer*. The transducer converts the electric signals to mechanical vibrations, or ultrasound; and these are introduced into the part. Echoes from various boundaries in the part are picked up by the same transducer and are reversibly converted from mechanical vibrations to an electric signal. This is further amplified and processed, and the information is displayed on one of several types of data presentations.

There are two categories of ultrasonic gages: (1) *resonance*, and (2) *pulse-echo*. Each has distinct electronic characteristics and readout methods. Both are dependent on transmission of the acoustic waves, reflections, and velocity in the material.

The *resonance* ultrasonic gages produce a frequency-modulated continuous-wave signal. This provides a corresponding swept frequency of sound waves introduced into the part. When the thickness of the part equals one-half wavelength, or multiples thereof, standing-wave conditions or mechanical resonances occur. The frequency of the fundamental resonance, or the difference frequency between two harmonic resonances is determined in the instrumentation. The thickness is determined by the formula

$$\text{Th} = \frac{\text{Vel}}{2F}$$

where Th = thickness of part under transducer
Vel = speed of sound in the material
F = frequency, Hz.

A popular readout for ultrasonic resonance gages is a large cathode-ray tube. Frequency indications on the tube are compared to an overlaid scale calibrated in inches, centimeters, etc., and thus direct thickness readings can be obtained. These gages can produce accuracies of 1% of nominal thickness.

The *pulse-echo* technique operates somewhat like a refined sonar system. Very short electric pulses, usually at discrete frequencies, are generated. These produce short acoustic pulses from the transducer which, in turn, pass through the material and reflect from the boundaries, just as in the resonance approach. The *transit time* of the pulses through the material is measured. The formula is

$$\text{Th} = \frac{\text{Vel} \times T}{2}$$

where Th = actual thickness of part under transducer or within sound beams
Vel = speed of sound in material
T = transit time of sound pulse through one round trip in the material.

One limitation of ultrasonic gaging is the requirement for coupling of the sound beam between transducer and part. See also **Ultrasonics**.

X-Ray Thickness Gaging. Noncontact X-ray gages measure thickness or density of hot or cold materials while in motion or when stationary. Steel, aluminum, brass, copper, glass, paper, and rubber — in continuous strip or sheets — as well as plastic films and material coats are typical of materials that can be gaged by this method. Different styles of X-ray gages will span a thickness range from 0.00025 inch (0.006 millimeter) in plastic through 2 inches (5.1 centimeters) in steel. An X-ray gaging system comprises three basic units: (a) a scanning unit that contains the X-ray generator and a detecting unit; (2) an operator control station; and (3) a power unit. Continuous X-ray gaging has become part of many computer-operated steel rolling mills. Automatic control based upon thickness measurements permits rolling to close tolerances, maximum on-gage length per ton, and less scrap or out-of-gage material at both ends of a coil or run. See Fig. 4.

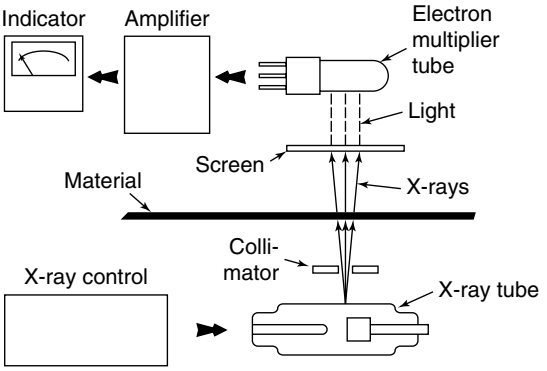

Fig. 4. Principal elements of an x-ray thickness gage.

THIN. A nontechnical word used by scientists with a variety of meanings. () In electronic metallurgy a thin film is a vapor-deposited coating having a thickness of only a single atom; such *monatomic* films, e.g., thorium on tungsten, are used in electronic devices such as cathodes. (2) A coating or film of fatty acid on water that is one molecule thick (about 200Å) is called *monomolecular* film. (3) In thin-layer chromatography the term applies to a specially prepared mixture of adsorbents spread on a glass slide to a thickness of 1/100 inch. (4) The word is also used in the sense of a liquid of low viscosity, as in paint thinner and thin-boiling starch.

THIN FILMS. The term *thin films* is used for a wide variety of physical structures. Self-supporting solid sheets usually are called foils when thinned from thicker material by such methods as rolling, beating, or etching, and films when obtained by stripping a deposited layer from its substrate. Supported thin films are deposited on planar or (in special cases) curved substrates by such methods as vacuum evaporation, cathode sputtering, electroplating, electroless plating, spraying, and various chemical surface reactions in a controlled atmosphere or electrolyte. Thicknesses of such supported films range from less than an atomic monolayer to a few micrometers (1 $\mu m = 10^{-4}$ centimeter). Thin films not forming a continuous sheet are called "island films." Particularly noble metals may condense as islands of considerable thickness (up to $(\sim)10^2$ micrometer).

In scientific studies and technical applications, the use of well-controllable deposition methods such as vacuum evaporation and cathode sputtering are generally preferred. The film structure is markedly influenced by such deposition parameters as substrate composition and surface structure, source and substrate temperatures, deposition rate, and composition and pressure of the ambient atmosphere (where applicable). In general, the structure of films is more disordered than the corresponding bulk material. Smaller grains, higher dislocation concentrations, and deviations from stoichiometry are typical, and films approach bulk structure only as a limiting case. Under certain growth conditions, films exhibit preferential crystal orientations or even epitaxy. (Epitaxy means that the film structure is determined by the crystal structure and orientation of the underlying substrate.)

Solid thin films are common study objects in most phases of solid state physics. They supply the samples for the study of general structural and physical properties of solid matter where special beam methods require small quantities of material or extremely thin layers. For example, thin films are used in transmission electron microscopy and diffraction, neutron diffraction, ultraviolet spectroscopy, and X-ray diffraction and spectroscopy. Thin films represent the best means for studying physical effects, where these effects are caused by the extreme thinness of the material itself. Examples are the rotational switching of ferromagnetic films, electron tunneling phenomena, electromagnetic skin effects of various kinds, and certain optical interference phenomena. Films also are convenient vehicles for the investigation of nucleation and crystal growth, and for states of extremely disturbed thermodynamic equilibrium.

Presently, films find three major industrial uses: the decorative finishing of plastics, optical coatings of various kinds (mainly antireflection coatings, reflection increasing films, multilayer interference filters, and fluorescent coatings), and in electronic components.

Nucleation, Growth and Mechanical Properties of Films

In vacuum evaporation, molecules or atoms of thermal energy are deposited at a uniform angle of incidence and under well-defined environmental conditions. Most nucleation and growth studies, therefore, have been made on evaporated films. A particle approaching the substrate enters close to its surface a field of attracting short-range London forces with an exchange energy proportional to $-1/r^6$. At a still shorter distance r, repulsive forces proportional to $e^{-r/\text{constant}}$ resist the penetration of the electron clouds of the surface atoms. Due to the atomic or crystalline structure of the substrate, this potential field exhibits periodicity or quasiperiodicity in the substrate plane. The freshly condensed particles migrate over the surface with a jump frequency $i_{\mathrm{D}} propto \exp(-Q_{\mathrm{D}}/kT)$, or desorb with a frequency $i_{\mathrm{ad}} propto \exp(-Q_{\mathrm{ad}}/kT)$, where the activation energy Q_{D} is often approximately one-fourth of Q_{ad}. Permanent condensation occurs in most cases at distinct nucleation centers which may consist of deep potential wells of the substrate, clusters of condensed particles, or previously deposited "seed" particles of a different material. The number of nuclei formed in the second case is strongly temperature and rate dependent.

Most metals always condense in crystalline form, but the grain size is extremely small at low temperatures (in the order of a few micrometers) and increases markedly with increasing substrate temperatures. Grain size decreases with increasing deposition rates. The condensation of amorphous or quasi-liquid phases at low temperatures has been observed for such metals as antimony and bismuth and a few dielectrics. Some of these materials, on annealing, pass through otherwise unobserved and probably metastable phases.

Stresses of considerable magnitude are often observed in deposited films. The main causes of these stresses are a mismatch of expansion coefficients between substrate and film, enclosed impurity atoms, a high concentration of lattice defects and in very thin films, a variety of surface effects. Often, the stresses resulting from lattice defects can be minimized by the choice of a higher substrate temperature during deposition, or they can be reduced by a post-deposition anneal. Metal films frequently exhibit tensile strengths that are considerably larger than those of the corresponding bulk materials.

Thin-Film Optics

Deposited metal mirrors probably represent the oldest optical application of films. High-quality mirrors usually are produced by the vacuum evaporation of aluminum on an appropriately shaped glass substrate. Often, a glow-discharge cleaning of the substrate or a chromium undercoat is first applied to increase the adhesion of the aluminum. After deposition, the aluminum is protected by anodic oxidation or an evaporated overcoat of SiO, SiO_2, or Al_2O_3.

For SiO, maximum reflectance in the visible spectral region is achieved at a thickness of about 1400 micrometers. Rapid SiO evaporation reduces the reflectance at shorter wavelengths.

Single or multilayer coatings find increasing use as optical interference filters. These film stacks may consist solely of transparent films of different refractive indices n_{f}, or a combination of absorbing and nonabsorbing layers. Common low-index materials for glass coatings in the visible region of the spectrum are MgF_2 ($n_{\mathrm{f}} = 1.32$ to 1.37), and cryolite Na_3AlF_6 ($n_{\mathrm{f}} =$ 1.28 to 1.34); high-index materials are SiO ($n_{\mathrm{f}} = 1.97$), ZnS ($n_{\mathrm{f}} \approx 2.34$), TiO_2 ($n_{\mathrm{f}} = 2.66$ to 2.69) and CeO_2 ($n_{\mathrm{f}} = 2.2$ to 2.4). The indices are given for the sodium D-line. Various semiconductors are used for infrared coatings.

At each air-film, film-film, or film-substrate interface, the incident light amplitude is split into a reflected and a transmitted fraction according to the Fresnel coefficients

$$f_{j-1} = (\hat{N}_{j-1} - \hat{N}_j)/(\hat{N}_{j-1} + \hat{N}_j) \text{ and } g_{j-1} = 2\hat{N}_{j-1}/(\hat{N}_{j-1} + \hat{N}_j)$$

where j and $j-1$ denote the number of the optical layer counted from the side of the incident beam, $\hat{N}_j = N/\cos\Theta_j$ for p polarization or $\hat{N}_j = N_j/\cos\Theta_j$ for s polarization is the effective refractive index, and $N_j = n_j - ik_j$ the refractive index of the j layer.

$$\cos\Theta_j = \sqrt{\sqrt{(p_j^2 + q_j^2 + p_j)}/2} - i\sqrt{\sqrt{(p_j^2 + q_j^2 + p_j)}/2}$$

$$p_j = 1 + (k_j^2 - n_j^2)[n_0 \sin\theta_0/(n_j^2 + k_j^2)]^2$$

$$q_j = -2n_j k_j [n_0 \sin\theta_0/(n_j^2 + k_j^2)]^2$$

The symbol θ_0 is the angle of incidence in the incident medium.

For nonabsorbing film stacks ($k_i = 0$; $i = 1, 2 \ldots, m+1$), the overall reflectance and transmittance may be obtained by summing the multiple coherent reflections between the film boundaries. A more general treatment based on electromagnetic theory yields for amplitude reflectance and transmittance the recursions formulas

$$r_{(j-1)-} = (f_{j-1} + r_{j-}\exp(-2i\hat{\Phi}_j))/(1 + f_{j-1}r_{j-}\exp(-2i\hat{\Phi}_j))$$

and

$$t_{(j-1)-} = (g_{j-1}t_{j-}\exp(-i\hat{\Phi}_j))/(1 + f_{j-1}r_{j-}\exp(-2i\hat{\Phi}_j))$$

$\hat{\Phi}_j = \Phi_j \cos\Theta_j$ is the effective phase thickness. $\Phi_j = (2\pi/\lambda)$. $N_j l_j$ where λ is the wavelength in vacuo, and l_j is the geometrical film thickness. The recursion is started on the side of emergence, using the initial conditions $r_{m-} = f_m$ and $t_{m-} = g_m$. Intensities are given by $R = |r_{0-}|^2$ and $T = (RN_{m+1}/n_0)|t_{0-}|^2$ where R denotes "real part of." If A_j is the absorption in the layer j, $R + T + \Sigma_j A_j = 1$.

A single antireflection coating of $\lambda/4$ optical thickness $n_{\mathrm{f}} l_{\mathrm{f}}$ yields zero reflectance at $n_{\mathrm{f}} = \sqrt{n_{\mathrm{glass}}}$. A double layer coating of $\lambda/4$ films requires $n_2/n_1 = \sqrt{n_g}$. The transmission of a Fabry-Perot interference filter consisting of a dielectric spacer layer between two partially reflecting metal films is given by $I/I_0 = [(1 + A/T)^2 + (4R/T^2)\sin^2(\delta - 1)]^{-1}$ where $\Phi = 2\pi\ nl\cos\theta/\lambda$. R, T, and A are the reflection, transmission, and absorption coefficients of the reflecting layers. The refractive index and thickness of the spacer film are n and l. θ is the angle of refraction in the spacer, and Δ the phase change for reflections at the spacer-metal film interfaces. $(I/I_0)_{\max} = (T/(1-R))^2$ and $(I/I_0)_{\min} = (T/(1+R))^2$. The band pass half-width is $\Delta\lambda_{1/2} \sim \lambda(1-R)/m\ \pi R^{1/2}$ for the interference order $m(m\pi = \Phi)$. More complex coatings and filters, and their various applications, cannot be discussed here. It should be mentioned, however, that films play a very important role today in the accurate determination of the optical constants of many materials, but particularly of metals.

Thin-Film Electronics

Deposited dielectric film materials are SiO, MgF_2, ZnS, and various organic compounds. Thin capacitive layers in the 100 to 500 micrometers thickness region are often produced by the anodization of tantalum and aluminum to Ta_2O_5 or Al_2O_3, respectively. The breakdown strength and dielectric constant of films approach bulk values, but might be reduced by surface roughness, structural faults, and lower density. According to the Lorentz-Lorenz formula, the dielectric constant D changes with reduced density ρ as $dD/d\rho = 3C/(1 - C\rho)^2$, where C is a constant depending on the material. On metal-dielectric-metal films, quantum mechanical tunneling through the dielectric film becomes observable below a dielectric thickness of about 100 micrometers. For applied voltages less than the metal-insulator work function ϕ, the tunneling current density J is proportional to the applied voltage V, demonstrating that the low-voltage tunneling resistance is ohmic. $J = (qV/h^2 s) \times (2m^*\phi)^{1/2} \exp[-(4\pi s/\mathrm{h})(2m^*\phi)^{1/2}]$. At high applied voltages ($qV > \phi$), the current increases very rapidly:

$$J = (q^2V^2/8\pi h\phi_s^2)\exp[-(8\pi s/3hqV)(2m^*)^{1/2}\phi^{3/2}].$$

s is the insulator thickness, m^* the electronic effective mass, and q the electron charge. Thicker dielectric films may exhibit in high fields appreciable Schottky or avalanche currents when they are greatly disordered.

Polycrystalline metal films generally show, due to their low structural order, a larger resistivity than the bulk material. According to Matthiessen's rule, the total resistivity can be expressed as $\rho = \rho(t) + \rho(i)$ where $\rho(t)$ is the temperature-dependent resistivity associated with scattering by lattice vibrations, and $\rho(i)$ is a temperature-independent resistivity caused by impurity or imperfection scattering. Very thin specimens with a thickness comparable to the electron mean free path show a $\rho(i)$

rapidly increasing with decreasing thickness. This increase is caused by an increasing contribution of non-specular electron scattering at the film surfaces. By annealing a metal film, $\rho(i)$ might be reduced permanently. A large $\rho(i)$ results in a small temperature coefficient α.

Many known superconductors can be deposited as superconductive films.

Through thin-film experiments, the energy gap in semiconductors can be measured, and material parameters, such as the penetration depth of magnetic fields, can be studied at dimensions less than the coherence range.

Studies of semiconductor films have shown many facets. The properties of epitaxial films have mainly been investigated on Ge and Si, and to a lesser degree on III–V compounds. Much work has been done on polycrystalline II–VI films, particularly with regard to the stoichiometry of the deposits, doping and post-deposition treatments, conductivity and carrier mobility, photo-conductance, fluorescence, electroluminescence, and metal-semiconductor junction properties. Among other semiconductors, selenium, tellurium, and a few transition metal oxides have found some interest.

Film resistors, capacitors, and interconnected R-C networks on planar glass or ceramic substrates are finding widespread industrial use. Common resistor materials are carbon, nichrome, and tin oxide in individual components; and nichrome, tantalum, tantalum nitride, SiO-chromium cermet, and cermet glazes in planar networks. Gold, copper, aluminum, or tantalum is used for termination lands, connection leads, and capacitor plates. SiO, MgF_2, and Ta_2O_5 serve as film capacitor dielectrics and crossover insulation. The geometrical configuration of the desired component or circuit pattern is obtained either by deposition through mechanical masks or by removing from a continuous sheet the undesired portions after the deposition process is completed. This removal is frequently accomplished by a combination of photolitho-graphic and etch processes.

The minimum length l and width w of a resistor are calculated from the given resistance R, the sheet resistance R in ohms per square, dissipated power P, and permissible power dissipation per square inch P by use of the formulas $w = \sqrt{(P \cdot R)/P \cdot R}$ and $l = wR/R$. The capacitance of film capacitors is given by $C = 0.225D(N-1)\ A/t$, where C is the capacitance in picofarads, D the dielectric constant, N the number of plates, A the area in square inches, and t the dielectric thickness in inches.

In retrospect, it is gratifying to note how much progress in thin-film electronics was made prior to a more penetrating and fundamental understanding of surface phenomena. It is only relatively recently that such experimental tools as angle-resolved photoelectron spectroscopy, synchrotron far-ultraviolet and X-ray spectroscopies, and back-scattering and channeling of energetic ions, have been used. New computational methods are now available for calculating detailed maps of the electron distribution at a surface. It has been found that the surface geometry is either a relaxed version of the bulk structure, or a reconstructed arrangement with symmetry wholly different from the bulk. A comparison of the electron spectroscopy results with theoretical predictions of surface state energy spectra based on a particular surface model allows confirmation of the assumed atomic arrangement. Together, the theoretical and experimental approaches have provided the first complete description of surfaces, including identification of the atomic species present, their atomic arrangement, and the distribution of valence electrons in space and energy. It is quite possible that these approaches will lead to a detailed picture at the atomic level of the interface structure, electron states, charges, reconstruction, and the related junction electronic properties of semiconductor-semiconductor and metal-semiconductor interfaces.

Various barrier layer diodes have exhibited impressive rectification ratios, but limited breakdown strength and low speed due to their large specific capacitance. Of the many film transistor concepts studied, the insulated gate field effect device has been promising. Its structure consists of a minute metal-dielectric-semiconductor capacitor. The semiconductor strip carries current between two terminals called source and drain. A field applied between metal "gate" and source modulates the semiconductor conductance and consequently the source-drain current. Usable semiconductor materials with a sufficiently low concentration of interface states are CdS, CdSe, and tellurium. These devices exhibit pentodelike characteristics with voltage gains ranging from 2.5 at 60 megahertz to 8.5 at 2.5 megahertz. The gain-bandwidth product GB, which is equal to the transconductance divided by 2π times the gate capacitance, reaches values of about 20 megahertz. It is determined by $GB = \mu_d V_D / 2\pi L^2$, where μ_d is the effective drift mobility of the electrons, V_D the source-drain potential, and L the source-drain spacing, which is usually selected between 5 and 50 micrometers.

An outgrowth of prior thin-film technology and of basic surface science research has been molecular beam epitaxy — the MBE formation of compound semiconductor films. The MBE technology involves the use of separate atomic and molecular beams from multiple thermal sources in high vacuum which irradiate a substrate at intensities selected to grow films having the desired composition and doping. The ability to achieve slow growth rates, together with independent control of the separate beam sources, permits the fabrication of semiconductor junction profiles, both in doping and in composition, with a precision approaching that of a single atomic layer. To date MBE has been used to prepare films and layer structures involving a number of GaAs and $Ga_xAl_{1-x}As$ devices. Included in such devices are varactor diodes having highly controlled hyperabrupt capacitance-voltage characteristics, IMPATT diodes, microwave mixer diodes, Schottky barrier field-effect transistors (FETs), injection lasers, optical waveguides, and integrated optical structures. Some authorities believe that the potential for MBE in solid-state electronics may be greatest for microwave and optical solid-state devices as well as for circuits where submicrometer layer structures are required. A recently demonstrated MBE GaAs Schottky barrier diode cryogenic mixer with a noise temperature of 315 K at 102 gigahertz is exemplary of the potential of MBE technology for millimeter wave electronics. See also **Schottky Defect**.

MBE superlattice structures also are very promising. These superlattice structures, with periodicities of 50–100 micrometers, show negative resistance characteristics attributed to resonant tunneling into the quantized energy states associated with the narrow potential wells formed by the layers. Detailed studies have shown that the potential well distributions may be controlled and positioned to a precision of a few atomic layers.

Thin-film technology has also played an important role in developing Josephson superconducting devices, which offer outstanding advantages in constructing ultrahigh-speed computers. These are tunnel-junction type devices. See also **Josephson Tunnel-Junction**.

Thin-film and surface phenomena are fundamental to the successful development, production, and use of solid-state devices. The research in this area is extensive. See also **Molecular and Supermolecular Electronics**.

Magnetic Films. Magnetic thin films of nickel-iron (usually deposited at an 80:20 composition by weight) exhibit a number of unusual properties, which have led to many experimental and theoretical studies, as well as to important applications in binary storage and switching, magnetic amplifiers, and magneto-optical Kerr-effect displays.

Such "Permalloy" films have two stable states of magnetization, corresponding to positive and negative remanence. When deposited in a magnetic field or at an oblique angle, they exhibit uniaxial anisotropy. In practice, this anisotropy shows some dispersion, since it results from the alignment of local lattice disturbances. The stable states result from the minimization of the free energy $E = MH_L \cos\theta - MH_T \sin\theta + K \sin^2\theta$, where the last term represents the anisotropy energy, and θ is the angle between the magnetization M and the easy axis. From an inspection of the derivatives of this equation follows the hard-direction straight-line and the easy-direction square hysteresis loops of aniso-tropic films. In the latter case, the magnetization is always either +M or −M, and the change occurs at $H_L = \pm H_K$. The transitions from unstable to stable states occur at $\partial^2 E/\partial\theta^2 = 0$, resulting in a critical curve $H_L^{2/3} + H_T^{2/3} = H_K^{2/3}$ which has the form of an asteroid enclosing the origin (see also **Magnetism**).

An important feature of magnetic films is the high speed with which the state of magnetization can be reversed. Dependent on film properties and magnetic fields, three modes of magnetization reversal occur: Domain wall motion, incoherent rotations, and the extremely fast coherent rotation of the magnetization. Wall motion switching is expected when the driving fields are smaller than the critical values. During the past decade, magnetic garnet films have gained prominence in a number of research and industrial applications.

See also **Magnetic Materials**.

Properties of Thin Films

Thin films formed by atomistic deposition techniques are unique materials that seldom have handbook properties. Properties of these thin films depend on several factors, including substrate surface condition, the deposition process used, details of the deposition process and system geometry, details of film growth on the substrate surface, and post-deposition processing and reactions. For some applications, such as wear resistance, the mechanical properties of the substrate is important to the functionality of the thin film. In order to have reproducible film properties, each of these factors must be controlled.

Film Adhesion. The adhesion of an inorganic thin film to a surface depends on the deformation and fracture modes associated with the failure (4). The strength of the adhesion depends on the mechanical properties of the substrate surface, fracture toughness of the interfacial material, and the applied stress. Adhesion failure can occur owing to mechanical stressing, corrosion, or diffusion of interfacial species away from the interface. The failure can be exacerbated by residual stresses in the film, a low fracture toughness of the interfacial material, or the chemical and thermal environment or species in the substrate, such as gases, that can diffuse to the interface.

Film Morphology and Density. Under many conditions, less-than-fully dense films are deposited by atomistic film deposition processes. This is usually a result of growth mode on the surface, which is controlled by geometric factors (4). For example, in the physical vapor deposition of films, submicrometer-size or larger features on a surface can cause geometrical shadowing, leading to growth of the peaks and shadowing of the valleys. This in turn leads to a columnar growth morphology, which is porous and less than fully dense, and has a high surface area.

Residual Film Stress. Invariably, atomistically deposited films have a residual stress that can be tensile or compressive in nature and that can approach the yield or fracture strength of the materials involved. The residual stresses can be a result of both stresses that arise from differences in coefficient of expansion of the film and substrate materials when using high temperature processing, and the growth or quenched-in stresses from the atoms not being in their lowest energy configurations when they become immobile on the substrate surface or from the incorporation of foreign species in the deposited material.

In physical vapor deposition processing, vacuum deposited films and sputter-deposited films prepared at higher (>0.6 Pa (5 mtorr)) pressures generally have tensile stresses that may be anisotropic with off-normal angle of incidence depositions. In low pressure sputter deposition and ion plating, energetic particle bombardment can give rise to high compressive film stresses resulting from the recoil displacement (atomic peening) of atoms in the near-surface region of the growing film. The residual film stress anisotropy may be very sensitive to the sputtering target configuration and gas pressure during sputter deposition.

In chemical vapor deposition processing, the principal source of residual stress is from a coefficient of expansion mismatch. One of the principal criteria for CVD processing is the matching of the coefficient of expansions of the film and substrate, which limits the possible film–substrate combinations that can be used.

In electrodeposition, the film stresses can vary with deposition parameters and be regulated by controlling the deposition parameters and the use of addition agents in the bath.

The lattice strain associated with the residual film stress represents stored energy, and this energy, along with a high concentration of lattice defects, can lead to: (*1*) lowering of the recrystallization temperature in crystalline materials; (*2*) a lowered strain point in glassy materials; (*3*) a high chemical etch rate; and (*4*) room temperature void growth in ductile materials and other such mass transport effects.

Surface Coverage. The surface-covering ability of deposition techniques is best when the materials are deposited from a vapor or from a fluid having no need for an applied voltage. The macroscopic and microscopic surface coverage of a thin film deposited by PVD techniques on a substrate surface may be improved by the use of gas scattering and concurrent bombardment during film deposition.

Electrical Properties. Generally, deposited thin films have an electrical resistivity that is higher than that of the bulk material. This is often the result of the lower density and high surface-to-volume ratio in the film. In semiconductor films, the electron mobility and lifetime can be affected by the point defect concentration, which also affects electromigration. These effects are eliminated by depositing the film at low rates, high temperatures, and under very controlled conditions, such as are found in molecular beam epitaxy and vapor-phase epitaxy.

Optical Properties. The index of refraction of a deposited material is sensitive to the film density. A lower index of refraction is found at less than bulk densities. The reflectance of a metallic surface is affected by the growth morphology of the film.

Medical Properties. The mechanical properties of thin films is affected by the film density and composition. In many applications, the properties of the substrate material is important to the functionality of the thin film in mechanical applications.

THIN-LAYER CHROMATOGRAPHY (TLC). A micro type of chromatography. The thin layer (0.01 inch) is the adsorbent, usually a special silica gel spread on glass or incorporated in a plastic film. Single drops of the solutions to be investigated are placed along one edge of the glass plate, and this edge then dipped into a solvent. The solvent carries the

constituents of the original test drops up the thin layer in a selective separation, so that a comparison with known standards and various identifying tests may be made on the spots formed.

See also **Thin**; and **Thin Films**.

THIN-LENS RELATIONSHIPS. Formulas relating image distance, object distance, focal length, index of refraction, curvature of surfaces, etc., of a lens which is sufficiently thin that, for the purpose of the calculation, the thickness may be neglected. The formula

$$\frac{1}{f} = \frac{1}{p} + \frac{1}{q} = (n-1)\left(\frac{1}{r_1} - \frac{1}{r_2}\right)$$

is a typical thin-lens formula.

THINNER. A hydrocarbon (naphtha) or oleoresinous solvent (turpentine) used to reduce the viscosity of paints to appropriate working consistency usually just before application. In this sense, a thinner is a liquid diluent, except that it has active solvent power on the dissolved resin.

THIOCYANIC ACID. [CAS: 463-56-9]. Aqueous solution of hydrogen thiocyanate, HSCN, formula weight 59.08, yellow solid below mp 5 °C (41 °F), unstable gas at room temperature. The acid is moderately stable only when dilute and cold. The salts of this acid are known as thiocyanates.

Thiocyanic acid is formed by reaction of barium thiocyanate solution and dilute sulfuric acid [CAS: 7664-93-9], and filtering off barium sulfate [CAS: 7727-43-7], or by the action of hydrogen sulfide [CAS: 7783-06-4] on silver thiocyanate [CAS: 1701-93-5], filtering off silver sulfide [CAS: 21548-73-2].

Sodium [CAS: 7440-23-5], potassium [CAS: 7440-09-7], barium [CAS: 7440-39-3], or calcium thiocyanate [CAS: 2092-16-2] may be made by reaction of sulfur and the corresponding cyanide by heating to fusion. Ammonium thiocyanate [CAS: 1762-95-4] (plus ammonium sulfide) [CAS: 12135-76-1] may be made by reaction of ammonia [CAS: 7664-41-7] and carbon disulfide, [CAS: 75-15-0] a reaction which probably accounts for the presence of ammonium thiocyanate in the products of the destructive distillation of coal. This reaction corresponds to the formation of ammonium cyanate from ammonia and carbon dioxide.

Silver, lead, copper(I), and thallium(I) thiocyanates are insoluble and mercury(II), bismuth, and tin(II) thiocyanates slightly soluble. All of these are soluble in excess of soluble (e.g., ammonium) thiocyanate, forming complexes. Iron(III) thiocyanate gives a blood-red solution, used in detecting either Fe(III) or thiocyanate in solution, and is extracted from water by amyl alcohol. It is not formed in the presence of fluoride, phosphate and other strongly complexing ions.

When thiocyanic acid [CAS: 463-56-9] is treated with certain oxidizing agents, e.g., nitric acid [CAS: 7697-37-2] , sulfuric acid and hydrocyanic acid [CAS: 74-90-8] are formed, but the action of lead tetraacetate [CAS: 546-67-8] on the acid, or of bromine [CAS: 7726-95-6] in ether on lead(II) thiocyanate, gives thiocyanogen ("Rhodan") NCSSCN, a yellow, volatile oil, mp about −3 °C (26.6 °F), which polymerizes irreversibly at room temperature to insoluble, brick-red parathiocyanogen $(NCS)_x$. Thiocyanogen [CAS: 505-14-6] reacts with organic compounds like a free halogen. It liberates iodine from iodides. In water it is rapidly hydrolyzed to sulfuric and hydrocyanic acids. When thiocyanic acid is treated with reducing agents, e.g., aluminum and dilute hydrochloric acid, hydrogen sulfide plus carbon [CAS: 7440-44-0] plus ammonium chloride [CAS: 12125-02-9] are formed.

Esters

Ethyl thiocyanate [CAS: 542-90-5] $C_2H_5 \cdot SCN$, colorless liquid, bp 142 °C. Formed by reaction (1) of potassium thiocyanate [CAS: 333-20-0] and potassium ethyl sulfate, (2) of cyanogen chloride [CAS: 506-77-4] and ethane-thiol [CAS: 75-08-1]. Oxidizable with fuming nitric acid to ethyl sulfonic acid $C_2H_5 \cdot SO_2OH$, and reducible with zinc and dilute sulfuric acid to ethane thiol C_2H_5SH. Ethyl isothiocyanate [CAS: 542-85-8] $C_2H_5 \cdot NCS$, colorless, odorous liquid, bp 132 °C (270 °F). Formed by reaction of ethyl amine and carbon disulfide (cf. the formation of ammonium thiocyanate from ammonia and carbon disulfide). Reducible to ethyl amine $C_2H_5NH_2$ plus methylene sulfide CH_2S. Allyl isothiocyanate ("mustard oil") $C_3H_5 \cdot NCS$ liquid, bp 151 °C (301 °F), odor of mustard, and causes blisters in contact with the skin.

THIOETHERS. Hydrogen sulfide [CAS: 7783-06-4] yields two classes of organic compounds: (1) hydrosulfides, and (2) sulfides. The sulfides are termed thioethers. A more general term, *thiols*, also is used. This term not only embraces thioethers, but also covers thioalcohols, sulfhydrates, and thiophenols.

Ethyl sulfide [CAS: 352-93-2] $(C_2H_5)_2S$, one of the better known thioethers, is an odorous, inflammable liquid, mp −102.1 °C (−151.8oF), bp 91.6 °C (197 °F), sp gr 0.837. The compound is insoluble in H_2O and soluble in alcohol and ether. It is prepared by distilling ethyl potassium sulfate [CAS: 7778-80-5] with potassium sulfide [CAS: 1312-73-8]. Chemically, ethyl sulfide [CAS: 352-93-2] behaves much like the ethers. For example, none of the hydrogen atoms can be displaced by metals and generally the compound is very inert. Additional thioethers can be prepared in a similar manner with the corresponding proper ingredients. Upon oxidation with HNO_3, thioethers are converted to sulfones. The latter are stable crystalline substances. An example is ethyl sulfone [CAS: 597-35-3] $(C_2H_5)_2SO_2$.

THIOKOL RUBBERS. See **Elastomers**.

THIOLS. The chemistry of organic sulfur compounds is very rich and organosulfur compounds are incorporated into many molecules. Thiols, or mercaptans as they were originally called, are essential as feedstocks in the manufacture of many types of rubber and plastics. They are utilized as intermediates in agricultural chemicals, pharmaceuticals, in flavors and fragrances, and as animal feed supplements. Many reviews have been undertaken on the chemistry of the thiols, regarding both their preparation and their reactions. See also **Mercaptans**; **Pharmaceuticals**; **Plastics**; **Rubber Chemicals**; and **Rubber, Natural**.

Thiols are still commonly named as mercaptans, although the proper nomenclature is that established by the International Union of Pure and Applied Chemists (IUPAC). A listing of the IUPAC name, common name, and structure, is shown in Table 1.

TABLE 1. NOMENCLATURE OF THIOLS

IUPAC name	Common name	Structure
Methanethiol	Methyl mercaptan	CH_3SH
Ethanethiol	Ethyl mercaptan	CH_3CH_2SH
2-Propanethiol	Isopropyl mercaptan	$CH_3CH(SH)CH_3$
2-Butanethiol	*sec*-Butyl mercaptan	$CH_3CH(SH)CH_2CH_3$
1-Butanethiol	*n*-Butyl mercaptan	$CH_3CH_2CH_2CH_2SH$
2-Methyl-2-propanethiol	*t*-Butyl mercaptan	$(CH_3)_3CSH$
2,4,4-Trimethyl-2-pentanethiol	*tert*-Octyl mercaptan	$(CH_3)_2C(SH)CH_2C(CH_3)_3$
Cyclohexanethiol	Cyclohexyl mercaptan	$C_6H_{11}SH$
Benzenethiol	Thiophenol	C_6H_5SH
α-Toluenethiol	Benzyl mercaptan	$C_6H_5CH_2SH$

Cysteine [CAS: 52-90-4] is a thiol-bearing amino acid which is readily isolated from the hydrolysis of protein. There are only small amounts of cysteine and its disulfide, cystine, in living tissue. Glutathione [CAS: 70-18-8] contains a mercaptomethyl group, $HSCH_2-$, and is a commonly found tripeptide in plants and animals. Coenzyme A [CAS: 85-61-0] is another naturally occurring thiol that plays a central role in the synthesis and degradation of fatty acids.

Methanethiol has been found in sewer gases and is thought to be produced by the bacterial degradation of methionine. Methanethiol (CAS: 74-93-1) [CAS: 74-93-1], 1-butanethiol (butyl mercaptan) [CAS: 109-79-5], and 2-methyl-1-propanethiol (isobutyl mercaptan) [CAS: 513-44-0] are produced by the bacterial degradation of blue-green algae. Some yeasts produce ethanethiol [CAS: 75-08-1], 2-propanethiol is produced

by actively growing *Microcystis flosaquae*. Methanethiol, ethanethiol, 1-propanethiol, 2-propanethiol, 2-methyl-1-propanethiol, 2-methyl-2-propanethiol, and 1-butanethiol are found in the environment near domestic animal pens.

Skunks excrete 1-butanethiol and 2-methyl-1-butanethiol [CAS: 1878-18-8] as a natural defense mechanism. Methanethiol is found in cheese, milk, coffee, and oysters. It is also found in the kurrin fruit, which is endemic to Southeast Asia.

Physical Properties

The physical characteristic of thiols that most distinguishes them is their odor. Thiols have been used since the late 1800s as malodorants in combustible gases. In the 1930s the U.S. Bureau of Mines published a series of reports regarding the intensity of odors of warning agents that put this practice on a scientific basis. There have been innumerable studies since that time regarding the odor intensity of thiols, primarily about their role in the odorization of natural gas and propane gas. All of the definitive studies on thiol threshold odor levels have been brought together and normalized to give a standardized odor scale. Even the heavier mercaptans have a significant odor, particularly when heated.

Thiols range over the gamut of physical properties. Most of the important thiols are liquids, however methanethiol is a gas, and 1-hexadecanethiol and 1-octadecanethiol are waxy solids. Table 2 list a variety of physical properties for the more important thiols.

Preparation

Thiols can be prepared by a variety of methods. The most-utilized of these synthetic methods for tertiary and secondary thiols is acid-catalyzed synthesis; for normal and secondary thiols, the most-utilized methods are free-radical-initiated, alcohol substitution, or halide substitution; for mercaptoalcohols, the most-utilized method is oxirane addition; and for mercaptoacids and mercaptonitriles, the most-utilized methods are Michael-type additions.

Reactions

Disulfides are prepared commercially by two types of reactions. The first is an oxidation reaction utilizing the thiol and a suitable oxidant. The most common oxidants are chlorine, oxygen, elemental sulfur, or hydrogen peroxide. Carbon tetrachloride has also been used. This type of reaction is extremely exothermic. Some thiols, notably tertiary thiols and long-chain thiols, are resistant to oxidation, primarily because of steric hindrance or poor solubility of the oxidant in the thiol. This type of process is used in the preparation of symmetric disulfides, RSSR. The second type of reaction is the reaction of a sulfenyl halide with a thiol. This process is used to prepare unsymmetric disulfides, RSSR′ such as 4,4-dimethyl-2,3-dithiahexane.

Thiols react readily with alkenes under the same types of conditions used to manufacture thiols. In this way, dialkyl sulfides and mixed alkyl sulfides can be produced. Sulfides are a principal by-product of thiol production.

Thiols react with carbonyl compounds to form dithioacetals and thioacetals. The dithioacetals have been utilized as protecting groups for carbonyl compounds. They generally require stringent conditions to remove the blocking groups. The thioacetals are not overly stable. At least two thioacetals, 2,2,2-trichloro-1-thioethylethanol and 1-dodecanethiomethanol, are stable.

Thiols decompose by two principal paths. These are the carbon–sulfur bond homolysis and the unimolecular decomposition to alkene and hydrogen sulfide.

Thiols undergo photolytic reactions.

The interchange between thiols and disulfides is base-catalyzed. It involves the nucleophilic attack of a thiolate ion on a disulfide. In rubber production, the thiol acts as a chain transfer agent, in which it functions as a hydrogen atom donor to one rubber chain, effectively finishing chain growth for that polymer chain. The sulfur-based radical then either terminates with another radical species or initiates another chain. The thiol is used up in this process.

In general, rubber manufacturers balance thiol reactivity and odor. The structure of the thiol plays a significant role in its ability to be transported

TABLE 2. PROPERTIES OF THIOLS

Compound	CAS Registry Number	Molecular Weight	Melting point, K	Boiling point, K
Methanethiol	[74-93-1]	48.11	150.18	279.11
Ethanethiol	[75-08-1]	62.14	125.26	308.15
2-Mercaptoethanol	[60-24-2]	78.14	200.00	430.90
1,2-Ethanedithiol	[540-63-6]	94.20	231.95	419.20
Mercaptoacetic acid	[68-11-1]	92.12	256.65	493.00
1-Propanethiol	[107-03-9]	76.16	159.95	340.87
2-Propanethiol	[75-33-2]	76.16	142.61	325.71
3-Mercaptopropionic acid	[107-96-0]	106.15	290.65	501.00
1-Butanethiol	[109-79-5]	90.19	157.46	371.61
2-Butanethiol	[513-53-1]	90.19	133.02	358.13
2-Methyl-1-propanethiol	[513-44-0]	90.19	128.31	361.64
2-Methyl-2-propanethiol	[75-66-1]	90.19	274.26	337.37
2,2′-oxybisethanethiol	[2150-02-9]	138.26	193.15	490.15
1-Pentanethiol	[110-66-7]	104.22	197.45	399.79
Cyclohexanethiol	[1569-69-3]	116.23	189.64	431.95
1-Hexanethiol	[111-31-9]	118.24	192.62	425.81
Benzenethiol	[108-98-5]	110.18	258.26	442.29
1-Heptanethiol	[1639-09-4]	132.27	229.92	450.09
a-Toluenethiol	[100-53-8]	124.21	243.95	472.03
1-Octanethiol	[111-88-6]	146.30	223.95	472.19
2,4,4-Trimethyl-2-pentanethiol	[141-59-3]	146.30	199.00	428.65
1-Nonanethiol	[1455-21-6]	160.32	253.05	492.95
1-Decanethiol	[143-10-2]	174.35	247.56	512.35
1-Undecanethiol	[5332-52-5]	188.38	270.15	530.55
1-Dodecanethiol	[112-55-0]	202.40	265.15	547.75
tert-Dodecanethiol[a]	[25103-58-6]	202.40		515.65
1-Hexadecanethiol	[2917-25-2]	258	291–293	$396–401_{0.07}$[b]
1-Octadecanethiol	[2885-00-9]	286	301	$461_{0.1}$[b]

[a] tert-Dodecanethiol is a mixture of isomers.
[b] Subscripted value represents pressure in kPa at which boiling point was taken. To convert kPa to mm Hg, multiply by 7.5.

within the polymer matrix, particularly in emulsion polymerizations, ie, mixed water–monomer emulsion. The odor of light thiols is generally too strong for most rubber manufacturers, as it is generally hard to remove residual odors from polymers.

Another area in which sulfur compounds have long found use is in the area of agricultural chemicals. Many of these materials had been produced by the manufacturer of the agricultural chemicals, but difficulties in containing odor and the use of hydrogen sulfide in heavily populated areas again pushed toward specialization by several companies. Over the years, a diverse group of products made use of the rather unique chemistry of organosulfur chemicals (Table 3).

TABLE 3. USES OF ORGANOSULFUR CHEMICALS

Thiol	Application
Methanethiol	DL-Methionine
Ethanethiol	Propane odorant
2-Methyl-2-propanethiol	Natural gas odorant components
1-Octanethiol	Water repellants
Cyclohexanethiol	Prevulcanization inhibitor
2-propanethiol	Flocculent Natural gas odorant component
tert-Nonanethiol	Polysulfides for oil additives
tert-Dodecanethiol	Polysulfides for oil additives Surfactants
2-Mercaptoethanol	PVC stabilizers Solvent for acrylic fibers

Organosulfur chemicals serve a diverse group of industries. In these applications ways have been found to control the odor of the thiols, thus utilizing these compounds effectively in a wide range of products.

Toxicology and Handling

The toxicology and procedures for handling thiols used in gas odorants have been reviewed, as have thiols as a whole. A listing of known TLV values and odor thresholds for a variety of thiols is given in Table 4.

TABLE 4. ODOR THRESHOLD LEVELS AND THRESHOLD LIMIT VALUES (TLV)

Thiol	Odor threshold, ppb	TLV, ppm
Methanethiol	1.05	0.5
Ethanethiol	1.07	0.5
1,2-Ethanedithiol	19.50	
1-Propanethiol	1.26	
2-Propanethiol	0.35	
2-Propene-1-thiol	0.40	
1-Butanethiol	1.41	0.5
2-Butanethiol	0.18	0.5
2-Butene-1-thiol	0.13	
2-Methyl-1-propanethiol	1.12	0.5
2-Methyl-2-propanethiol	0.33	0.5
1-Pentanethiol	0.12	0.5
2-Methyl-1-butanethiol	0.26	
2-Methyl-2-butanethiol	0.72	
Benzenethiol	0.31	0.1
4-Methylbenzenethiol	1.70	
α-Toluenethiol	1.58	
1-Dodecanethiol	0.25	
2-Methyl-1-undecanethiol	190.55	

Thiol spills are handled in the same manner that all chemical spills are handled, with the added requirement that the odor be eliminated as rapidly as possible. In general, the leak should be stopped, the spill should be contained, and then the odor should be reduced. The odor can be reduced by spraying the spill area with sodium hypochlorite (3% solution), calcium hypochlorite solution (3%), or hydrogen peroxide (3–10% solution). The use of higher concentrations of oxidant gives strongly exothermic reactions, which increase the amount of thiol in the vapor, as well as pose a safety hazard. The application of an adsorbent prior to addition of the oxidant can be quite helpful and add to the ease of cleanup.

Thiols interact readily with many rubber-containing materials. For this reason, care should be taken in the selection of gasket and hose materials. Teflon, Kel-F, Viton, or other suitable fluoroelastomers function as gasket materials. Viton is suitable for hoses. Carbon steel is useful for many thiols, although some thiols become very discolored when carbon steel is utilized. In these cases, the use of stainless steel is very desirable. Isolation from air and water also minimizes color formation. 2-Mercaptoethanol and 1,2-ethanedithiol should be stored in stainless steel.

See also **Thioethers**.

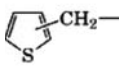
THIOPHENE AND THIOPHENE DERIVATIVES. [CAS: 110-02-1], $\langle(CH{:}CH)_2\rangle S$, formula weight 84.13, colorless liquid resembling benzene [CAS: 71-43-2] in odor, mp −30 °C (−22 °F), bp 84 °C (183 °F), sp gr 1.070. Thiophene and its derivatives closely resemble benzene and its derivatives in physical and chemical properties. Thiophene is present in coal tar and is recovered in the benzene distillation fraction (up to about 0.5% of the benzene present). Its removal from benzene is accomplished by mixing with concentrated sulfuric acid [CAS: 7664-93-9], soluble thiophene sulfonic acid being formed. Thiophene gives a characteristic blue coloration with isatin in concentrated sulfuric acid.

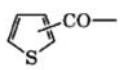
The basic nomenclature of the thiophene ring system and its derivatives is indicated by the following: the sulfur atom is number 1, positions 2 and 5 are equivalent in the parent ring, as are the 3 and 4 positions.

thiophene

thienyl



thenyl



thenoyl

Table 1 indicates the significant physical properties of thiophene and 2- and 3-methylthiophene.

Reactions

Electrophilic substitution of thiophene occurs largely at the 2-position and the reactivity of the ring is greater than that of benzene. 3-Substituted derivatives are generally prepared by indirect means or through ring cyclization reactions.

TABLE 1. PHYSICAL PROPERTIES OF THIOPHENE AND METHYLTHIOPHENES

Property	Thiophene	2-Methylthiophene	3-Methylthiophene

[c] To convert kJ/mol to kcal/mol, divide by 4.184.

Thiophenes can be alkylated in the 2-position using alkyl halides, alcohols, and olefins. Choice of catalyst is important; the weaker Friedel-Crafts catalysts, eg, $ZnCl_2$ and $SnCl_4$, are preferred. It is often preferable to use the more readily accomplished acylation reactions of thiophene to give the required alkyl derivatives on reduction. Alternatively, metalation or Grignard reactions, on halothiophenes or halomethylthiophenes, can be utilized.

To achieve acylation of thiophenes, acid anhydrides with phosphoric acid, iodine, or other catalysts have been widely used. Acid chlorides with $AlCl_3$, $SnCl_4$, $ZnCl_2$, and BF_3 also give 2-thienylketones. All reactions give between 0.5 and 2.0% of the 3-isomer.

Many different halogenating reagents have been used to accomplish halogenation of the thiophene ring. Excess of reagent gives di-, tri-, and even tetrahalogenation of thiophene itself. The bromothiophenes are often the preferred target. Bromine in acetic acid or chloroform has been the traditional route, but utilizes just one of the atoms of bromine. Addition products are often observed, particularly when proceeding through to di- and tribromothiophenes.

Direct reaction of thiophene and butyllithium in diethyl ether gives 2-thienyllithium [CAS: 2786-07-4], a valuable intermediate and source of many further derivatives. Thienyllithiums can also be prepared by halogen exchange from bromothiophenes and butyllithium, but this requires low temperature to avoid any possible proton−lithium exchange, or rearrangement by the halogen dance mechanism. Thienyl Grignard reagents are also prepared from the bromothiophenes and can be used in reaction schemes to give many other derivatives.

Strong oxidizing agents can rupture the thiophene ring structure, eg, nitric acid gives maleic acid. In the vapor phase, oxidation can lead to loss of aromaticity, producing thiomaleic anhydride [CAS: 6007-87-0]. Oxidation of alkylthiophenes can lead to carboxylic acids. A useful reagent for this is neutral sodium dichromate under autogenous pressure at 270 °C (518 °F). Oxidation at the sulfur atom with peroxides and peracids leads to the sulfone. This material readily undergoes Diels Alder reaction and a dimer has been isolated.

Reduction of thiophene to 2,3- and 2,5-dihydrothiophene and ultimately tetrahydrothiophene can be achieved by treatment with sodium metal−alcohol or ammonia. Hydrogen with Pd, Co, Mo, and Rh catalysts also reduces thiophene to tetrahydrothiophene [CAS: 110-01-0], a malodorous material used as a gas odorant.

Rigorous hydrogenating conditions, particularly with Raney Nickel, remove the sulfur atom of thiophenes. With vapor-phase catalysis, hydrodesulfurization is the technique used to remove sulfur materials from crude oil. Chemically hydrodesulfurization can be a valuable route to alkanes otherwise difficult to access.

Reaction of thiophene with aqueous formaldehyde solution in concentrated hydrochloric acid gives 2-chloromethylthiophene [CAS: 765-50-4]. This relatively unstable, lachrymatory material has been used as a commercial source of further derivatives such as 2-thiopheneacetonitrile [CAS: 20893-30-5] and 2-thiopheneacetic acid [CAS: 1918-77-0]. Similar derivatives can be obtained by peroxide, or light-catalyzed halogenation of methylthiophenes, eg, *N*-bromosuccinimide/benzoylperoxide on 2-, and 3-methylthiophenes gives the corresponding bromomethylthiophenes.

Useful nucleophilic substitutions of halothiophenes are readily achieved in copper-mediated reactions. Of particular note is the ready conversion of 3-bromoderivatives to the corresponding 3-chloroderivatives with copper(I)chloride in hot *N*,*N*-dimethylformamide. High yields of alkoxythiophenes are obtained from bromo- and iodothiophenes on reaction with sodium alkoxide in the appropriate alcohol, and catalyzed by copper(II) oxide, a trace of potassium iodide, and in more recent years a phase-transfer catalyst.

Toxicity. Thiophene is harmful by inhalation, in contact with skin, or if swallowed; it is also a skin-irritant. Thiophene may act as a central nervous system depressant; some evidence for liver damage in rats also exists. The methylthiophenes are irritating to skin, eyes, and the respiratory system. Thiophene and the methylthiophenes give a negative response in the Ames test for bacterial mutagenicity. Thiophene is harmful in the aqueous environment and is nonbiodegradable. Thiophene is regulated as a hazardous material under OSHA and also regulated under the Clean Air Act, Section 110, 40 CFR 60.489, but there are no exposure limits or controls set for 3-methylthiophene.

Uses. Thiophene and its derivatives find applications in the pharmaceutical area over a wide range of drug types, which can be divided into four main groups, veterinary and agrochemical products, and dyestuffs.

Nonsteroidal Antiinflammatory Rheumatoid and Osteoarthritis Drugs. Of the many drugs in this area on the market, a number contain the thiophene moiety, and new ones are coming through trials, prior to entering the market. Tenoxicam (Mobilflex) [CAS: 59804-37-4] (Hoffmann La Roche), a cyclooxygenase/ lipoxygenase inhibitor developed as an antiinflammatory, is also used to treat arthritis. Although it has been launched in over 70 countries, it has not been introduced into the United States. A near relative, Lornoxicam [CAS: 70374-39-9] (Haflund/Nycomed), is in trials as a nonsteroidal antiinflammatory (NSAI) analgesic and for the treatment of post-operative pain. Lornoxicam is said to be 10 times more effective than tenoxicam and is to be marketed to control severe pain. See also **Analgesics, Antipyretics, and Antiinflammatory Agents**.

An established product, Surgam [CAS: 33005-95-7] (Roussel UCLAF), is still in production in the 1990s. One of the newer drugs coming into this area is Tenidap [100599-27-7] (Pfizer), derived from 2-thiophenecarboxylic acid.

Hypertension and Heart Drugs. Heart disease and failure has a number of causes: hypertension, coronary artery disease, congestive heart failure, and arrhythmia of the heart. There are drugs that assist and control one or more of these conditions: angiotensin-converting enzyme (ACE) inhibitors, calcium antagonists, diuretics, and beta-blockers, respectively. Eprosartan [CAS: 133040-01-4] (SB) in phase-three clinical trials is one of a new class of drugs that can be used to control both congestive heart failure and hypertension. Ticlopidine [CAS: 55142-85-3] (Sanofi/Syntex)

and Clopidogrel [CAS: 90055-48-4] (Sanofi/BMS) are both antithrombotic drugs that prevent heart attacks, strokes, and peripheral arterial disease by acting as platelet aggregation inhibitors. Ticlopidine was the first such drug on the U.S. market following FDA approval in 1990. Clopidogrel is a similar product for the same purpose, with reported increased potency and fewer side effects. It is expected to have a bright future.

Antibiotics. Cephaloridine and Cephalothin (Glaxo) were early thiophene-containing, cephalosporin antibiotics. They have largely been replaced by later products, of which Cefoxitin [CAS: 35607-66-0] (Merck) is the principal thiophene-containing example. See also **Antibiotics**.

Ticarcillin [CAS: 34787-01-4] (SB) is a significant penicillin antibiotic that incorporates the thiophene ring system. A number of routes to the required intermediate, 3-thiophenemalonic acid [CAS: 21080-92-2], have been used over the years. Those from thiophene-based starting materials have involved 3-methylthiophene and 3-bromothiophene.

Veterinary Products. Principal users of thiophene are the anthelmintics Pyrantel [CAS: 15686-83-6] and Morantel [CAS: 20574-50-9] (Pfizer), based on 2-thiophenecarboxaldehyde and 3-methyl-2-thiophenecarboxaldehyde [CAS: 5834-16-2], respectively. Tioconazole, one of a range of fungicidal products incorporating thiophene, has also found veterinary applications.

Agrochemical Products. The principal thiophene derivative in herbicidal protection, one of a range of sulfonylurea herbicides, is Harmony [CAS: 79277-27-3] (Du Pont), based on the intermediate methyl 3-aminothiophene-2-carboxylate. The product is characterized by a rapid biodegradability in the soil. Many other thiophene derivatives have been shown to have agrochemical activity, but few of these have been developed to the commercial level.

Dyestuffs. The use of thiophene-based dyestuffs has been largely the result of the access of 2-amino-3-substituted thiophenes via new cyclization chemistry techniques. Intermediates of type are available from development of this work. Such intermediates act as the azo-component and, when coupled with pyrazolones, aminopyrazoles, phenols, 2,6-dihydropyridines, etc, have produced numerous monoazo disperse dyes. These dyes impart yellow–green, red–green, or violet–green colorations to synthetic fibers, with excellent fastness to light as well as to wet- and dry-heat treatments.

THIOPHOSGENE. See **Sulfur Compounds**.

THIOUREA. [CAS: 62-56-6], $(NH_2)_2CS$, formula weight 76.12, white crystalline solid, mp 180–182 °C (356-360 °F), decomposes before boiling at atmospheric pressure, sp gr 1.405. Thiourea is moderately soluble in H_2O, soluble in alcohol, and slightly soluble in ether. Sometimes referred to as thiocarbamide, sulfurea, and sulfocarbamide, thiourea may be considered chemically analogous to urea and is oxidized to urea by cold potassium permanganate solution. The compound is easily hydrolyzed to NH_3, CO_2, and H_2S. Upon long heating below the melting point, thiourea is transformed to ammonium thiocyanate [CAS: 17692-95-4]. Thiourea is attractive for plastics manufacture because of the greater ease with which substitution can be made on the sulfur atom of thiourea than on the oxygen atom of urea.

Thiourea is formed by heating ammonium thiocyanate at 170 °C (338 °F). After about an hour, 25% conversion is achieved. With HCl, thiourea forms thiourea hydrochloride; with mercuric oxide, thiourea forms a salt; and with silver chloride, it forms a complex salt.

Symmetrical diphenyl thiourea (thiocarbanilide) $(C_6H_5NH)_2CS$ is a solid, mp 154 °C (309 °F). When heated with concentrated HCl, the compound yields aniline plus phenylisocyanate. Formed by the reaction of aniline [CAS: 62-53-3] and CS_2 [CAS: 75-15-0], symmetrical diethylthiourea $(C_2H_5NH)_2CS$ is a solid, mp 77 °C (171 °F).

In addition to its use in plastics manufacture, thiourea is used in some photographic processes and photocopying papers; in organic synthesis as an intermediate (drugs, dyes, cosmetics); in rubber accelerators; and as a mold inhibitor.

THISTLE FAMILY. See **Artemisia**.

THIXOTROPIC SUBSTANCE. See **Colloid System**; and **Fluid**.

THIXOTROPY. The ability of certain colloidal gels to liquefy when agitated (as by shaking or ultrasonic vibration) and to return to the gel form when at rest. This is observed in some clays, paints, and printing inks that flow freely on application of slight pressure, as by brushing or rolling. Suspensions of bentonite clay in water display this property, which is desirable in oil-well drilling fluids.

See also **Rheology**.

THOMAS-FERMI DIFFERENTIAL EQUATION. An equation which occurs in studying the electron distribution in an atom

$$y''\sqrt{x} = y^{3/2}$$

Although a special solution can be given as $x^3y = 144$, it is required for physical reasons that $y(0) = 1$, $y(\infty) = 0$. Solutions satisfying these boundary conditions must be found by numerical or graphical methods.

THOMSON, J.J. (1856–1940). Joseph John Thomson was an English physicist. At age fourteen, his father sent him to Owens College for preparatory scientific training. His attendance here was important to his career because this college had an outstanding science faculty and it also offered many experimental physics courses.

Thomson earned his engineering degree from Owens. Then he attended Trinity College of Cambridge University and studied mathematics and theoretical physics. When he graduated he began working in the Cavendish Laboratory at Cambridge and by age twenty-seven became its director. Thomson's main research was on the conduction of electricity through gases. After, Roentgen's discovery of X-rays in 1895, Thomson started working with Rutherford and found that passing X-rays through gases greatly increased their ability to conduct electricity. Much of Thomson's further research dealt with the composition of cathode rays. He believed that cathode rays were streams of tiny charged particles. His work concluded that the atom was not the fundamental unit of matter. He devised a model of the atom incorporating his theory of *corpuscles*. Later, the name "electron" was adopted.

In 1906, Thomson received the Nobel Prize for Physics "in recognition of the great merits of his theoretical and experimental investigations on the conduction of electricity by gases." Between the years of 1906 and 1914, Thomson studied canal rays and worked on separating the different kinds of atoms and atomic groupings present in them. In 1903, Thomson proposed a discontinuous theory of light, with light rays being composed of separate particles rather than continuous streams, and later Einstein developed the photon theory of light.

Thomson's work revolutionized scientific understanding of the atom and ushered in a new era in physical science. He is also remembered for his excellent teaching at Cavendish Laboratory.

See also **Electricity**; and **Electron Theory**.

J. M. I.

THOMSON (Law of). (Or *Law of Helmholtz; Thomson's Rule*.) In an electric cell, the heat of reaction is a direct measure of the electromotive force, i.e., the chemical energy is simply converted into electrical energy. This is only approximately true, for part of the energy of an electric cell appears as heat, either absorbed or evolved, as the case may be.

THOMSON PARABOLA METHOD. The method of investigating the charge-to-mass ratio of positive ions in which the ions are acted upon by

electric and magnetic fields applied in the same direction normal to the path of the ions. It can be shown that ions of a given charge-to-mass ratio but different velocities will be deflected so as to form a parabola.

THOMSON PRINCIPLE. The hypothesis that, if thermodynamically reversible and irreversible processes take place simultaneously in a system, the laws of thermodynamics may be applied to the reversible process while ignoring for this purpose the creation of entropy due to the irreversible process. Applied originally by Thomson to the case of thermoelectric effects. Also used in the treatment of electrochemical cells, thermal diffusion.

THOMSON SCATTERING. See **Scattering**.

THORAX. 1. The division of the arthropod body between the head and abdomen. It consists of three or four metameric segments of the body, often closely united so that their boundaries are difficult to determine. It bears a pair of jointed appendages on each segment, developed for walking or swimming, and in some species for grasping, and in the insects the two posterior segments may bear a pair of wings each. The three segments of the insect thorax are known as the pro-, meso-, and metathorax.

2. A division of the trunk of vertebrates, just behind the head and neck. This region is supported by the ribs and contains the thoracic cavity, a division of the coelom. In the mammals it is separated from the abdominal cavity by the diaphragm and is further subdivided into the pleural cavities containing the lungs and the pericardial cavity containing the heart. It is a bony cage made of the sternum in front, the vertebral column behind, and the ribs connecting the two.

THORIANITE. This mineral of thorium oxide [CAS: 1314-20-1], ThO_2, is isomorphous with uraninite and occurs in black, nearly opaque cubic crystals in Ceylon and in Madagascar. Often containing rare-earth metals and uranium, the ore is strongly radioactive. Because of its radioactivity, it is valuable in helping to date the relative ages of rocks in which it occurs.

THORITE. The mineral thorite is a silicate of the rare element thorium and corresponds to the formula $ThSiO_4$. It is tetragonal and exhibits a prismatic cleavage. The original thorite was black in color with a specific gravity of 4.4–4.8. A variety orangite, so called from its orange-yellow color, has a specific gravity of 5.19–5.40. It has been found partly altered to thorite. Uranothorite contains uranium oxide. Thorite occurs in Norway in augite syenites. Thorite and orangite occur in Sweden, and orangite and uranothorite are found in Madagascar. Uranothorite is found in Ontario.

THORIUM. [CAS: 7440-29-1]. Chemical element symbol Th, at. no. 90, at. wt. 232.038, is the second radioactive element of the Actinide Series, mp 1750 °C (3182 °F), bp 4790 °C (8654 °F), density 11.5–11.9 g/cm^3 (17 °C (63 °F)). Thorium metal is dark gray, dissolves in HCl, is made passive in HNO_3, and is not affected by fusion with alkalis. The element combines with chlorine or sulfur at 450 °C (842 °F); with hydrogen or nitrogen at 650 °C (1202 °F). All thorium-containing substances are radioactive. The element was discovered in 1828 by the Swedish chemist Jöns Jakob Berzelius in a Norwegian mineral. Thorium is named after Thor, the Norse god of thunder. The metal had virtually no uses until the invention of the lantern mantle in 1885. The electronic configuration

$$1s^2 2s^2 2p^6 3s^2 3p^6 3d^{10} 4s^2 4p^6 4d^{10} 4f^{14} 5s^2 5p^6 5d^{10} 6s^2 6p^6 6d^2 7s^2.$$

The chemistry of thorium, dominated by the +4 oxidation state, is similar to that of the lanthanides and the Group 4 (IVB) elements, Ti, Zr, and Hf. Compounds containing thorium in lower oxidation states are known, but exceedingly rare in contrast to its lanthanide homologue, cerium. Reduction of Th(IV) to lower oxidation states is very difficult, especially in solution. Standard potentials of Th(IV) in aqueous solutions have been estimated based on spectroscopic measurements, or determined indirectly from thermodynamic data. The electrochemistry of actinide elements has been reviewed, and the data span a wide range. The values most often quoted are those calculated using a modified ionic model to obtain the Gibbs free energy of formation for the Th(IV) aquo ion. The predicted standard electrode potentials from this approach are as follow:

$$Th^{4+}|Th^{3+} - 3.0V$$
$$Th^{3+}|Th^{2+} - 2.8V$$
$$Th^{2+}|Th^{0} - 0.77V$$
$$Th^{3+}|Th^{0} - 1.44V$$
$$Th^{4+}|Th^{0} - 1.82.0V$$

Twenty-five isotopes of thorium have been observed having masses ranging from 212 to 236. Radioactive half-lives range from 0.1 μs for ^{218}Th to 1.405×10^{10} yr for ^{232}Th. The latter is the predominant isotope in nature. The light thorium isotopes having masses of 212 to 232 decay by emission of α-particles; the heavy thorium isotopes, ie, 231 and 233–236, decay by β-emission. Thorium is a member of all three naturally occurring decay series of the long-lived isotopes, ^{232}Th, ^{235}U, and ^{238}U, as well as the synthetic Np series. ^{232}Th is the progenitor of the 4n decay series (Fig. 1), which includes ^{228}Th as a transient. ^{234}Th and ^{230}Th (4n+2), ^{231}Th and ^{227}Th (4n+3), and ^{229}Th (4n+1) are daughters in other decay series. The most commonly used isotopes after ^{232}Th include ^{228}Th (1.91 yr, α), ^{230}Th (7.54×10^4 yr, α), and ^{234}Th (24.5 d, β). See also **Radioactivity**; and **Radioisotopes**.

Occurrence. Thorium has a wide distribution in nature and is present as a tetravalent oxide in a large number of minerals in minor or trace amounts. Thorium is significantly more common in nature than uranium, having an average content in the earth's crust of approximately 10 ppm. By comparison, Pb is approximately 16 ppm. Thorium has a seawater concentration of $<0.5 \times 10^{-3}$ g/m^3. Thorium refined from ores free of uranium would be almost monoisotopic ^{232}Th, ie, the ^{228}Th from its own decay chain would be one part in 10^{10}. The presence of uranium in the ore introduces infinitesimal amounts of short-lived ^{231}Th and ^{227}Th from the decay of ^{235}U, and ^{234}Th from ^{238}U decay. The isotopes ^{232}Th and ^{228}Th occur in thorianite, ThO_2, and thorite, $ThSiO_4$; ^{234}Th and ^{230}Th are present in naturally occurring uranium; ^{231}Th and ^{227}Th occur in uranium minerals as members of the ^{235}U decay chain. The remaining isotopes are formed upon neutron bombardment of those isotopes discussed, or by charged particle bombardment of various targets.

Thorium isotope concentrations and ratios, as well as parent and daughter isotope concentrations, are used to date and study the formation and metamorphosis of rocks and sediments. For example, ^{230}Th / ^{234}U

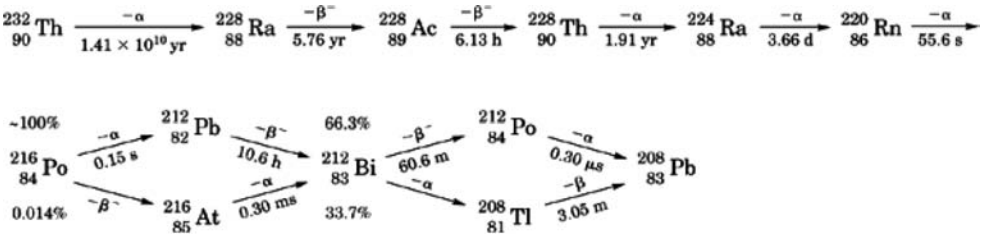

Fig. 1. The 4n decay series.

has been used to date coral reef terraces. ^{238}U / ^{230}Th disequilibria and ^{230}Th / ^{232}Th ratios are used to determine the source and history of basalts. In addition to dating and petrogenetic studies, thorium isotopes are used as magma source tracers.

There are only a few minerals where thorium occurs as a significant constituent. The commercially important ore is the golden-brown, lanthanide phosphate, monazite [CAS: 1306-41-8], $LnPO_4$, where Ln = Ce, La, or Nd, in which thorium is generally present in a 1–15% elemental composition. Monazite is widely distributed around the world. Some deposits are quite large. Beach sands from Australia and India contain monazite from which concentrates of lanthanides, titanium, zirconium, and thorium are produced. The Travancore deposits in India are the most famous, and have been perhaps one of the most significant sources of commercial thorium. See also **Mineralogy**.

Thorium occurs in earth minerals, an average content estimated at about 12 ppm. Findings of the *Apollo 11* space flight indicated that thorium concentrations in some lunar rocks are about the same as the concentrations in terrestrial basalts.

Chemistry and Compounds. Thorium has the oxidation state of (IV) in all of its important compounds. Its oxide, ThO_2, and its hydroxide are entirely basic. The nature of the ions present in a number of solutions of the soluble compounds is not known with certainty. Complex ions involving sulfate are suggested by the increased solubility of the sulfate in solutions of the acid sulfates. Similarly, other complex ions are suggested by the solubility of the carbonate in excess alkali carbonate and of the oxalate in ammonium oxalate. Such ready complex ion formation is consistent with the high positive charge of the thorium-(IV) ion.

Although the exact extent is not known accurately, hydrolysis of various salts is known to occur. Since the hydroxide is not precipitated it is assumed that the hydrolysis product is some ion on the form $Th(OH)_2^{++}$ or $ThOH^{3+}$. The solution chemistry of thorium is made more complicated because of the hydrolytic phenomena observed and the polynuclear complex ions that are formed at low acidities and higher thorium concentrations.

Studies of the complex ions formed by Th^{4+} with various complexing anions have given much information. For example, the equilibria and ionic species involved in the chloride complexing of aqueous thorium have been studied through the method of measuring the distribution between H_2O and benzene containing thenoyltrifluoroacetone [CAS: 326-91-0]. The conclusion: that there is successive complexing involving the species $ThCl^{3+}$, $ThCl_2{}^{2+}$, $ThCl_3^+$ and $ThCl_4$. Similarly, all the intermediate chelate complex ions between thorium and acetylacetone [CAS: 123-54-6] exist in aqueous solution of proper acidity.

Thorium dioxide [CAS: 1314-20-1] (face-centered cubic structure) is very insoluble in H_2O, but dissolves in acids to yield salts.

Thorium forms one series of halides, another one of oxyhalides, and also a series of double or complex halides. In general, stability of these compounds toward heat decreases as the atomic weight of the halogen increases. These compounds are often isostructural with the corresponding compounds of other actinide elements in the (IV) oxidation state.

Thorium metal reacts with hydrogen at moderately elevated temperatures to yield two hydrides: (1) ThH_2, which has a pseudotetragonal body-centered unit containing two metal atoms, isomorphous or pseudoisomorphous with thorium carbide, zirconium hydride [CAS: 13940-37-9], and zirconium carbide [CAS: 12070-14-3], ThC_2, ZrH_2, and ZrC_2; and (2) a hydride of approximate composition $ThH_{3.75}$ or ThH_4, possessing a unique cubic structure unrelated to that of the parent metal.

Thorium sulfide, ThS_2, is obtained by the action of H_2S or sulfur on thorium metal. The oxysulfide, ThOS, has been obtained in several ways, one of which is by the action of CS_2 on thorium dioxide at elevated temperatures. At 800 °C and under pressure, sulfur combines with thorium to yield compounds with approximately the formulas ThS, Th_2S_3, and Th_3S_7. The first two have semimetallic properties and may be employed as ceramics for use with highly electropositive metals, whereas the last appears to be a polysulfide.

Anhydrous thorium sulfate, $Th(SO_4)_2$, is obtained by the action of concentrated H_2SO_4 on thoria (ThO_2). A solution of this salt deposits crystals of $Th(SO_4)_2 \cdot 9H_2O$ at about 15 °C (59 °F), $Th(SO_4)_2 \cdot 8H_2O$ near 24 °C (75 °F), and $Th(SO_4)_2 \cdot 4H_2O$ around 45 °C (113 °F). At 100 °C (212 °F) other hydrates change to $Th(SO_4)_2 \cdot 2H_2O$. In aqueous solution, the salt is considerably hydrolyzed to an oxysulfate — for instance, $ThOSO_4 \cdot H_2O$.

Thorium nitrate, [CAS: 13823-29-5], $Th(NO_3)_4 \cdot 12H_2O$, is obtained by dissolving thorium hydroxide in HNO_3.

Thorium orthophosphate, $Th_3(PO_4)_4 \cdot 4H_2O$, is precipitated by adding a solution of sodium phosphate to an acidic solution of a thorium salt. Thorium pyrophosphate, $ThP_2O_7 \cdot 2H_2O$, precipitates when an acidic solution of thorium nitrate is treated with one of tetrasodium pyrophosphate.

Thorium has been used as a fuel for nuclear reactors since it is a fertile material for the generation of fissionable uranium-233. Some experts have estimated that the energy available from the world's reserves of thorium is greater than all of the remaining fossil fuels (coal and petroleum) and of all of the remaining uranium, combined. Thorium oxide is used for gas mantles. The oxide also helps to control grain size in tungsten filaments and strengthens nickel alloys (TD nickel). Thorium is also used as an alloying addition in magnesium technology and as a deoxidant for molybdenum, iron, and other metals. Several applications for thorium are found in electronic technology.

Thorium oxide has a high refractive index and low dispersion and thus finds use in high-quality camera and scientific instrument lenses. Thorium oxide also is used as a catalyst in the conversion of ammonia to nitric acid, in petroleum cracking, and in sulfuric acid production.

Health and Safety. Thorium is potentially hazardous. Finely divided thorium metal and hydrides can be explosive or inflammatory hazards with respect to oxygen and halogens. Finely divided ThO_2 and other inorganic salts also present an inhalation and irritation hazard. The use of standard precautions, skin covering, and a conventional dust respirator should be sufficient for handling thorium materials.

The long half-life of ^{232}Th makes it a minimal radiation hazard. External radiological hazards are generally not of concern because γ-rays from thorium daughter products have low abundance and many are in the x-ray range, ie, <85 keV, where they are absorbed in the source material. There are some residuals in the 240 and 727 keV energy range that can lead to radiation effects from ton quantities of materials. Such sources merit safety precautions in terms of distance and shielding.

When inhaled, ingested, or adsorbed through the skin, thorium isotopes are potentially harmful because of ionizing radiation and chemical toxicity. If Th(IV) is injected as the soluble nitrate form, it can cause hemolysis. Thorium is generally insoluble in the presence of organic complexing agents and mainly retained in the bones, lungs, lymph nodes, and parenchymatous tissues. In animal experiments, not more than 10^{-4}% of thorium was absorbed from the gastrointestinal tract (91). Prolonged retention of thorium, particularly in a fixed location, allows the possibility of radiation damage by the energetic α-particles of some of the short-lived daughter members of the decay chain, of which there are five for every thorium alpha.

Thorium compounds are legally classified as source materials for nuclear energy and thus are regulated by various government agencies, eg, the Nuclear Regulatory Commission. The relevant regulations cover licensing and safety aspects.

THRASHER *(Aves, Passeriformes)*. Moderately large North American birds related to the wrens, the mockingbird, and the catbird. They have a long curved beak. Several of the species are among our finest singers.

The brown thrasher, *Toxostoma rufum*, is a familiar bird east of the Rockies. Our six other species are western and southwestern.

THREADWORMS. See **Nematodes**.

THREE-BODY PROBLEM (Astronomy). Assuming that three or more objects exist in the universe, and that each of them attracts the others in accordance with the law of gravitation, there is the problem of predicting subsequent positions and motions. This problem is commonly referred to as the three-body, or *n*-body, problem.

The two-body problem has been completely solved, and the full solution may be expressed in comparatively few words and symbols. However, if one or more bodies is added, the solution becomes an exceedingly complex one that has never been reached in any form at all suitable for computational purposes. In fact, only one complete solution has ever been arrived at, in spite of the labors of practically all the great mathematicians of the past three centuries.

Despite the fact that no general solution of the problem is available, there are several practical computational methods for determining the positions of planets and other members of the solar system, taking into account the gravitational attraction of all effective members. All such solutions are made by successive approximations and various methods of computing perturbations rather than by the application of any general solution. In addition, a number of particular solutions of the three-body problem have been made by mathematicians. Lagrange, notably, showed that it is possible for an asteroid to be stable in such a position that it is equidistant from both the sun and Jupiter. In such a case, the three objects would be on the vertices of an equilateral triangle, and the asteroid orbit would have the same period as Jupiter. This case is illustrated in nature by the members of the so-called Trojan group.

THREE-PHASE EQUILIBRIUM. For every pure, chemically stable substance there is a certain temperature and pressure at which it can exist in all three states or phases, solid, liquid, and vapor, each phase being in equilibrium with each of the others. At higher temperatures and pressures than those at this so-called "triple point," the liquid and vapor states may attain equilibrium; solid-vapor equilibrium is possible at lower temperatures and pressures; and solid liquid equilibrium can be obtained at higher pressures and at lower or higher temperatures according as the substance contracts or expands upon melting. These three equilibria may be represented by three temperature-pressure graphs, which converge at the triple point. Figure 1 illustrates the case of water.

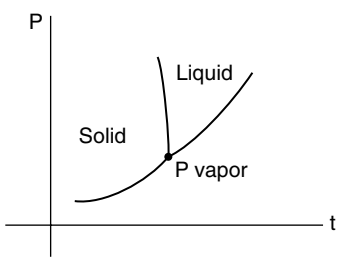

Fig. 1. Triple-point (P) on temperature-pressure diagram.

In 1954, the thermodynamic temperature scale (i.e., the absolute Kelvin scale was redefined by setting the triple point temperature for water equal to exactly 273.16 K).

THRESHER SHARK. See **Sharks**.

THRESHOLD DECODING. See **Information Theory**.

THRESHOLD DETECTOR. A circuit that provides an indication (digital) that a signal input is in excess of a predetermined magnitude. Assuming a predetermined threshold value were 6 V, an input of 6.5 V will result in an output representing a binary 1 and an input of 5.5 V causes a digital output representing a binary 0. Thus, a threshold detector is a form of comparator. The terms sometimes are used interchangeably. See also **Comparator Amplifier**. However, the term *comparator* may refer only to a circuit that detects whether or not an input signal has changed polarity.

From a practical standpoint, a band of uncertainty surrounds the predetermined threshold value. Thus, an input signal with a value that falls within the deadband will produce an indeterminant output, that is, one that cannot be interpreted as either a 1 or a 0. Increasing the gain of the threshold circuit will reduce the magnitude of the deadband. However, stability and overload considerations place limitations upon gain.

Threshold circuits are extensively used in data-acquisition and instrumentation systems. The terms *voltage sense* and *level sense* sometimes are used to describe a threshold circuit in digital systems. The devices are commonly used in instrumentation alarm systems for monitoring circuits, as for example, the output of a thermocouple to initiate a visual or audible alarm should a temperature rise too high or fall too low in a process.

THRESHOLD ILLUMINANCE. The lowest value of illuminance that the eye is capable of detecting under specified conditions of background luminance and degree of dark adaptation of the eye. Also called *flux-density threshold*. This threshold, which controls the visibility of point light sources, especially at night, cannot be assigned any universal value, but nonflashing lights can generally be seen by a fully dark-adapted eye when the lights yield an illuminance of the order of 0.1 lumen per square kilometer at the eye.

THRIP *(Insecta, Thysanoptera)*. An order of minute insects, with or without wings. Their mouths are formed for sucking, the tarsi (feet) have an expanded tip, and the metamorphosis is gradual. When wings are present, there are two pairs, both formed of slender membranes with very long fringes. The insects are quite small, seldom over $\frac{1}{8}$ inch (3 millimeters) long. The thrips generally like to live in the floral portion of plants, but are found elsewhere, always feeding upon the sap. Some species are very serious pests on such crops as vegetables, fruits, field crops, and decorative flowers, notably those cultivated in glasshouses. The mouth portion of a thrip can be described as having an action that lies between that of the chewing insect and the piercing-sucking insect. Some thrips live on other small insect eggs and mites and thus, in certain cases, have an economic value. The thrips tend to specialize. Some of the major species injurious to crops are described in the remainder of this entry.

Bean Thrip (*Hercothrips fasciatus*, Pergande). These insects feed on the foliage of bean, pea, and several other vegetable crops. They leave the plant with a silvered-bleached appearance and covered with very small black spots of excrement of the nymphs. The latter covering is sometimes called soot. Left uncontrolled, an infestation of thrips causes wilting and ultimately kills the plant.

Citrus Thrips. There are three principal species that seriously damage citrus and many deciduous fruits. The species we describe here is *Scirtothrips citri* (Moulton). This insect can be quite damaging to citrus crops in Arizona and California, particularly in very dry, warm weather. The insect is less active in Florida. This insect winters in the egg stage. The eggs are deposited on the leaves and stems of infested trees. A female may deposit up to 250 eggs.

Dusting with very fine sulfur powder can be effective. Sulfur sprays also can be used.

Damage rendered by the thrip is by way of attacking buds and new growth, thus retarding the general development of an entire tree. The thrip also injures the fruit, causing a scarring of the skin and deformation of the fruit. Sometimes there is a telltale round mark or ring around the stem end of the fruit, indicating where thrips have fed beneath the sepals at the time the fruit was quite small. In very heavy infestations, crop losses approaching 90% have been recorded. See Fig 1.

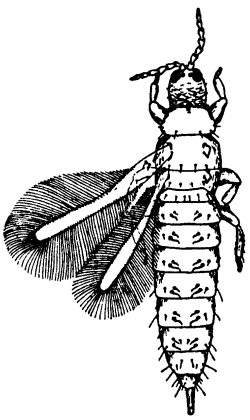

Fig. 1. Thrip.

Onion Thrip (*Thrips tabaci*, Lindeman). This insect damages nearly all garden crops, some weeds and field crops. This thrip is particularly injurious to bean, beet, cabbage, cauliflower, cucumber, melon, onion, squash, sweet clover, tomato, and turnip. It is distributed in all regions where onions are grown. On these plants, the thrip punctures leaves and sucks the exuding sap, leaving whitish areas on the leaves. In a severe infestation, most of the leaves are destroyed and the plant winters and dies. Unless controlled, the pest can destroy entire crops, notably in very dry seasons.

Pear Thrip (*Taeniothrips inconsequens*, Uzel). In addition to pear, which this insect attacks vigorously, it also damages apple, apricot, cherry, grape, peach, plum, prune, and other fruit trees and bushes. The pear thrip was observed in the United States for the first time in the early 1900s in California. It has spread throughout the Pacific coastal area to British Columbia. It is also now found in the eastern states, principally Maryland, New York, and Pennsylvania.

THROAT. Internally, the pharynx: the cavity behind the mouth into which the nasal passages open and from which the esophagus and trachea lead. Externally, the ventral part of the neck.

THROMBIN. A proteolytic enzyme that catalyzes the conversion of fibrinogen to fibrin and thus is essential in the clotting mechanism of blood. It is present in the blood in the form of prothrombin under normal conditions; when bleeding begins, the prothrombin is converted to thrombin, which in turn activates the formation of fibrin.

See also **Anticoagulants**; and **Blood**.

THROMBOCYTES. See **Blood**.

THROMBOLYTIC AGENTS. See **Coronary Artery Disease (CAD)**.

THROMBOPLASTIN. See **Blood**.

THROMBOSIS. Thrombosis is the formation of a clot or thrombus inside a blood vessel, obstructing the flow of blood through the circulatory system. This is always abnormal and is often dangerous, as it can reduce or stop the flow of blood. When thrombosis affects important arteries, such as the coronary arteries (causing a heart attack) or the arteries supplying the brain with blood (causing a stroke), it is a major cause of death and serious illness. See also **Blood Clotting: General Pathway**.

Thrombosis of arteries supplying the legs leads to pain on using the leg (or even when at rest if the thrombosis is severe). If the blood flow is cut off completely, the leg dies and becomes gangrenous. If this happens in the arteries to the intestines, gangrene of a segment of bowel follows. This is a surgical emergency. Thrombosis of the arteries to the kidneys can cause serious kidney damage.

Thrombosis of deep leg veins causes swelling, redness and pain in the leg. A clot may break off and, carried with the flow of blood, lodge in the lungs. This is called a *pulmonary embolism* and is a common cause of sudden, unexpected death. See also **Arteries and Veins (Vascular System)**.

Thrombosis of superficial veins in the legs has no connection with deep-vein thrombosis and is not dangerous. It can be caused by skin infection or repeated blows to the skin over the veins. In intravenous drug abusers it can occur where a vein is regularly punctured with a needle.

Introduction

Thrombosis is clearly the most common cause of death in the United States. About two million individuals in the U.S.A. die each year from an arterial or venous thrombosis or the consequences.

By comparison, about 540,000 individuals in the USA die each year from cancer. About 80% to 90% of all causes of thrombosis can now be defined with respect to cause. Of these, up to 90% of all patients harbor a congenital or acquired blood coagulation protein or platelet defect which caused or contributed to the thrombotic event. See also **Blood Coagulation**; and **Platelets**.

It is obviously of major importance to define those individuals harboring such defects, as this allows:

1. appropriate antithrombotic therapy to decrease risks of recurrence,
2. determination of the length of time the patient should remain on therapy for secondary prevention,
3. testing of family members in patients having a blood coagulation protein or platelet defect which is hereditary (about 50% of all coagulation and platelet defects).

Some of the blood coagulation protein / platelet defects leading to arterial and venous thrombosis (blood clots) are found at Blood Proteins.

Aside from mortality, significant additional morbidity (interference with quality of life and creation of significant handicaps) occurs from both arterial or venous thrombosis, including, but not limited to: Paralysis (non-fatal thrombotic stroke); cardiac disability (repeated coronary events); loss of vision (retinal vascular thrombosis) and recurrent miscarriage syndrome (placental vascular thrombosis); and stasis ulcers and other manifestations of post-phlebitic syndrome (recurrent deep vein thrombosis).

Almost all of these events are avoidable with appropriate diagnosis and specific therapy defined for individual defects. Specific examples are as follows: Recurrent Miscarriage; Deep Vein Thrombosis; TIA's and Stroke; Retinal Vascular Thrombosis; Coronary Thrombosis; and Peripheral Thrombosis.

The causes of hypercoagulability and overt thrombosis are becoming more clear and often definitive with enhanced knowledge of hemostasis and the development and extended utilization of testing systems useful for evaluating patients with thrombotic and thromboembolic disorders. Using these test systems, in conjunction with careful clinical assessment of patients, about 80%–90% of patients with thrombosis will have a defined etiology. Many of these will have an obvious clinical condition leading to thrombosis and at least 50%–80% will have an underlying hereditary or acquired blood protein / platelet defect causing thrombosis.

It must be remembered that today a diagnosis of thrombosis is almost meaningless and similar to and as general as a diagnosis of "anemia;" one must, in all instances, as in anemia, ask next: What is the Specific Cause of the Thrombosis? Like anemia, appropriate therapy is highly dependent upon defining the cause. Thrombosis, be it arterial or venous, can no longer be viewed as a general diagnosis; approaching thrombosis in this manner

probably accounts for not only many treatment failures, but also for often confusing and conflicting results of clinical trials.

Coronary Thrombosis. The heart is surrounded by three major coronary arteries that supply it with blood and oxygen. If a blood clot develops in one of these arteries, the blood supply to that area of the heart muscle will stop. This is known as a coronary thrombosis, a myocardial infarction or heart attack.

Most commonly a coronary thrombosis will cause severe chest pains behind the sternum (breast bone), often radiating towards the left arm. The area of muscle to which there is insufficient supply stops working properly if the blood clot is not dissolved quickly, e.g., with thrombosis dissolving (thrombolytic) medication.

Coronary thrombosis, which usually takes place in the coronary arteries, frequently develops at the site of an atherosclerotic plaque rupture. Most people in the developed world have atherosclerosis (hardening of the arteries) in some parts of their body, without ever noticing it. Atherosclerosis may start around the age of 20 and develops gradually with increasing age. See also **Arties and Veins**; and **Ischemic Heart Disease**.

Some people have symptoms of atherosclerosis in the coronary arteries which shows up as angina (pains in the chest). Conversely, plaque rupture leading to a coronary thrombosis often occurs in someone with no previous history of angina. See also **Angina**.

It is the lining of the artery supplying the heart muscle that forms an atherosclerotic plaque. This diseased area of the coronary artery can, if it ruptures, develop a blood clot on it, comprising blood clotting proteins, platelets and red blood cells. This formation has the potential to seal off the blood supply.

Numerous "risk factors" are known to be associated with the development of coronary thrombosis. These include: a family history of atherosclerosis; a high content of cholesterol in the blood; hypertension (high blood pressure); smoking; male gender; if one suffers from diabetes Type 1 or Type 2; being overweight; stress; and lack of exercise.

See also **Coronary Thrombosis**.

Deep Vein Thrombosis and Pulmonary Embolus. Deep vein thrombosis (also called DVT) is a blood clot in a vein deep inside the body. These clots usually occur in your leg veins. While DVT is a fairly common condition, it is also a dangerous one. If the blood clot breaks away and travels through your bloodstream, it could block a blood vessel in the lungs. This blockage (called a pulmonary embolism) can be fatal.

Three main factors (known as Virchow's triad) can contribute to deep vein thrombosis: injury to the vein's lining, an increased tendency for blood to clot, and slowing of blood flow.

Veins may be injured during surgery, by injection of irritating substances, or by certain disorders, such as Buerger's disease. They may also be injured by a clot, making formation of a second clot more likely.

Some disorders, such as disseminated intravascular coagulation, cause blood to clot when it should not. Some cancers and, rarely, use of oral contraceptives can cause blood to clot more readily. Sometimes blood clots more readily after childbirth or surgery. Among older people, dehydration and smoking are common causes of this tendency and can therefore contribute to deep vein thrombosis.

During prolonged bed rest, blood flow slows, because the calf muscles are not contracting and squeezing the blood toward the heart. For example, deep vein thrombosis may develop in people who have had a heart attack and lie in hospital beds for several days without sufficiently moving their legs or in people whose legs and lower body are paralyzed (paraplegics). Deep vein thrombosis can develop after hip repair or replacement. Thrombosis can even occur in healthy people who sit for long periods, for example, during long drives or airplane flights. See also **Deep Vein Thrombosis & Pulmonary Embolus**; and **Arties and Veins (Vascular System)**.

Peripheral Thrombosis. The incidence of peripheral arterial thrombosis in the USA is not clear, but is a common problem. Although PAT may not always be fatal, it usually leads to significant morbidity.

At least 30% of patients with PAT have a blood coagulation protein / platelet defect causing or contributing to the defect. As with the other defects discussed, it is very important to define the presence of these defects to (1) design effective therapy to prevent another event (2) to determine how long the patient should be treated and (3) to determine if the defect is hereditary, so appropriate family members can be tested, and treated before an event, when indicated.

Retinal Vascular Thrombosis. Although the incidence of retinal arterial or venous thrombosis is unclear and death does not occur, significant visual impairment is a major problem. At least 30% of individuals suffering from retinal vascular thrombosis have a blood coagulation protein or platelet defect; some are hereditary and some are acquired.

Defining the defect will allow one to optimize antithrombotic therapy for preventing another episode, thus preserving sight as much as possible; this is the best way to make sure appropriate therapy can be delivered to decrease, as much as possible, another event. If the defect is hereditary, appropriate family members should be assessed and, when indicated, treated to potentially prevent the first retinal or other type of thrombosis.

Recurrent Miscarriage Syndrome. Recurrent miscarriage syndrome (RMS) is characterized by recurrent spontaneous abortion. RMS is generally defined when a woman suffers one miscarriage and has a first order genetic relative with a miscarriage (mother or sister) or suffers two unexplained miscarriages.

There are many causes of RMS, including anatomical anomalies (about 10% of unexplained miscarriages), endocrine or hormonal abnormalities (about 15% of unexplained miscarriages), genetic / chromosomal abnormalities (about 10% of RMS and blood coagulation protein / platelet defects, which account for 50%–60% of recurrent miscarriages. Many of these are treatable, leading to normal term pregnancy, if the clinician is astute and vigorously pursues a thorough evaluation of why the patient has suffered unexplained, spontaneous miscarriages.

There is no uniform agreement on how many spontaneous unexplained miscarriages constitute FWS; we generally pursue an evaluation for causation if a women has had two or more such events, or one event with a positive family history for unexplained miscarriage.

The coagulation protein and platelet defects associated with fetal wastage include Factor XIII and Factor XII defects, dysfibrinogenemia, antiphospholipid syndrome including both anticardiolipin antibodies (ACLA) and lupus anticoagulant (LA), plasminogen defects, other fibrinolytic system defects such as elevated plasminogen activator inhibitor, Type 1 (PAI-1) or low tissue plasminogen activator (t-PA), congenital protein S defects, Prothrombin 20210A and Sticky Platelet Syndrome.

Bleeding defects (rare) lead to inadequate fibrin-induced implantation of the fertilized ovum into the decidua. However thrombotic defects (extremely common), including antiphospholipid syndrome, plasminogen defects, fibrinolytic system defects, some cases of dysfibrinogenemia, Sticky Platelet Syndrome and other hypercoagulable blood protein/platelet defects leading to accelerated clotting are associated with thrombosis of the early placental blood vessels, precluding viability of the implanted ovum or fetus.

The diagnosis of fetal wastage syndrome due to blood coagulation protein/platelet defects is made by noting two or more unexplained spontaneous abortions, usually in the first trimester and a high index of suspicion, followed by appropriate clinical and laboratory evaluation. We have reported our experience, including prevalence and management, in women with fetal wastage syndrome due to blood protein/platelet defects.

TIA's and Stroke. Cerebrovascular thrombosis (CVT) occurs in over 1,500,000 individuals yearly in the USA; of these, 66% suffer death or severe permanent paralysis. In those suffering CVT, including transient cerebral ischemic attacks (TIA's), small stroke syndrome (SSS) and frank thrombotic stroke, at least 30% harbor a blood coagulation protein or platelet defect causing thrombosis.

Like the disorders discussed above, the need for defining the presence or absence and type of defect is of obvious importance. Once the defect is defined, effective therapy can be offered to significantly decrease the chances for another event. Also, since 50% of these defects are hereditary, appropriate family members can be assessed, treated when appropriate, and potentially be saved the first thrombotic stroke or TIA. See also **Cerebrovascular Diseases**; and **Stroke**.

THROTTLE. To throttle means to choke. Throttling a fluid flow is to decrease the cross-sectional area of flow at some point, as by partly closing a valve, damper, or gate in the conduit.

This word is in common usage to denote the adjustable control on the quantity of the working medium entering prime movers and hence has become synonymous, in common usage, with the control of prime mover power.

THROUGHPUT. In vacuum technology, the quantity of gas in pressure-volume units at a specified temperature flowing per unit time across a specified open section of a pump or pipeline. The specified temperature may be the actual temperature of the gas or a standard reference temperature. It is recommended that throughput be referred to standard room temperature. The recommended unit of throughput is the torr liter per second at 20 °C. Other units of throughput in common use are micron liters per second at 25 °C and micron cubic feet per minute at 68 °F. Under conditions of steady-state conservative flow the throughput across the entrance to a pipe is equal to the throughput at the exit. In this case throughput can be defined as the quantity of gas flowing through a pipe in pressure-volume units per unit time at room temperature.

THROWING POWER. A term used to denote the relative effectiveness of various electrolytic cells for the deposition of metal at the cathode. It is commonly determined by means of two half-cathodes which give the values for the relation between the distance from the anode and the weight of metal deposited.

THRUSH *(Aves, Passeriformes)*. In the broad sense, a bird of the family *Turdidae*, but the term is most widely applied to the members of this family that retain a spotted breast as adults, while other species which lose the spots as their adult plumage develops receive other names. Among the latter are the robin and bluebirds of North America. The North American thrushes are of moderate or small size, brown, gray, or olive above and white below, with spots similar to the back. The wood thrush, *Hylocichla mustelina*, is widely distributed in the eastern half of the United States (Fig. 1), and the hermit thrush, *H. guttata*, is even more widely distributed, though less commonly known. The veery, also called Wilson's thrush (*Hylocichla muscescens*) also is found in eastern North America.

Fig. 1. Wood thrush. Bright brown above; white below, with large round spots on the breast and sides.

The family includes the European fieldfare, redwing, and blackbird, the ring-ouzel, and the Old World chats. In North America it is also represented by the Townsend solitaire and the wheatear, in addition to the robin and the several species of bluebirds.

The song-thrush of Europe, *Turdus philomelus*, is also called the mavis, and in America the term *thrush* is misapplied to the Louisiana water thrush, which is a warbler, because of its similar color and pattern.

See also **Passeriformes**.

THRUST. 1. The pushing or pulling force developed by an aircraft engine or a rocket engine. 2. The force exerted in any direction by a fluid jet or by a powered screw, as the thrust of an antitorque rotor. 3. Specifically, in rocketry, $F = mv$, where m is propellant mass flow and v is exhaust velocity relative to the vehicle. Also called *momentum thrust*.

THRUST AND DRAG. See **Aerodynamics**; **Airplane**; **Helicopters and V/STOL Craft**; and **Supersonic Aerodynamics**.

THUJA. See **Arborvitae**; and **Cedar Trees**.

THULIUM. [CAS: 7440-30-4]. Chemical element, symbol Tm, at. no. 69, at. wt. 168.934, twelfth in the Lanthanide Series in the periodic table, and the least abundant of the rare-earths, mp 1545 °C (2813 °F), bp 1950 °C (3542 °F), density 9.321 g/cm^3 (20 °C (68 °F)). Elemental thulium has a close-packed hexagonal crystal structure at 25 °C (77 °F). The pure metallic thulium is gray in color, with no evidence of tarnishing up to a temperature of 200 °C (392 °F). Above 200 °C, the element combines with oxygen, sulfur, nitrogen, carbon, and hydrogen and will form intermetallic compounds with most metals. At higher temperatures, halogen gases react vigorously with the element to form trihalides. Naturally occurring thulium is composed of 1 stable isotope, ^{169}Tm (100% natural abundance). 31 radioisotopes have been characterized, with the most stable being ^{171}Tm with a half-life of 1.92 years, ^{170}Tm with a half-life of 128.6 days, ^{168}Tm with a half-life of 93.1 days, and ^{167}Tm with a half-life of 9.25 days. All of the remaining radioactive isotopes have half-lifes that are less than 64 hours, and the majority of these have half lifes that are less than 2 minutes. This element also has 14 meta states, with the most stable being ^{164}Tm ($t_{1/2}$ 5.1 minutes), ^{160}Tm-160m ($t_{1/2}$ 74.5 seconds) and ^{155}Tm ($t_{1/2}$ 45 seconds). The isotopes of thulium range in at. wt. from 145.966 (^{146}Tm) to 176.949 (^{177}Tm). The primary decay mode before the most abundant stable isotope, ^{169}Tm, is electron capture and the primary mode after is beta emission. The primary decay products before ^{169}Tm are element 68 (erbium) isotopes, and the primary products after are element 70 (ytterbium) isotopes. Average content of the earth's crust is estimated at 0.48 ppm thulium, making this element the least abundant of the rare-earth elements. Even at this level, however, thulium is potentially more available than antimony, bismuth, cadmium, or mercury. The element was first identified by Per Teodor Cleve in 1879 by looking for impurities in the oxides of other rare earth elements (this was the same method Carl Gustaf Mosander earlier used to discover some other rare- earth elements). Cleve started by removing all of the known contaminants of erbia (Er_2O_3) and upon additional processing, obtained two new substances; one brown and one green. The brown substance turned out to be the oxide of the element holmium and was named holmia by Cleve and the green substance was the oxide of an unknown element. Cleve named the oxide thulia and its element thulium after Thule, an ancient Roman name for a mythical country in the far north, perhaps Scandinavia. . Electronic configuration

$$1s^2 2s^2 2p^6 3s^2 3p^6 3d^{10} 4s^2 4p^6 4d^{10} 4f^{12} 5s^2 5p^6 5d^1 6s^2.$$

Ionic radius Tm^{3+} 0.880 Å. Metallic radius 1.746 Å. First ionization potential 6.18 V; second 12.05 V. Other physical properties of thulium are given under **Rare-Earth Elements and Metals**.

Thulium occurs in apatite and xenotime and is derived from these minerals as a minor coproduct in the processing of yttrium. Processing involves organic ion-exchange, liquid-liquid, or solid-liquid, techniques. Prior to the development of cation exchange resins capable of separating the chemically similar rare earths, thulium was practically unavailable in pure form. Thulium metal is made by the direct reduction of thulium oxide by lanthanum metal at high temperature in a vacuum.

Thulium has a low-to-moderate acute toxic rating and should be handled with care. Metallic thulium in dust form presents a fire and explosion hazard.

Important scientific and industrial applications for thulium and its compounds remain to be developed. In particular, the photoelectric, semiconductor, and thermoelectric properties of the element and compounds, particularly behavior in the near-infrared region of the spectrum, are being studied. Thulium has been used in phosphors, ferrite bubble devices, and catalysts. Irradiated thulium (^{169}Tm) is used in a portable x-ray unit.

THYMUS GLAND. Situated within the chest cavity close to the heart, the thymus gland has been known for centuries and was believed to be the seat of courage and affection in ancient times because it is situated close to the heart. The word *thymus* is derived from a Greek word having two meanings, "courage" and "thyme." The shape of the organ resembles the leaves of the thyme plant. The thymus is not always the same size, and it does not grow progressively as most organs do. From the day of birth to the age of approximately 12 years, the thymus grows gradually until it reaches a maximum size and weight. At this time, the organ is the size of a small egg — with about the same weight. At about age 15, the thymus begins to diminish in size and weight. In old age, the gland is practically nonexistent. During pregnancy, the thymus usually becomes smaller than normal but recovers its original size after delivery. Infectious diseases, x-rays, and hormones also can act on the thymus to decrease its size.

The thymus has a central role in establishing the immunological capacities of the body. The thymus elaborates hormones responsible for the production of cells with the capability of making antibodies and rejecting foreign elements in the body. During the first weeks of life, the thymus produces the *basic cells* that are then distributed throughout the body to other lymphocyte production centers, namely, the lymph nodes and spleen. At short notice, these organs can mass-produce lymphocytes and carry on the production of antibodies, which protect the body against invading microbes or foreign tissues.

During the 1960s, it was found that the thymus processes bone marrow stem cells into T-cells, the latter cells known to provide the body with cellular immunity. It was also learned that the thymus produces protein hormones. Initially, two thymic hormones were identified — *thymosin* and *thymopoietin*. Others have since been identified. These hormones participate in varying ways in the formation of different types of T cells. In the mid-1970s, thymic hormones were administered to children with immunodeficiency diseases resulting from an underdeveloped thymus and immature T cells; and to children whose T cells had been depressed by drugs, notably immunosuppressant drugs used in cancer treatment. Good results generally were obtained.

When the role of the thymus was further delineated, a distinction was made between thymus-*independent* (B) lymphocytes and thymus-*dependent* (T) lymphocytes. Although the specificity of B lymphocytes in their immune roles is well understood, information on the specificity of T lymphocyte receptors is still limited. It is known that the T cells display a restricted range of specificity as compared with the B cells. As pointed out by Paul and Benacerraf 1977, thymus-dependent lymphocytes react particularly to thymus-dependent protein and cell surface antigens and to products of genes encoded in the major histocompatibility complex (MHC). Additionally, T lymphocytes have important functions in regulating the immune response and in discriminating of self from nonself. Recent work indicates that individual T lymphocytes possess receptors that interact with both thymus-dependent antigens and MHC gene products, either independently or as associated structures. See **Immune System and Immunology**.

Some authorities have suggested that thymosin, which has been administered on a limited basis to some cancer patients has increased survival by nearly 200 days in cases of small cell or "oat cell" lung cancer. This is probably the result of increasing the number of T cells. No direct action of thymosin on the tumors per se has been demonstrated. Research also suggests that thymosin hormone may provide better protection for the elderly who possess an aging immune system.

The hormones from the adrenal cortex and the sex hormones act on the thymus and inhibit its function. But the hormone from the thyroid gland has a stimulating effect on the organ. The pituitary gland, by acting on the adrenals and gonads, inhibits the thymus; by acting on the thyroid, it stimulates the thymus.

The thymus on occasion may become larger than normal. The condition usually is associated with disturbances in other endocrine glands. In cases of adrenal insufficiency, the thymus and other lymphoid organs increase in size; similar effects are observed when the thyroid gland becomes overactive. This enlargement is thought to be in rare instances associated in some way with the cause of sudden death in apparently healthy children or young adults exposed to some stress, such as surgery.

The thymus, like all organs of the body, may be the site of tumor formation. There are several types of tumors that may develop, some rare, others more common. Whatever type of tumor, the symptoms manifest themselves by local pressure, difficulty in breathing, and bluish coloration of the skin. The symptoms are probably the result of pressure by the tumor on the windpipe and nerves in the chest. Tumors of the thymus are removed surgically; or if surgery is not possible, they may be destroyed by X-rays. When surgery is done early, it often effects permanent cure.

The thymus has been found to be enlarged in many cases of *myasthenia gravis*, a disease of the muscles. Some patients suffering from this disease have benefited by a removal of the enlarged thymus. Recent studies indicate that thymosin may also alleviate this condition.

Physiological and Pathological Considerations

Physiological Factors Altering Thymic Functions

Aging. In most mammals, the thymus reaches a maximal size around puberty and decreases thereafter. In humans, contrary to general belief, the thymus reaches its full size (30–40 g, 20 cm^3) after the first year of life and begins to decrease from around 5–7 years. At puberty, when sex steroids are maximal, the thymic epithelium begins to atrophy severely, with associated enlargements of the perivascular space, Hassall corpuscles and connective tissues. After puberty, the thymus, in particular the connective tissue and the perivascular space, is gradually invaded by adipose tissue, such that in adults its capacity for thymopoiesis is generally less than 1% of maximum; however all the major thymocyte and stromal cell subsets are still present, if very poorly organized, and there is a low level of new T cells migrating to the periphery. See also **Gerontology**; and **Geriatrics**.

Stress. In all species, from fish to humans, the thymus is particularly susceptible to the action of the stress hormone, cortisone, which rapidly induces thymocytes (mainly double-positives) to undergo apoptosis. Under stress conditions, the thymus atrophies with a subsequent block in T-lymphocyte production. It is believed that this would be beneficial to the animals by preventing the production of a TCR repertoire shaped in the presence of foreign antigens, or modified self antigens, resulting from infections, injuries or diseases.

Pregnancy. Pregnancy is recognized to induce a transient thymic involution, ending with the termination of lactation. This effect, involving the presence of female sex hormones, estrogen and progesterone, and related receptors expressed by thymic epithelial cells, leads to the arrest of early steps of double-negative thymocyte differentiation. It is associated with a dramatic decrease in the size of the thymic cortex and a slight enlargement of the medulla. Recent evidence suggests that pregnancy induces a thymic involution and thus allows normal development of embryos carrying paternal antigens.

Major Thymus-Related Diseases

DiGeorge Syndrome. In 1965, A.M. DiGeorge reported a syndrome of complex congenital malformations found in humans at a frequency of approximately 1/3000. This disease is associated with T lymphopenia and severe thymic hypoplasia, characterized by the absence of Hassall corpuscles, although cortical and medullary regions are evident. The exact nature of this genetic defect, showing variable degrees of penetrance, is unclear but lies in a 22q11.2 chromosomal deletion causing abnormal migration of the neural crest into an ill-developed third pharyngeal pouch.

The Nude (nu/nu) Mutation. Nude mice and rats have a thymic rudiment lacking a well-defined cortex, and medullary structures are not colonized by lymphoid precursors. These animals do not produce significant numbers of mature T lymphocytes because of a genetic defect resulting in abnormal development of the ectodermal tissue from the third pharyngeal cleft. This defect, responsible for the hairlessness (nude) and the absence of a thymus, is controlled by a recessive gene (*whn*), encoding for a member of the winged-helix transcription factor family.

Severe Combined Immunodeficiency. Individuals with severe combined immunodeficiency (SCID) have profound lymphopenia that stems from a variety of genetic inherited defects. X-linked SCID (IL-7 receptor γ-chain gene: Xq13-21.1) and adenosine deaminase deficiency, causing adenosine and deoxyadenosine toxicity in lymphoid precursor (20q.13-ter), represent the most common forms of human SCID associated with impaired thymopoiesis. In the mouse, a SCID mutation characterized by the lack of TCR (and immunoglobulin) gene rearrangement points toward one protein (Ku80) of the enzymatic complex deoxyribonucleic acid (DNA)-dependent protein kinase involved in DNA repair.

Ataxia-Telangiectasia. Patients suffering from ataxia–telangiectasia display several clinical features, with neurological, endocrinological and immunological abnormalities, DNA repair defect, and a predisposition to lymphomas. They show a recessive mutation linked to 11q22-23 translocation, often involving break points in the TCR genes, and thus a possible role in the transformation of immature T lymphocytes. The thymus of these patients is hypoplastic, ill organized and lacks Hassall corpuscles, although there is no direct proof for this being the cause for the abnormalities observed among their T lymphocytes in the periphery. A DNA-dependent protein kinase, responsible for ataxia–telangiectasia, was recently cloned.

Myasthenia Gravis. Myasthenia gravis is an autoimmune disease involving autoantibodies reacting to the acetylcholine receptor; it targets females preferentially. The aetiology of this disease is still unknown. Through an undefined mechanism, thymectomy is known to improve this condition in young individuals. Approximately 10% of patients with myasthenia gravis develop lymphoepithelial thymomas. See also **Myasthenia Gravis**.

Other Autoimmune Diseases. Given that autoimmunity is a breakdown in self tolerance, it is not surprising that abnormalities in thymic structure and function have been shown to be associated with these diseases. In lupus-prone mice and in nonobese diabetic (NOD) mice there is a profound disturbance of the cortical and medullary epithelium, with pockets of the latter being present throughout the cortex. Such disturbances occur well before disease onset and have been proposed to induce premature maturation of the cortical thymocytes, promoting their development and bypassing their sensitivity to negative selection. Autoimmune thyroiditis has also been associated with a loss in TNCs.

Thymoma. Thymomas are thymic tumors of epithelial origin, either cortical, medullary or mixed, most commonly seen in adults over the age of 40. Only 30–40% of these are malignant and may be invasive. Around 30% of patients with thymoma suffer from myasthenia gravis.

Thymus-Derived Lymphomas. One of the most common (30%) form of nonHodgkin lymphoma in young individuals is the lymphoblastic lymphoma which predominantly involves tumors of thymocyte origin. Most patients with lymphoblastic lymphoma display an enlarged thymus with possible infiltration of other tissues (bone, bone marrow, central nervous system, lymph nodes).

Acquired Immune Deficiency Syndrome. The acquired immune deficiency syndrome (AIDS), caused by the *Human immunodeficiency virus* (HIV), is renowned for killing T_H cells. Moreover, AIDS patients are characterized by a dramatic decrease in thymic cellularity, affecting primarily double-positive thymocytes, thus further reducing the number of peripheral T cells via a drop in T-cell production. Also, thymic stromal components are affected in those patients, with a reduction in medullary epithelial cells and Hassall corpuscles. Nonetheless, strategies are now been designed to boost thymic production and replenish the peripheral pool of T cells in patients after the clearance of HIV particles by antiviral therapy. See also **Acquired Immune Deficiency Syndrome (AIDS)**; and **Human Immunodeficiency Viruses (HIV)**.

Hormonal Functions of the Thymus Gland. Historically, the thymus was referred to as a gland well before the characterization of its endocrine function. Several factors have been identified, although their respective activities are still poorly defined. In addition to their action on the immune cells, thymic hormones also include neuropeptides and neurotransmitters. For example, thymulin, a nonapeptide hormone (formerly called *facteur thymique sérique*), can modulate the expression of, as well as being modulated by, other hormones like prolactin and growth hormone. Thymulin represents a gear box between the lymphoid and the nervous system. Thymic humoral factor (e.g. THF γ2) is an octapeptide with stimulating activities upon hematopoietic progenitors. Thymosin (e.g. TF5, with 28 amino acids) activates the differentiation and maturation of T cells. Other thymic hormones include thymopentin and thymopoietin.

Summary

The thymus, a bilobate gland located in the upper anterior thorax in higher vertebrates, is the major site of T-lymphocyte production. This primary lymphoid organ is seeded by hematopoietic precursors, which differentiate upon intimate contacts with the thymic microenvironment composed of various nonlymphoid elements, referred to as the thymic stroma. These stromal elements govern many aspects of lymphoid precursor differentiation, such as lineage commitment, rearrangement of the TCR, shaping of the TCR repertoire and maturation into competent cells, including $\alpha\beta$TCR-bearing T_H, T_C and T_{NK} cells, and $\gamma\delta$TCR-bearing T cells. Disturbances in either the stroma or the T cells disrupt the tightly coordinated production of mature T cells and can be of aetiological significance in several disease states.

THYRISTOR. A generic title referring to a class of electronic devices consisting of four layers of semiconductor material alternately doped with *p* and *n* type impurities (see also **Transistor**) to form a *p-n-p-n* structure. Included in this category are the silicon-controlled rectifier (SCR), silicon-controlled switch (SCS), gate-turn-off switch (GTO), various forms of the *p-n-p-n* diode, light-activated SCR (LASCR), and three-element static ac switch (TRIAC).

THYROID GLAND. An endocrine gland located in the neck, the thyroid is shaped something like a butterfly. It is one of the largest endocrine glands in the body, averaging 0.7 ounce (~20 grams) in weight. It is the first gland to develop both in the individual and in the evolvement of the species. The gland is situated in the front of the neck where the latter joins the chest. The "wings" of the butterfly lie on either side of the windpipe and are referred to as lobes. The body of the butterfly is represented by a small bridge (isthmus) which passes in front of the windpipe and connects the "wings." The normal thyroid is packed so neatly between other adjoining structures in the neck that it can neither be seen as a bulge, nor felt as a distinct organ.

The gland has a brownish red, pulpy appearance and has one of the most copious blood supplies of any organ in the body. The average adult possesses approximately 5 quarts (4.7 liters) of blood, an amount that passes through the thyroid gland once per hour. The rapid flow, which brings about thyrotrophic hormone (a thyroid-stimulating hormone of the anterior pituitary gland) and iodide (for building thyroid hormones), exerts a considerable influence on thyroid activity.

Viewed through a microscope, the thyroid is seen to be composed of a great many small, hollow, ball-like units known as *follicles*. The average diameter of each follicle is about 1/100th inch (25 millimeters), although there is considerable variation in size in the healthy gland, and even variations when diseases are present. The functional cells of the thyroid (*acinar cells*) make up these follicles, the walls of which are one cell in thickness. Each follicle has its own small artery that supplies blood to a network of capillaries which themselves subsequently reunite to form a small vein.

Inside each follicle is a jelly-like material composed of thyroglobulin and called *colloid*. The raw material for hormone production is brought to the thyroid cells by the blood, and the finished products, known as thyroxine and triiodothyronine, are necessary for growth, development, and metabolism.

The metabolism of iodine is centrally involved in thyroid physiology. The daily ration of iodine is absorbed into the blood from the gastrointestinal tract as iodide. Iodide circulating in the blood enters the thyroid by a mechanism known as the "iodide trap," which concentrates iodide to a level 25 times that in the blood. The thyroid then builds the hormones *triiodothyronine* and *thyroxine* which are stored in the thyroid colloid for release as required.

In response to the stimulus of a center in the brain, thyroxine and triiodothyronine are released into the blood stream. A small portion of the thyroxine is "free" in the blood stream (only free thyroxine can enter the cells of the body), but most of it is chemically bound to a protein. Triiodothyronine is less closely bound to protein. Probably more than 80% of the iodine in the blood is in the form of thyroxine; the rest in triiodothyronine. Protein-bound thyroid hormone normally is greatly increased during pregnancy and during treatment with estrogen. See also **Endocrine System**.

The two thyroid hormones have the same effects on the body qualitatively, but quantitatively there are differences. Their function is to stimulate metabolism of nearly all cells except those of the brain, thyroid, testis, spleen, and uterus. The effect of thyroxine is not observed until one or more days after administration, but the effect is maintained and is lost only after several days. The response to triiodothyronine may occur within 6 hours after administration, and by 36 to 48 hours the response has disappeared.

The growth and function of the thyroid are under the control of the *thyrotrophic hormone* secreted by the anterior pituitary. These cells, in turn, vary their secretion rate in response to the amount of thyroid hormone in the blood. Thus, a fall in the amount of thyroid hormone in the blood is countered by an increased secretion of thyrotrophin, which stimulates the thyroid to increase the production of hormones. This feedback system maintains a balance in thyroid activity. The role of pituitary in this system is at least partially controlled by stimulation from the hypothalamus.

The exact means by which the thyroid hormone influences the cells of the body are not fully understood. One of the most striking effects is upon the consumption of oxygen by living cells. One of the main tasks of the thyroid hormone appears to be the maintenance of the "burning" process (*metabolism*) at an optimal level. In this connection, the quantity of thyroid hormone is small, but powerful. Even in the severest form of hyperthyroidism, the amount is increased to only about 0.000007 unit per unit of blood.

Tests of Thyroid Function. The principal objectives of thyroid function tests are to assess the rate of production of thyroid hormone and to explain findings obtained by physical examination of the gland. The total serum thyroxine (T_4) level may be determined by radioimmunoassay and most closely approximates the functional state of the thyroid gland in most patients. The radioactive iodine uptake test measures the percent of a tracer dose that enters the thyroid in any given period of time. Overactive glands generally show an increased avidity for iodine; the reverse holds for underactive glands. The test is used less often than in the past because of a number of shortcomings. Other radioimmunoassay determinations may include serum thyroglobulin, thyroid-stimulating hormone (TSH), and thyrotropin-releasing hormone (TRH) testing. The probable pathologic basis of thyroid enlargement may be studied by using a thyroid scan. Scintiscanning with technetium radioisotope demonstrates iodide-concentrating capacity in the thyroid. Scanning with isotopes of iodine reflects both concentration and binding. Scanning by ultrasound also provides a valuable approach in exploring nodular lesions of the thyroid. Excellent results have been obtained in discriminating between cystic and solid thyroid nodules.

Thyroid Disorders

The thyroid gland is subject to a variety of diseases. In addition to hypo- or hyperactivity, the gland may become enlarged for a number of reasons.

Goiter. The most common disease of the thyroid. The term simply means enlargement of the thyroid. The degree of enlargement is not always related to the degree of function. The largest goiters seldom produce excessive thyroid hormone. *Endemic goiter* is the most common form. This occurs most frequently in those areas of the world where the supply of iodine has been washed out of the soil (common in mountain areas). Enlargement of the thyroid seemingly results as a means of compensating for a lack of iodine. Sometimes this compensation is successful; often not. Of course, no degree of enlargement can compensate fully if there is an absolute deficiency of iodine. Upon gaining a supply of iodine, an enlarged gland will shrink to some extent but will not return to normal size. Individuals affected with this kind of goiter are likely to have low basal metabolic rates. If the condition exists during infancy, there is a serious interference with normal growth and development, and the resulting individual is known as a *cretin*. See also **Iodine**.

Lack of iodine in the diet is not the only circumstance that may lead to development of goiter. A large number of vegetables have goiter-producing qualities. Cabbage, Brussels sprouts, cauliflower, turnips, rutabaga, and soybeans, if taken daily into the body over long periods, may lead to the development of goiters. This does not mean that these foods are unsuitable or dangerous; quite the contrary is true. Only great amounts and high frequency of use need be avoided. There are few authentic cases on record of patients who ingested sufficiently large amounts of any of these foods to cause serious difficulty.

Fortunately, the systematic consumption of iodized table salt has largely eliminated the endemic goiter problem in the United States and to a considerable degree in other traditional goiter belts of the world. In Switzerland, at one time, the problem was very serious.

Simple goiters (growths) are not related to the presence of iodine. The cause of simple goiter is largely unknown. Since some foods are known to inhibit the production of thyroid hormone, it has been postulated that dietary factors may be responsible for simple goiter. Simple goiter is seen most often in adolescent girls; thus endocrine factors may play a role.

Nodular goiter, not related to the presence of iodine, may develop in an otherwise normal thyroid gland. Single or multiple nodules most often occur in older individuals. Many of the nodules, if examined microscopically, resemble the embryonic thyroid gland. Some produce no thyroid hormone; others produce no more per gram of tissue than the surrounding normal thyroid gland; still others produce abnormally large quantities of hormone. In the latter event, the cells in the normal thyroid tissue, in which the adenoma is growing, go into a resting phase, but even this shutdown is not sufficient to prevent the blood level of thyroid hormone form becoming too high. The incidence of cancer is much lower if more than one nodule, or adenoma, exists in the thyroid gland, or if the thyroid is overactive. The possibility that a nodule in this organ is a cancer is even greater if the patient is in the younger age groups.

Hyperthyroidism (Graves' Disease). There are several forms of this disease. The most spectacular type is sometimes called *exophthalmic goiter* or *Graves' disease*. In the fully developed case, patients begin to notice increased nervousness and irritability, often crying over trivial incidents. There is a great increase in appetite; food may be taken almost constantly through the day and part of the night. There may be a tendency toward insomnia. The heart beats rapidly and forcibly. Sometimes each beat visibly shakes the whole body. Despite increased intake of food, there is constant weight loss. Perspiration increases and the affected individual feels uncomfortably warm under circumstances that are comfortable to others. The skin becomes hot, moist, smooth, almost velvety. The nails are thin, concave, and may actually separate from the tissues of the finger or toe for some distance from their free margin. The hair becomes silky. If the hands are extended, there is an uncontrollable trembling. As weight loss increases, weakness becomes pronounced, and the patient may require assistance to rise from a chair. One or both eyes may protrude from their sockets (*exophthalmos*), in serious cases to such a degree that the eyelids cannot be closed, and even in sleep the eyes may remain open. The lids and "white" of the eyes become puffy. Because of the protrusion of the eyes, the face has the appearance of fright or anger.

The eye symptoms in patients with hyperthyroidism vary in degree from minimum to very severe exophthalmos. Fortunately, in most patients, the eye symptoms are mild; they are characterized by a retraction of the lids, resulting in a stare or a wide-eyed look. The patient also may blink frequently.

In patients with this disease, the thyroid gland enlarges, and the rate of blood flow through the organ is considerably increased. Typically, the basal metabolic rate is elevated and the degree of elevation correlates with the severity of the syndrome of hyperthyroidism. The thyroid gland may be from $2\frac{1}{2}$ to 4 times its normal size. In extreme situations, it may be 10 or more times normal size. The colloid is usually completely lost, and the thyroid acinar cells lose their normal appearance.

Most of the difficulty seen in Graves' disease can be traced directly to the abnormally high level of hormone circulating in the blood, or to some abnormality in the secretion itself. Everything is speeded up; more food is burned; more heat is produced; the sweat glands secrete faster; the heart beats faster; the muscles move faster; and the brain thinks faster. The human body, while capable of responding to emergencies, is not able to withstand continuous operation at a maximum rate. Thus, unchecked hyperthyroidism materially shortens life.

Much remains to be learned concerning the cause of hyperthyroidism. There appears to be a genetic relationship involved. In one study group of patients suffering from Graves' disease, it was found that 50% of the relatives had a change in thyroid function. Patients with this disorder also often relate the beginning of their symptoms to major emotional or traumatic crises in their lives. It has not been proved, however, that these are precipitating factors. Some endocrinologists believe that Graves' disease is basically a familial condition in which the full-blown affliction is simply triggered into existence by emotional or physical stress.

In many patients, the overactivity of the thyroid gland can be controlled by treatment with antithyroid drugs or iodide. For others, removal of the thyroid gland is practical and a fairly simple operation. However, patients with hyperthyroidism are poor surgical risks unless certain steps are taken to control their disease before the gland is removed. Most of the symptoms, except those involving the eyes, may be relieved either partially or fully by the use of iodine. If the disease has not run a long course, the surgical removal of most, but not all, of the diseased thyroid gland usually results in restoration of good health and relief of symptoms. The eyes, however, may not return to normal, but there often is improvement.

Certain foodstuffs are known to produce goiter. These chemical substances may be useful in the treatment of patients with hyperthyroidism. The substances, known as *thiouracils*, have made possible improvement in the medical treatment of patients with Graves' disease during recent years.

The specific treatment that best serves a given patient with hyperthyroidism is not always easy to select. Antithyroid drugs, such as propylthiouracil or methimazole, are reversible, effective in a large number of cases, and usually safe. The principal side effects are allergic reactions, which occur in a minority of cases. Treatment may be required for several weeks and sometimes up to 4 or 6 months. Some physicians maintain the treatment for about a year, carefully observing the patient after the drug is withdrawn. Other physicians withdraw treatment as soon as the patient becomes euthyroid (symptomless). If the treatment is too rapid or maintained too long, the patient may show signs of hypothyroidism. It is estimated that only about 30% of patients remain euthyroid after antithyroid drugs are discontinued. The rate of permanent remission is considerably lower than once believed. Some physicians use propanolol as an adjunctive therapy, taking advantage of the betablocking effect of this drug to ameliorate several of the symptoms of the disease, such as palpitations, excess sweating, tachycardia, nervousness, and tremor. Because of possible side effects of propanolol, the drug must be given judiciously. When applicable, the adjunctive therapy provides the patient with relief from several of the disturbing symptoms while the basic condition is being treated.

Subtotal thyroidectomy is an approach that has been used for many years, particularly prior to the availability of effective antithyroid drugs. The operation is considered difficult. Many specialists reserve this approach as one of the last elective measures.

Since the mid-1940s, therapy with radioactive iodine has been used widely and it estimated that nearly three-fourths of a million patients have been treated this way in the United States during the interim. After years of experience with the therapy, only two principal risks appear to be involved — that of developing hypothyroidism and, difficult to measure, possible genetic damage to gametes (of particular concern to women of childbearing age).

In a comparatively few patients, a so-called thyroid storm may develop. The manifestations are fever, severe tachycardia, extreme sweating, marked restlessness, leading, if left untreated, to dehydration and shock. The episode rarely occurs as the initial symptom of hyperthyroidism. It may in some instances, however, be the precipitating cause for the patient first consulting a physician. Regimens have been developed for the prompt and effective relief of such an episode.

Hypothyroidism and Myxedema. These conditions arise from the inadequate production of thyroid hormone. Patients may be classified as having (1) adult myxedema, (2) juvenile myxedema, or (3) cretinism. A majority of the body tissues become infiltrated with a mucuslike fluid which causes puffiness of the skin and may even cause interference with the normal function of certain of the internal organs. The skin becomes excessively dry; the hair is brittle, falls out, and is difficult to comb or curl; the fingernails are brittle; and the loose tissues of the face become characteristically puffy. The result is that the affected individual appears to be wearing a mask. The skin may become slightly tinged with yellow as a result of inability of the body to convert carotene, a yellow material present in vegetables, to vitamin A. Subsequently, vitamin A deficiency leads to roughening of the skin on certain areas of the body, notably around the elbows. The tongue enlarges. The vocal cords are affected such as to produce a peculiar huskiness or hoarseness and deepening of the voice. The speed of thinking is slowed. Patients with myxedema tire easily and usually feel sleepy most of the time. They often feel cold, even in warm weather. If left untreated, the heart may become enlarged and mental weakness may develop.

The treatment of hypothyroidism has improved markedly during the last several years. Fortunately, thyroid hormone replacement is reliable, nontoxic, nonallergenic, and inexpensive, but reliable diagnosis is a required prelude. Shortly after L-thyroxine is administered, the patient senses much improvement. However, several months of therapy may be required before the patient is fully restored to a normal state. Older patients and younger patients (with cardiac disease) must commence the

therapy on small doses. Careful monitoring of thyroid-stimulating hormone (TSH) is required during therapy. In years past, hypothyroidism was considered irreversible and usually progressive. Long-term therapy, of course, is required. A suggested correlation between thyroid therapy for hypothyroidism and increased incidence of breast cancer has not been proved and thus most physicians do not consider this a deterrent to the use of the therapy.

Thyroiditis. The thyroid gland is no exception to susceptibility to inflammatory infection. The majority of patients with this disease are thought to suffer from infection by small viruslike particles, which are not harmed by such agents as penicillin, aureomycin, and so on. The common type of thyroiditis occasionally gives evidence of being contagious. A satisfactory treatment appears to be the administration of *prednisone*, a compound related to the hormones of the adrenal cortex. The swelling of the gland is often quickly relieved, and with it, the discomfort. Hydrocortisone, ACTH, and a small amount of X-ray therapy also may be used. Some of the noninfectious diseases of the thyroid, not fully understood, include *Hashimoto's struma*, where the gland becomes moderately enlarged and has been compared in consistency to the granular structure of an apple. The disorder may lead to the destruction of the gland and resulting hypothyroidism. In *Riedel's struma*, which usually occurs after middle-life in women, the effect on the thyroid gland is one of great disorganization and destruction of the functional architecture. The gland may become enlarged but usually manages to produce sufficient hormone to prevent the average person from developing serious hypothyroidism or myxedema.

Tumors. There is a wide spectrum of activity or aggressiveness on the part of cancers arising in the thyroid gland. Cancer of the thyroid gland can occur at any age. There is a sudden increase in the rate at about the time of puberty. The usual treatment of thyroid cancer is early, thorough removal by surgery. If untreated, the spread of the tumor is limited for a time to the lymph nodes in the neck; secondary tumors later may appear in all tissues of the body, the lungs and bones being frequent sites. It is estimated that about 60% of cases treated by adequate surgical methods have no further trouble. Since 1940, radioactive iodine has been successful in partially and temporarily controlling certain secondary tumors from the thyroid. See also **Hormones**.

TICK *(Arachnida, Acarina)*. A blood-sucking parasite related to the spiders and mites. The body of the tick is leathery and sack-like, with piercing mouth parts forming a small protuberance called the capitulum and a shield or scutum marking the dorsal surface in most species. See Fig. 1. The ticks are larger than their relatives, the mites, ranging from $\frac{1}{8}$ to $\frac{1}{4}$ inch (3 to 6 millimeters) in length. When filled with blood, a female tick may reach a length of about $\frac{1}{2}$ inch (12 millimeters). Of major importance to food-production operations, the cattle tick, the fowl tick, and the wood tick are widely distributed. The sheep tick is not a true tick, but is a member of *Diptera* and described separately. See also **Sheep Tick**. The Rocky Mountain wood tick, also called castor-bean tick or dog tick, is a dangerous pest to human beings and rodents, causing Rocky Mountain spotted fever. See also **Rickettsial Diseases**.

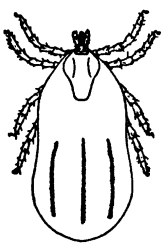

Fig. 1. Tick.

Cattle tick (*Boophilus* or *Margaropus annulatus*, Say). Of the family *Ixodidae*, this tick is considered the most destructive of the parasites that attack cattle, particularly in the southern United States. The tick not only attacks cattle, but also is a pest on sheep, mules, horses, and deer. One of the most injurious factors ascribed to this pest is that it is a vector for transmitting *Texas fever* (also called cattle fever, splenetic fever, and tick fever). Symptoms of this disease in cattle include: (1) pink to red coloration of the urine; (2) a dry muzzle; (3) an arched back; (4) a high fever; (5) drooping ears; and, upon a closer examination, (6) an enlarged spleen; and (7) congested liver. The cattle tick carries the cause of the disease, a minute parasite or protozoan (*Babesia bigemina*, Smith and Killbourne). The parasite destroys red blood corpuscles. Ticks do not transfer from one host to the next, but transmission occurs by way of the tick eggs and the young ticks resulting from their hatching. In some years, the loss of cattle to Texas fever has run into the many millions of dollars. The damage caused by the cattle tick is further magnified by the fact that the punctures made by the tick in the animal's flesh also attract the screw-worm fly which causes a condition known as *myiasis*, another severely damaging disease. See also **Screw-Worm**.

Losses arise not only from the death of cattle. (About 10% of those cattle attacked during summer months die; about 90% die if attacked during the fall and winter. The high Figures are notably true in the case of cattle that may have been imported to the south from the northern states.) In the case of dairy cows, milk production is often severely reduced even though the cow may recover from the fever. Hides also are badly damaged and their market price is similarly lowered.

In the United States, the cattle tick is found mainly in those states south of 36°N. Although other species of tick may be involved, the same disease is found in Central and South America and portions of Africa, Europe, and

southeast Asia, including the Philippines. The tick cannot survive winters in northern climes.

In affected areas, the cattle tick winters over as eggs or very small, 6-legged ticks, which are about $\frac{1}{32}$ inch (0.8 millimeter) in diameter (they are essentially round), and which are referred to as "seed ticks." These small ticks are found in different places, including grass, weeds, debris, almost wherever infested cattle have been located. Adult and nymph ticks also winter over in the skin of the affected cattle. Mating occurs within the host animal. After mating and when the female tick is satiated with the host's blood, she drops to the ground. At this time, the female is close to $\frac{1}{2}$ inch (12 millimeters) in length and may be of an olive-green or blush-gray hue and with a bean-shaped body. The skin is hard and shiny, but a bit wrinkled. In a period ranging from 2 to 6 weeks, the female then lays many hundreds of eggs (up to 5000), which are ejected from the front portion of her head. The mass of eggs is placed in the soil. Hatching requires from 2 to 6 weeks, although the eggs may be viable for several months. These eggs are also referred to as seed ticks. The newly hatched young crawl about on the ground, in grass, etc. and soon climb aboard a likely host animal. The larvae feed and then transform into nymphs and hence to adults, all the time clinging to and feeding on the host animal. The full life cycle is about 2 months.

Control in the United States and a number of regions of the world has been accomplished mainly by quarantine procedures. Control chemicals include arsenic trioxide, lindane, and toxaphene. Dipping of all cattle and farm animals once every 2 weeks in the proper formulation is an excellent procedure for eradicating the pest. Rotation of pasture land is also a good practice, leaving infested parcels of land free of cattle for a time sufficient to permit all ticks to die of starvation. In recent measures, these controls and quarantining procedures have proved very effective.

Ear Tick (*Otobius* or *Ornithodoros megnini*, Duges). This pest also prevails in the southwestern United States. The tick is named because it inhabits the outer ears of cattle and other farm animals, including dogs, for a period of months. The tick ranges up to $\frac{1}{3}$ inch (8 millimeters) in length. The invasion is by the nymph stage; adult ear ticks do not live on the host. The procedure of producing seed ticks and reinvasion of a host is similar to that described for the cattle tick.

Gulf Coast Tick (*Amblyomma maculatum*, Koch). This is another pest of the southern states and is extremely irritating to cattle. The tick is also found on certain of the native birds, including quail and meadow larks. The tick is similar in habit to the ear tick.

Control of the ear and Gulf Coast ticks is by use of a formulation containing lindane, xylene, and pine oil.

Wood Tick (*Dermacentor variabilis*, Say). Also known as the American dog tick, a serious interest in this pest, which attacks cattle, hogs, sheep, dogs, cats, rabbits, various wild animals, as well as humans, was established when it was found that this tick is the carrier of Rocky Mountain spotted fever (caused by *Rickettsia rickettsii*), in the midwestern and eastern United States. The tick also is a carrier of bovine anaplasmosis and tularaemia. Control chemicals effective against this tick include chlordane, dieldrin, toxaphene and DDT (or substitutes where DDT is not available).

Fowl Tick (*Argas persicus*, Oken). Also known as the *adobe tick*, or *bluebug*, the effects of an attack by the fowl tick is similar to that of the poultry mite, described in the entry on **Mite**. Most fowls are attacked, but the parasite prefers chickens. The pest is distributed in warm, dry regions throughout the world. In the United States, it is found in the southwestern states as well as in Florida. The presence of the fowl tick is complicated by the fact that it is the carrier of the dangerous poultry disease known as *fowl spirochaetosis*. For control measures, see previously mentioned coverage of poultry mite in entry on **Mite**. See also **Lyme Disease**.

TIDAL BORE. See **Bore (Tidal)**.

TIDAL DEFORMATION (Earth). See **Earth**.

TIDAL ENERGY. Although Sir Isaac Newton explained the underlying causes of the tides, i.e., the attraction exerted by the moon and the sun on the molecules of the oceans, and thus provided an immediate explanation for the variation of the time of high tide with the moon, for the modification of the tidal range during the half lunar month, and for the spring tides at suitable conjunctions of the moon and the sun, Newton nevertheless did not offer explanations of why tidal variations exist from one place on the Earth to the next. For example, Newton's explanations did not clarify such situations as: (1) Why do the high and low tides in Tahiti occur at the same time every day regardless of the phases of the moon? (2) Why is the tidal range at Mont Saint-Michel in the Rance Estuary (France) more than 13 meters, whereas it is measured in decimeters in the Mediterranean? (3) Why, although a double impulse causes the tide to ebb and flow along the coasts each day, a simultaneous reversal of flow and the rise in water level takes place in the Atlantic but is not observed in the English Channel? or (4) Why is there only one high tide every 24 hours at Do-Son in Tonkin? See Figures 1 and 2. Over the years, the principal explanations of these puzzles have stemmed from studies of tides as resonance phenomena.

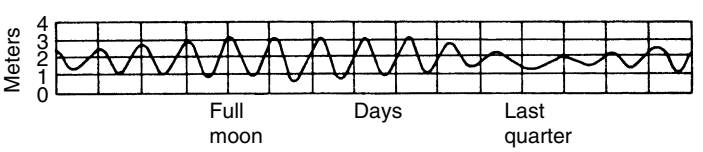

Fig. 1. One full tide daily at Do-Son. (Tonkin.)

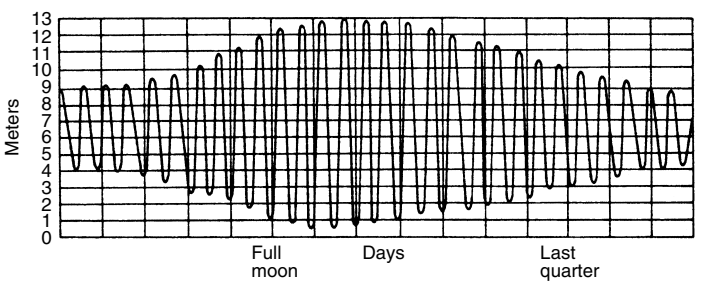

Fig. 2. Two full tides daily at Mont Saint-Michel, France.

Laplace, in 1774, introduced hydrodynamics into tidal theory with the development of the concept of resonance between the periods of the moon and sun and the oscillatory periods of various water basins, such as the English Channel. While Newton earlier concentrated on basic cause, scientists who followed had to direct their attention to the response characteristics of various bodies of water to the prime cause. Notably, during the first half of the twentieth century, the problem was attacked by investigators including Allar, Belidor, Bonnefile, Caquot, Gibrat, Jeffreys, Lacombe, and many others.

The greatest variation the moon produces in the attraction exerted by the Earth on a molecule of water is six million times smaller than gravity, and the sun has a still smaller effect than the moon. The following observations are a summary of the observations made by Robert Gibrat, Consulting Engineer to Electricité de France for tidal power stations, as interpreted by reference to the literature. Altogether, if the free surface of the sea were to remain in equilibrium, and that is Newton's basic assumption, there would be a tide amounting to but a few decimeters as a result of the variation in the horizontal component of gravity and one amounting to 0.9 meter (2.95 feet) as a result of variation in the vertical component. This obviously would leave the 13-meter tide at Mont-Saint-Michel unexplained. Newton's theory thus is inadequate for a full understanding. As the sea's surface cannot remain in equilibrium, the water flows back and forth and never comes to rest. As programs of capturing tidal energy, such as utilization of the enormous store of energy in the English Channel, come to the fore, considerably more sophisticated investigations of tidal phenomena must continue. The ratio of the energy taken up to the energy actually made available by the sea can no longer be neglected. The tides will certainly be modified and possibly in an unexpected manner since one is concerned with resonance, which, by definition, is very sensitive to variations of the main parameters. So, in considering a large tidal energy installation, it is necessary to know how and to what extent it may modify prior tidal conditions.

A few calculations of an elementary nature can clarify the essential concepts and provide an introduction to the methods of developing tidal energy. Utilizing tidal energy is very simple. A dam is built in a bay or estuary separating a basin from the sea. Suitable generating sets, which operate in both directions, make it possible to use the water to produce electrical energy as it flows back and forth. If it is assumed that the tide has a range A, the difference in level between high and low tide, and that a volume V can be stored between these two levels below elevation A, what then is the upper limit, if it exists, of the energy that can be used during each tide? To further simplify calculations, let it be assumed that the machines have an efficiency of unity and that there is no limitation on the discharges that can be used.

Under head H, a discharge q (using suitable units) will produce a power output qH. If $S(z)$ is the area of the pool at elevation Z, the energy generated by emptying a section dz is $S(z)z\,dz$. The energy produced per cycle will be:

$$\int_0^A S(z)\,dz \qquad \text{(during emptying)}$$

$$\int_0^A S(z)(A-z)\,dz \qquad \text{(during Filling)}$$

on the assumption that horizontal sections can be emptied or filled at the turn of the tide, the sea being at elevation O or A. With the simplifying assumptions made, the total energy per cycle with double working will be:

$$A\int_0^A S(z)\,dz = AV$$

or the production of the tidal range and the volume used, a formula which, it may be observed, is valid for a basin of any shape. Thus, one can call this quantity the "natural" energy of the basin for tide A. But, this name can be deceptive.

Each cubic meter of water entering the basin is thus used under a head A. If all tides had the same range A, at the end of the year, the 705 tides[1] would have provided a cumulative head of 705 A for each cubic meter of basin storage capacity. However, in fact, A varies throughout the year, together with V which is directly dependent upon it, since the basin does not fill or empty completely except at the maximum spring tides. The question may be asked, "Is the 'natural' energy the maximum amount of energy that can be obtained from a single tide?" Surge-wave propagation phenomena will quickly show that this is not so. See also **Tides**.

As early as 1942, a scale-model test made by a number of scientists in France had demonstrated how to exceed AV. At high tide (level A), the gates are suddenly opened without using the energy of the water as it passes through. A wave is propagated up the estuary and, increasing in amplitude, is reflected at the other end. The gates are closed at the moment when the wave returns and when the direction of flow at the dam is about to change. Finally, the water surface settles down to a level higher than A. On a scale model, $1.5A$ was attained without any difficulty. In a rectangular canal with a constant cross section, it can easily be seen that the level theoretically attains 2A in the absence of losses. In this process, the energy transformed while filling is zero; during emptying at low-tide slack water, it can be as much as:

$$\tfrac{1}{2}S(2A)^2 = 2SA^2 = 2AV$$

The energy obtained thus is twice the "natural" energy, and one enters into the realm of paradoxes. It might be hoped that this is a result of the surge wave and that all is worked out by nature. The answer is negative — because with a single basin, one could consider using power from the grid, using a double working cycle including pumping, a forerunner of the most complex real cycles.

Consider four phases as follows:

1. At the end of a cycle when the basin has been emptied to low-tide level and the gates are closed, power from the grid is used to pump water to the sea, lowering the level in the basin to $-B$. The energy used is:

$$E_p = \int_{-B}^0 S(z)(-z)\,dz \qquad (z \le 0)$$

2. The tide rises and at high tide the basin is filled during slack water, producing filling energy as follows:

$$E_r = \int_{-B}^A S(z)(A-z)\,dz \qquad (-B \le z \le A)$$

3. Still at the turn of the tide, water is pumped from the sea to the basin, using power from the grid a second time, and the water level rises to C. The energy thus used is:

$$E_{p^1} = \int_A^C S(z)(z-A)\,dz \qquad (A \le z \le C)$$

4. At low tide slack, the basin is emptied from C to zero, producing the following energy:

$$E_v = \int_C^0 S(z)\,dz \qquad (0 \le z \le C)$$

After having accounted for the energy E_p and E_p^1 used for pumping, there remains a total of:

$$E_r + E_v - E_{p^1} = A\int_{-B}^C S(dz) = A(V + V_p + V_{p^1})$$

The transformed energy is equal to the sum of the "natural" energy plus *A times the total volume pumped and can thus be as large as desired if the area of the basin for* $z > A$ can be made large enough.

A double working cycle including pumping would seem capable of using energy without any restrictions other than those resulting from plant limitations.

This cannot be so, and it is essential to properly understand why. If not, one would make the same mistake as an electrician who knows the voltage at a power point and wants to work out the available wattage without taking

[1] The lunar day is $\sim 24^h50^m28^s$ in length versus a calendar day of 24^h. Thus, $2 \times 365 \times 86{,}400\text{s}/89{,}428\text{s} = \sim 705$ tides.

into account the voltage drop and phase change resulting from plugging in an appliance. To forget the connection impedance would be disastrous. It becomes necessary at this point to analyze the physical process of energy transfer by the tides and to understand that the actual propagation of the energy drawn to the power station produces modifications to the range of the tide and the tidal currents which can appreciably alter the movement of energy. Certainly there is a "natural" limit for a given site, but basin capacity and tidal range are not enough to determine it.

The analogy of the energy of rivers may be helpful. In developing a site on a river, the energy produced is taken from the energy which was formerly dissipated naturally in whirlpools, eddies, and various forms of friction before the dam was built. The transformation energy limit is obviously the total of these losses. In similar fashion should the energy dissipated by the tide be taken as the "natural" limit that is being sought? The answer is negative — because a calculation shows that the mean power dissipated by friction in the Rance Estuary (France), for example, is at most 60,000 kilowatts, while the installed power plant facility there has a capacity of 240,000 kilowatts and is far from taking up all the utilizable energy. It is estimated that the additional energy imparted by the heavenly bodies is less than 1,000 kilowatts for the whole estuary. Thus, a further paradox. On the average, the total power dissipated in the entire English Channel is estimated at 157 million kilowatts.

Tidal energy is of a very special nature, however, and one cannot draw an analogy with the energy of a river without risking grave errors. The tidal phenomenon giving rise to this energy is essentially a resonance effect, which is very exceptional. Further, using such energy often causes the modifications thus made to the tidal regime to spread over a great distance and thereby considerably distort the initial phenomenon.

According to calculations made by Jeffreys, the mean power dissipated by the tide over the entire world is about 1,100 million kilowatts, most being supplied by shallow narrow seas like the English Channel, the Irish Sea, the North Sea, and mainly the Bering Straits, which account for 70% of the total.

At the time of Jeffrey's calculations (1952), a comparison between observations of the moon's movements and the numerical consequences of the theory led astronomers to assume the existence of a residual secular acceleration not arising from celestial mechanics. It was thus shown that the Earth's rotational speed was decreasing and releasing about 1,400 million kilowatts, which agreed quite satisfactorily with the order of magnitude of Jeffrey's calculations. It consequently seemed plausible to assume that the energy of the tide was derived from that of the Earth's rotation by friction between the water and the sea bed, thus slowing up the Earth.

During the early 1960s, however, the picture became much *less* clear. Observations made in the nuclear submarine *Nautilus* indicated that Jeffrey's Figures should be reduced by three-fourths. Also, some leading astronomers were of the opinion that the rotational speed of the Earth might be constant. The basic question remains without full proof, although there are numerous scientific opinions, "Is the Earth's kinetic energy, or the sun's thermal energy the source of tidal energy?"

Obviously, this complex topic is well beyond the scope of this volume. Reference to sources listed at the end of this article is suggested.

Tidal Energy Installations. The tides as a source of energy were exploited as early as the Middle Ages. For example, tidal power was used in the coastal areas of Brittany in France and in the British Isles to drive watermills from the 12th century onwards. See Fig. 3. In continuous operation for eight centuries, a mill on the Deben River at Woodstock in Suffolk, England was not retired until 1956, at which time it became an historic monument. In Brittany, as recently as 1959, a few small tidal mills were in operation — at the time Electricité de France decided to proceed with the construction of what is today the world's largest tidal generation station, installed in the maritime estuary of the Rance River (between Saint Malo and Dinard in Brittany). The French people have made the greatest advances in understanding and utilizing tidal energy to date.

In 1967, a tidal power plant was installed at Kislaya Bay in the U.S.S.R. Power engineers and scientists in Canada and the United States have considered the exploitation of locations in the Northeast, notably the Bay of Fundy which lies between the Canadian provinces of New Brunswick and Nova Scotia, and, in the United States, Passamaquoddy and Cobscook Bays in Maine. In Canada several decades ago, the "Little Kodiak" project in the Bay of Fundy studied the potential of tidal power. In the United States, an abrupt start was made with the Passamaquoddy project, also on the Bay of Fundy, in the early 1930s. At that time, National Recovery Administration (NRA) funds were made available to hire about 5000 persons for the project, but a subsequent and serious study showed that the scheme would not be economical and the work was halted. In North America, interest in tidal energy waned for several decades and it was not until the 1970s that serious consideration of tidal energy potential was shown. Current activities are described a bit later.

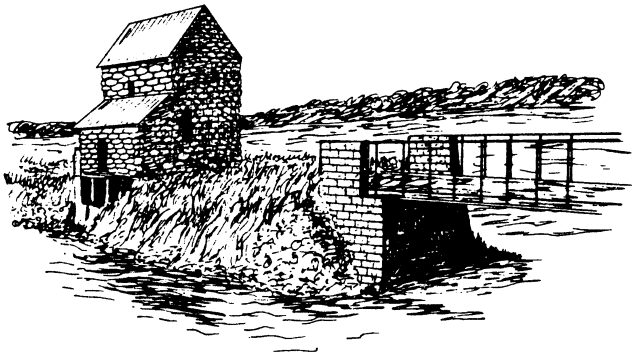

Fig. 3. Early tidal mill at Saint Suliac, Brittany.

Potential Tidal Energy Plant Locations. For a viable tidal energy plant, a mean tidal range of 5 meters (16.4 feet) is considered mandatory. Nonconventional approaches have been proposed within the last few years and these are described later. Known ranges of spring tides in excess of 5 meters are shown in Table 1. However, these areas do not necessarily coincide with the present selections of some scientists. For example, as observed by Isaacs and Schmitt (1980), nearshore areas with a great tidal range and potential for tide power development are widely distributed and include the coasts of Alaska and British Columbia, the Gulf of California, the Bay of Biscay, the White Sea, the central Indian Ocean, and the coasts of Maine and eastern Canada. Or, as observed by Ryan (1980), internationally, the areas that appear to hold the most immediate promise are the upper Bay of Fundy, Canada; Chausey in the Bay of Mont St. Michel in France; the Gulf of Mezen in the Soviet Union; the Severn River Estuary in England; the Walcott Inlet in Australia; San José, Argentina; and Asan Bay in South Korea. Of these areas, the most active projects are in South Korea, France, and Canada. A 450-megawatt plant is in the planning stage in the inner basin and an 810-megawatt plant in the outer zone of Asan Bay (South Korea). Studies also have been made for a 330-megawatt project in Incheon and at Garorim.

TABLE 1. RANGES OF SPRING TIDES IN EXCESS OF 5 METERS

Location	Tidal Range	
	Meters	Feet
Bruntcoat Head, Nova Scotia (Bay of Fundy)	14.49	47.5
Rance Estuary, France	13.5	44.3
Anchorage, Alaska	9.03	29.6
Liverpool, England	8.27	27.1
St. John, New Brunswick, Canada	7.20	23.6
Dover, England	5.67	18.6
Cherbourg, France	5.49	18.0
Antwerp, Belgium	5.43	17.8
Rangoon, Burma	5.19	17.0
Juneau, Alaska	5.06	16.6
Panama (Pacific Side)	5.01	16.4

Duff (1978) suggests that, in addition to the Bay of Fundy and currently operating locations, appropriate locations for extraction of tidal power include Cook Inlet, Alaska, the coastline of the English Channel and the Irish Sea, the Sea of Okhotsk off the coast of the former U.S.S.R., the coast of the Yellow Sea off Korea, and the inlets of the Kimberly Coast in

Australia, indicating these as convenient sites for constructing tidal power conversion machinery.

Rance Estuary Facility. Study of methods of equipping the estuary of the Rance (Brittany) for production of electrical energy on a large scale (240 megawatts) was commenced quite early in the twentieth century, although detailed design and construction did not commence until the early 1960s. Final connection of the 24 turboalternator sets to the electrical grid occurred in early December 1967.

Successful operation of a plant of this magnitude had to await the development of three major factors: (1) a far greater, if not full, understanding of tidal phenomena; (2) development of a new type of turboalternator set, known as the bulb unit, which is able to use low heads to drive a turbine in either direction of flow, and also to function as a pump; and (3) cutting off the estuary of the Rance, which meant damming a river with a maximum flow of 18,000 cubic meters per second, both at flood and at ebb. The first factor, of course, involved highly analytical mathematical and theoretical investigations. The latter two factors involved solutions to difficult problems in mechanical, electrical, civil, hydraulic, and materials engineering.

The installation extends from Pointe de la Brebis on the left bank of the estuary to Point de la Briantais on the right bank, a distance of some 750 meters (~2,460 feet). See Fig. 4. The tidal generating facilities consist basically of the tidal basin constituted by the estuary of the river Rance, separated from the sea by a dam. Sluice gates built into the dam can be operated to adjust the natural rate of drainage from the basin to the sea

Fig. 4. View of Rance Estuary tidal power plant in France. (*Photo by Glenn D. Considine*.)

with outgoing tides, or the rate at which the basin is filled with incoming tides. The difference in levels between the basin and the sea thus can be controlled and, when it reaches an appropriate figure, the basin is filled (or emptied) through the dam. The flow of water is used to move the wheels of hydraulic turbines which, in turn, drive alternators. These turboalternator sets, of which there are 24, produce electrical energy.

Apart from the three functional elements (dam, sluices, turboalternators), additional requirements had to be met, including: (a) the dam was not to be an obstacle to navigation between the sea and the estuary and so had to incorporate a lock; (b) the general appearance of the installation had to respect the natural features of the site; and (c) the construction had to serve as the basis for a road across the Rance. Geologically, the Rance estuary was formed by subsidence, and its banks are sharply outlined. The useful volume of the tidal basin is 184 million cubic meters (~6.5 billion cubic feet) between the extreme of zero elevation at ebb tide and the 13.5 meters reached in exceptionally heavy spring tides. The corresponding areas of the basin are 4.3 square kilometers (~1.7 square miles) at zero elevation and 22 square kilometers (8.5 square miles) at 13.5 meters.

In the early 1940s, designers were well familiar with low-head river site harnessing problems as the result of river installations in France and other parts of Europe, but this knowledge could not be applied directly to tidal plant design. One of the particular features of a tidal plant is its range of turbine operation in either direction of flow, with both head and discharge varying considerably. Power plant operational studies soon pointed to the advantage of pumping at around high tide slack water so as to overfill the basin; and so as to overempty it at low tide. This required machines capable of running as low-delivery head pumps. Design studies by Robert Gibrat clearly showed the tremendous potential scope of tidal power plant operating cycles. In order to derive maximum benefit from these cycles, it was essential to develop units capable of operating as turbines, pumps, or orifices with flow in either direction. Cross section of a bulb unit is shown in Fig. 5.

As of the early 1980s, the French were reevaluating the feasibility of establishing a giant multi-basin tidal power station (6,000 to 12,000 megawatts) at Chausey in the Bay of Mont. St. Michel, a location not far from the present Rance Estuary facility.

Canadian Plans. It was not until 1977 that the Federal/Provincial Tidal Power Review Board (TPRB) of Canada concluded that tidal power from the Bay of Fundy can compete on economic terms with electricity from fossil fuels. In 1969, a study had suggested three Bay of Fundy sites. See Fig. 6. One of these is Economy Point on the Minas Basin. Some of the world's highest diurnal tides are experienced at this location. Other locations with potential are the Cumberland Basin and Shepody Bay near the border between New Brunswick and Nova Scotia. It has been envisioned that a plant located at Economy Point would have a capacity of 3800 megawatts, about equivalent to four nuclear facilities, with an electric power output considerably greater than the requirements of Canada's Maritime Provinces.

The importance of resonance in the exploitation of tidal power resources, previously mentioned in this entry, has been a major consideration of the Canadian planners in selecting Bay of Fundy sites. Even though maximum exploitation may not be envisioned for many years, an early site based upon short-term needs could adversely affect the ultimate tidal power available at later sites. For example, a reduction in the length of the Bay, resulting from construction of a barrier, will result in some disturbance of the natural resonance. It has been estimated that resonant high tides in the Bay are likely to occur with a natural period of 12 hours, 25 minutes. Canadian engineers have estimated that a barrier at a wide site, such as Chignetco Bay (Fig. 6), a point where the Bay divides, might reduce the tidal amplitude by as much as one-third and thus greatly reduce the effectiveness of plants at Shepody Bay and Cumberland Basin. The TPRB reached a general conclusion that sites of tidal barriers should be located as near to the heads of bays as possible.

Calculations of tidal resonance and behavior do not always match actual observed behavior. For example, early calculations indicated that the natural period of the Bay of Fundy is 9 hours, much lower than observed values. Models and calculations must take adjacent large bays into consideration, even though at some distance, because the resonance appears to be an integration of a whole system of bays, not an isolated region. Thus, the Gulf of Maine must be considered in making plans for the Bay of Fundy. Further, it is now believed that, because of the shallowness of the Georges Bank, much of the tidal wave energy enters the Bay of Fundy by way of a submarine canyon some 150 fathoms deep. The future progress of sedimentation as the result of barrier construction also must be taken into consideration.

Tidal Power Potential in the United States. In the United States, tidal power facilities appear to be limited principally to Cook Inlet, Alaska (7.5 meters; 24.6 feet); and Passamaquoddy and Cobscook Bays in Maine, each with a tide of about 5.5 meters (18 feet).

In recent years, there has been more interest shown by energy planners in the United States to newer, unconventional methods for extracting tidal energy as contrasted with the kinds of installations previously described in this entry. As recently as March 1979, the U.S. Army Corps of Engineers concluded a preliminary economic study of the Cobscook Bay area in Maine and observed that although tidal power from this site is more competitive than in decades past, a program still is not justified.

In a new concept proposed and patented by A.M. Gorlov (Northeastern University), a very thin plastic barrier (called a water sail) would replace the conventional dam. The reinforced plastic membrane would be hermetically anchored to the bottom and sides of the bay. It is proposed

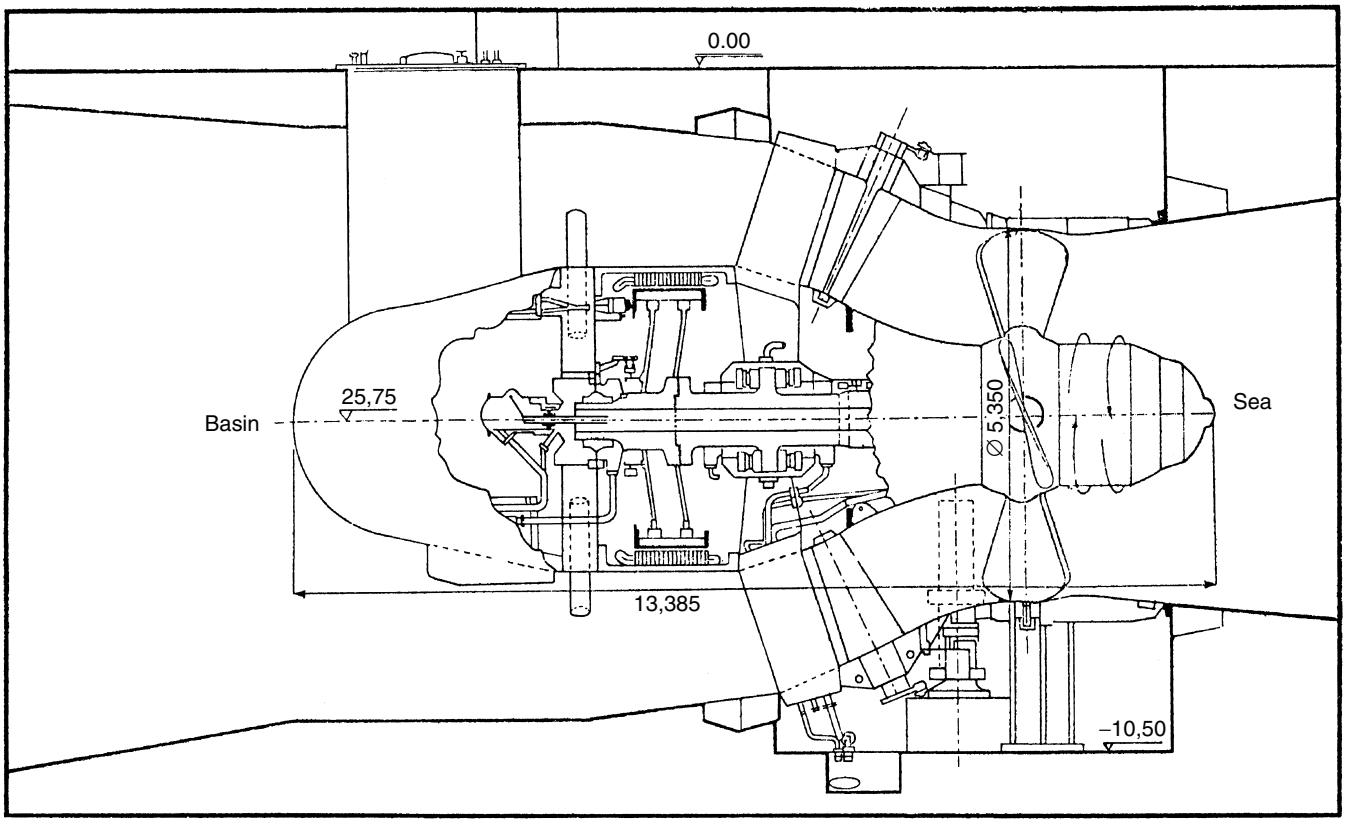

Fig. 5. Sectional view of reversing bulb-type unit used at the Rance estuary tidal power plant. A total of 24 units of this type is used. (*Electricité de France*.)

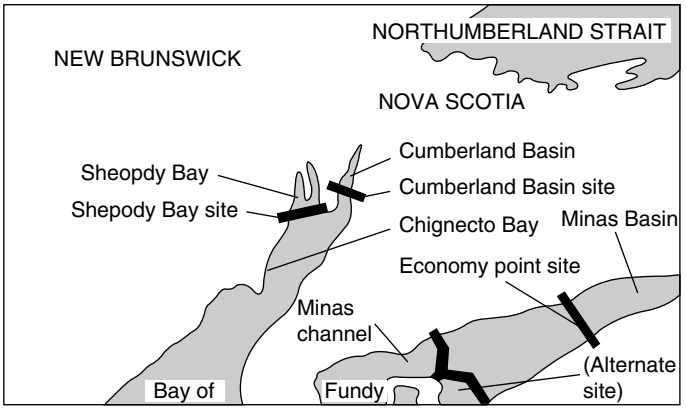

Fig. 6. Selection of tidal power plants to take advantage of the large tides in the Bay of Fundy.

that the membrane would be constructed in sections so that, if necessary, it could be pulled aside. As explained by Ryan (1980), "The top of the barrier would be supported by a cable spanning the entrance to the bay. The cable would be fixed to several specially designed floats that would keep the barrier above the surface of the water, maintaining the desired differential level — approximately 2 meters (6.5 feet) of head between the ocean and basin side — during rising and receding tides. The underwater part of the barrier would be exposed to a net water pressure equal to the difference in water levels across the dams. It would therefore be called upon to withstand pressure of 2 meters of water (0.2 atmosphere) — well within the strength limits of today's reinforced plastic materials."

Conversion of tidal energy would be through the use of compressed air. It is envisioned that two chambers connected to an air motor, essentially a large piston, would be used. As of the early 1980s, the concept is undergoing early feasibility tests.

In the United Kingdom, as of the early 1980s, there was considerable competition in technical circles between using conventional approaches to exploiting tidal power as, for example, the Severn estuary between England and Wales, and the use of wave power.

TIDAL WIND. See **Winds and Air Movement**.

TIDE CLOCK. See **Clocks**.

TIDE GAGE. A device for measuring the height of tide. It may be simply a graduated staff in a sheltered location where visual observations can be made at any desired time; or it may consist of an elaborate recording

instrument (sometimes called marigraph) making a continuous graphic record of tide height against time. Such an instrument is usually actuated by a float in a pipe communicating with the sea through a small hole, which filters out shorter waves.

TIDES. The periodic rise and fall of the oceans, or other large bodies of water, relative to the surrounding land is commonly known as the tides. Since the Earth itself is not a perfectly rigid body, there are tides in the Earth itself, and observations of the land tides have provided useful information regarding the rigidity of the interior of the Earth.

Tides are produced by the combination of a number of external forces, with the principal force being the gravitational attraction of the moon. Owing to the differences of distance of the moon from various portions of the Earth, the amount of the attractive force will be different in different places and tend to produce a deformation. Figure 1 indicates (on a very much exaggerated scale) the deformation forces, and the resultant tides in a very deep ocean surrounding a rigid Earth.

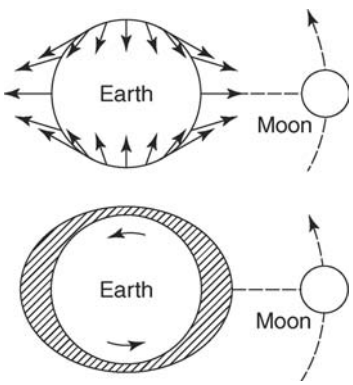

Fig. 1. Tides in a very deep ocean. If the whole earth were covered by very deep water and if the Earth's rotation were slower, high tides would occur under and opposite the moon. The upper figure shows the tide-raising force of the moon at different places.

The tidal force due to the gravitational attraction of the sun ranks second in importance to the tide-raising forces from the moon. Twice during each month, at times of full and new moon, the forces from the sun and moon are acting in parallel directions and produce the maximum tide range known as "spring tides." At times of quarter-moon the forces are acting at right angles to each other and the resultant minimum range of tides is known as "neap tides." Other tidal forces due to the rotation of the Earth, the revolution of the Earth-moon system, and the revolution of the sun-Earth system, make the problem of tide prediction one of great complexity. Detailed harmonic analysis of the observed tides has indicated the presence of tidal forces due to the attractions of several of the major planets. In the open ocean, from observations taken on isolated islands, the average range of ocean tides relative to the land is about $2\frac{1}{2}$ feet (0.75 meters). Configuration of shore line and contour of the ocean floor greatly increase this range for most stations along the coasts of the continents. The maximum range of tides in the land is about 9 inches (23 cm).

If no other forces than lunar attraction were effective in producing the tides, the time of high water (the crest of the tidal bulge) would occur at a given point when the moon is on the local meridian (either at upper or lower culmination). Due to the other effective tidal forces the actual time of high tide differs from the instant of meridian passage of the moon by an amount known as the "lunar interval." The effect of lunar interval will average zero in the course of a long period of time, and the average interval between successive high tides is found to be 12 hours 25.5 minutes, which is $\frac{1}{2}$ the average interval between successive upper culminations of the moon.

The difference between the actually observed time of high tide and the time calculated from the instant of transit of the moon across the meridian, combined with the lunar interval, is known as the "establishment of the port." The values of the "establishment" are obtained observationally for various ports and are tabulated in tide Tables. The values obtained for two ports, which may be separated by only a few miles, may be very different owing to the configuration of the coast line between the ports.

TIFF (TAGGED IMAGE FILE FORMAT). See **Data Compression**.

TIGER. See **Cats**.

TIGER BEETLE *(Insecta, Coleoptera).* A small longlegged beetle of predacious habits. They are usually found on exposed earth or sand in the glare of the sun, where they both run and fly very rapidly. The numerous species are blue or green, reddish, or white, with or without a characteristic pattern of spots and dashes on the elytra. The larvae live in burrows in the ground, lying with the head at the entrance to the burrow ready to seize any victim that comes near.

TIGER'S EYE. See **Quartz**.

TIGER SHARK. See **Sharks**.

TILL. A general term for coarsely graded and extremely heterogeneous sediments of glacial origin. Till is generally classified as unstratified drift which may vary from clays to mixtures of clay, sand, and boulders. A particularly sticky form of clay till is called gumbo.

See also **Glacial Deposits (or Drift)**.

TILL (Blacialk). See **Glacial Deposits (or Drift)**.

TILTMETER. An instrument that measures slight changes in the tilt of the Earth's surface, usually in relation to a liquid-level surface or to the rest position of a pendulum. The instrument is used in volcanology and in earthquake seismology.

TILT TABLE. A device used to calibrate linear accelerometers with rated ranges of, or below, $+/-1.0$ g. It allows the accelerometer to be positioned at different angles in reference to a surface perpendicular to the direction of the earth's gravity, so that the applied values of acceleration are equal to the cosine of the angle between the reference surface and the direction of the earth's gravity.

TIMBRE. See **Acoustics**.

TIME. One of the criteria of scientific observation is the experimental measurement of time because events take place within the context of time reference systems. These systems, or clocks, include the frequency rates, or cycles, of the Earth — its spin on its axis or orbital revolution about the sun; the action of a pendulum or of a watch's balance wheel; controlled alternating electric current; the vibrations of a tuning fork or quartz crystals; radioactive decay; and the oscillations of the atom of cesium-133. Consequently, *time is what the clock reads*. There is, in short, no absolute time standard. Generally speaking, the more stable the cyclical system, the more precise and accurate will be the clock reading.

Apparent Solar Time, or so-called *sundial time*, is measured by the diurnal motion of the sun as observed from a point on the Earth's surface as the Earth (which is not a perfect sphere) rotates (not uniformly) on its axis, in an elliptical solar orbit in an orbital plane that does not coincide with the plane of its rotation at the equator. As a result, apparent solar days vary in length.

Mean Solar Time is apparent solar time averaged out to eliminate rotational and orbital variables, so that the mean solar day is the average of all apparent solar days in the orbital year. This is divided by 86,400 to

determine the *mean solar second*. The *equation of time*, with a numerical value of from 0 to about 16 minutes, describes the difference between the apparent and mean solar time; it is at maximum in February and November.

The Gregorian Calendar, instituted in 1582 by Pope Gregory XIII, reformed the Julian calendar, which had a mean year of 365.25 days, equivalent to 11 minutes and 14 seconds longer than the mean solar year, so that the Gregorian mean year has 365.2425 days. This reform involved (1) omitting a 10-day (October 5–14, 1582) period without interrupting the sequence of the days of the week to restore the date of the actual vernal equinox to March 21 — so as to (2) regulate Easter coincident with new rules for ecclesiastical feast days; and (3) omitting the Julian intercalary day in centurial years not divisible by 400 (such as 1800), although otherwise retaining the intercalary day inserted in every fourth, or Leap year.

The Gregorian calendar, adopted in 1752 by England and its American colonies, later came into almost universal civil use. Exceptions include Russia, which adopted the calendar in 1918 but has since developed a variant arrangement for intercalary days.

The calendar system based on the Julian Day Number, sometimes called the Astronomical Day System takes January 1, 4713 B.C. of the Julian calendar, starting at 12 noon, as Day 1, and counts all subsequent Days consecutively, as measured by the spin of the earth on its axis, without reference to the solar, or tropical year. Julian Days are divided decimally, rather than into hours, minutes, and seconds. See also **Calendar**.

> Editor's Note: In the paragraphs that follow, the NBS (National Bureau of Standards) is mentioned several times. Just a few years ago, the NBS was renamed and now is known as the National Institute of Technology and Standards (NIST).

Universal Time (UT), also called *Greenwich Mean Time* (*GMT*) because it is referenced to the Prime (or zero) Meridian at Greenwich, England, is also based on the earth's rotation; if uncorrected, therefore, its units are equal to the mean solar second. As a time scale, these units are designated as UT_0. The UT_1 scale is UT_0 corrected to allow for the polar motion, or nutation, of the earth. The UT_2 scale is UT_1 corrected for seasonal variations in the earth's rotation. UT is announced in International Morse Code each 5 minutes by radio stations WWV (Fort Collins, Colorado) and WWVH (Puuene, Maui, Hawaii) of the U.S. National Bureau of Standards. Other time signals broadcast by the stations are kept in close agreement with UT_2.

UT is also expressed in terms of the 24 *Standard Time Zones* that serially cover the Earth's surface at coincident intervals of 15 degrees longitude and 60 minutes UT, as agreed at the Washington Meridian Conference of 1884, thus accounting respectively for each of the 24 hours of the calendar day. These local *civil time zones*, with irregular statutory boundaries, were chosen so that noon occurs when the sun appears approximately overhead at the zone's central meridian. *Standard Time zones* were established in the United States in 1883. *Daylight Saving Time* was proposed by Benjamin Franklin and first adopted in Europe during World War I to cut electric power consumption. Since 1967, federal legislation in the United States has required the states to observe it uniformly. However, cities and other communities are not bound by this legislation. Daylight Saving Time was extended during the winter of 1973–1974 because of the energy crisis, was changed again in the autumn of 1974, and possibly may undergo additional shifts if this simple arrangement can be used effectively to save energy. An interesting and somewhat detailed explanation of the relationship between Standard and Daylight Saving Time will be found in "Standard and Daylight-Saving Time," by I.R. Bartky and E. Harrison, *Scientific American*, **240**, 5, 46–53 (1979).

The one-hour shift in standard time each 15 degrees longitude requires a one-day jump forward in date when moving from America to Asia and a one-day jump backward in date when moving from Asia to America. This data boundary running irregularly by treaty from the poles through the Pacific is the *International Date Line*.

Apparent Sidereal Time, the time scale generally used by astronomers, is measured by the apparent diurnal motion of a distant star (not the sun) as observed from a point on the earth's surface. This scale is more easily observed than apparent solar time.

Ephemeris Time. A definition of time based on idealized motions of the Sun and Moon that was adopted and introduced in the astronomical ephemerides on January 1, 1960, to free astronomical computations from the effect of the irregularities of the Earth's rotation. One second of Ephemeris Time is a specified fraction of the tropical year 1900 (equals 31,556,925,974.7 seconds of Ephemeris Time); the difference between Ephemeris Time and Greenwich Standard Time (Universal Time) is derived for each year from a comparison of the observed and computed position of the Moon.

Atomic Time is based on the atomic second, officially defined in 1967 by the 13th General Conference of Weights and Measures as 9,192,631,770 oscillations of the atom of cesium-133 (although this value was provisionally defined in 1964 as 9,192,631,770 plus or minus 20). This value expresses the ET second as closely as possible in terms of an atomic standard and was derived by a joint experiment of the U.S. Naval Observatory and Great Britain's National Physical Laboratory, using a dual-rate moon-position camera, developed by Dr. William Markowitz of the U.S. Naval Observatory, and a cesium-beam clock. The U.S. National Bureau of Standards used a cesium-beam clock as its NBS atomic frequency standard and, as a service, the Bureau provides UT_2 in cooperation with the U.S. Naval Observatory.

Corrections to the frequencies transmitted by NBS radio stations WWV and WWVH are determined with regard to the NBS atomic standard and are published monthly by the "Proceedings of the Institute of Electrical and Electronics Engineers." The stations' carrier and modulation frequencies are intentionally offset from the atomic frequency standard by a precisely known amount so that, on the average, the time signals broadcast remain as close as possible to UT_2. In 1966, 1967, and 1968, the offset was minus 300 parts in 10^{10} parts. This offset compensates, in effect, for the progressive changes in the speed of rotation of the earth so as to permit the radio service to offer UT_2 while retaining the atomic time standard to provide the unit of time, the second. The carrier frequency of NBS radio station WWVL (Fort Collins, Colorado) is also offset by the same amount, but NBS very-low frequency radio station WWVB (also in Fort Collins) transmits without offset to permit absolute frequency comparisons by user.

The cesium-beam clock of the National Bureau of Standards is referred to as a primary clock because independently of any other reference it provides highly precise and accurate time to scientific, research, industrial, defense, and public needs. Secondary clocks must, unlike primary clocks, be referenced to more accurate clocks for calibration. Today, quartz crystal clocks are the most frequently used secondary time standards. Master clocks, in contrast, are systems used to directly control subsidiary clocks. For example, the 60-cycle alternating current plug-in electric clock employs a synchronous motor controlled by the alternating current acting as a master clock system. A wrist timepiece, instead, has its own frequency standard, either a 2.5 to Hz balance wheel or a 360 Hz tuning fork.

The International Astronomical Union and the General Conference of Weights and Measures officially define international time standards, while the Bureau Internationale de l'Heure, at the Paris Observatory, Paris, France, provides and receives data to assist in the uniform international observation of time standards.

Continued Quest for Better Clocks and Frequency Standards. As observed by Wineland (1984), there is reason to believe that the inaccuracy of a time standard based on stored ions can eventually be much smaller than that of the cesium clock, which can have an accuracy of about one part in 10^{13} or less. In an experiment at the National Bureau of Standards (Boulder, Colorado) in 1983, the frequency of a particular hyperfine transition in the ground state of beryllium atomic ions was measured with an inaccuracy of only about one part in 10^{13}. In this experiment, the ions were confined or "trapped" in a small region of space by using static electromagnetic fields and their kinetic temperature was lowered to less than 1 K by a process sometimes called "*laser cooling*." In all of physics, only a few measurements can achieve a higher accuracy. Those

experiments measure similar transitions in neutral cesium atoms. Potential accuracies of frequency standards and clocks based on such experiments are anticipated to be better than one part in 10^{15}.

Time and Philosophy. Over the centuries, naturalists and poets alike have commented on the characteristics of time with relation to earthly and human events. Lord Byron in the first act of his play, *Cain, a Mystery*, quotes the fallen angel Lucifer as saying: "With us acts are exempt from time, and we can crowd eternity into an hour, or stretch an hour into eternity. We breathe not by a mortal measurement — but that's a mystery." Alfred North Whitehead said in The *Concept of Nature*, "it is impossible to meditate on time and the mystery of the creative passage of nature without an overwhelming emotion at the limitations of human intelligence." Martin Gardner, writing for "Mathematical Games" in *Scientific American*, **240**, 3, 21–27 (1979) explores two bizarre questions about time, namely: (1) Is it meaningful to speak of time stopping? (2) Is it meaningful to speak of altering the past?

An excellent book pertaining to the development of the mechanical clock in the last half of the 13th Century and of the clock's impact on society, industry, and commerce is "Revolution in Time" by David S. Landes, Harvard University Press, Cambridge, Massachusetts, 1983.

TIME (Biological). See **Circadian Clock**.

TIME CLOCK. See **Clocks**.

TIME CONSTANT. All physical systems require a certain amount of time to transmit signals from input to output. This time is simple resistance-capacitance and inductance-resistance systems is characterized by the system time constant. In the resistance-capacitance circuit (most common example of this concept), the time constant is equal to the product of the resistance and capacitance. In this case the resistance is measured in ohms and the capacitance in farads. The resultant time constant value is in seconds and is a measure of the time required for the circuit variable (voltage) to reach $1-\frac{1}{e}$ or 63% of the final value. In this notation, e is the base of the natural logarithms (2.71828...).

The differential equation for this simple circuit, using Fig. 1 as a reference, is as follows:

$$i = \frac{E_i - E_0}{R} \tag{1}$$

$$i = C\frac{dE_0}{dt} \tag{2}$$

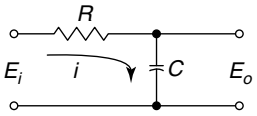

Fig. 1. Simple RC circuit.

Combining Equations (1) and (2) gives

$$\frac{E_i - E_0}{RC} = \frac{dE_0}{dt} \tag{3}$$

The solution of the first-order differential equation for a unit step change in E_i is

$$E_0 = 1 - e^{-t/T} \tag{4}$$

where $T = RC$. The time response for E_0 is shown in Fig. 2. Similar equations may be developed for the inductance-resistance circuit. In this circuit the time constant is equal to the inductance in henries divided by the resistance in ohms.

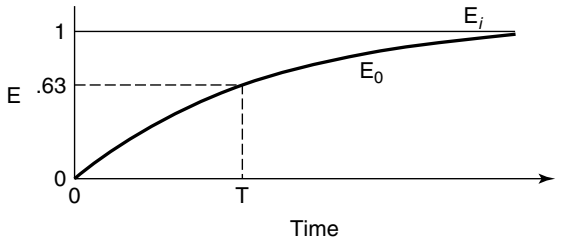

Fig. 2. Simple RC circuit time response.

The use of electrical examples in defining the time constant is in no way intended to limit this concept to electrical systems. The same concept may be applied to mechanical, thermal, pneumatic, hydraulic, and any other type of system having resistive and capacitive elements. This similarity between systems is the basis for all analog computer work. Due to the widespread application of this concept in systems analysis it has been assigned many names other than the time constant. Some of the terms in use, which have the same meaning, are exponential lag, first-order lag, and single capacity lag.

TIME DELAY. The time required by a specific voltage or current to travel through a circuit.

TIME DEMODULATION. The process by which information is obtained from a time-modulated wave about the signal imparted to the wave in time modulation.

TIME DISCRIMINATOR. A circuit that indicates the time equality of two events, or the sense and approximate magnitude of the inequality.

TIME-DIVISION MULTIPLEXING. The process or device in which each modulating wave modulates a separate pulse subcarrier, the pulse subcarriers being spaced in time so that no two pulses occupy the same time interval. Time division permits the transmission of two or more signals over a common path by using different time intervals for the transmission of the intelligence of each message signal.

TIME (Equation). See **Equation of Time**.

TIME GATE. A transducer that gives output only during chosen time intervals.

TIME HISTORY OF EVENTS AND MACROSCALE INTERACTIONS DURING SUBSTORMS (THEMIS). See **Explorers Program**; and **Space Science Missions: Sun**.

TIME MODULATION. Modulation in which the time of appearance of a definite portion of a waveform, measured with respect to a reference time, is varied in accordance with a signal.

TIME PATTERN. A picture-tube presentation of horizontal and vertical lines or dot-rows generated by two stable frequency sources operating at multiples of the line and field frequencies.

TIME REVERSAL INVARIANCE. See **Conservation Laws and Symmetry**.

TIME (Rise). See **Rise Time**.

TIME SERIES. The values of a variable generated successively in time. A continuous barograph trace is an example of a *continuous time series*, whereas a sequence of hourly pressures is an example of a *discrete time series*. Graphically, a time series is usually plotted with time as the abscissa and the values of the function as the ordinate.

TIME SHARING. The use of a device, particularly a computer or data-processing machine, for two or more purposes during the same overall time interval, accomplished by interspersing component and subsystem actions in time. In the case of a digital computer, time sharing generally connotes the process of using main storage for the concurrent execution of more than one job by temporarily storing all jobs, but the one in control, on auxiliary storage. This technique allows a computer memory to be used by several independent programs (users). The method most often is associated with a computer-controlled terminal system used in an interactive mode.

The prime objective in using an interactive time-sharing system is to permit more efficient use of the computer system in proceeding from initial specification of a program to a final checked-out operating revision and also the more efficient use of people in the solution of problems by providing answers and services in a short time on demand. The traditional batch-processing type of operation necessitates the coding and preparation of a program as a separate first step. Submission of the job to a computer control center for inclusion in a batch run can result in several hours of delay. The problem of writing and checking out a large, complex program in this fashion does not efficiently use the programmer's time because of loss of continuity in the problem. Time-sharing systems are designed to allow a user to operate the computer in an interactive manner, by way of a variety of console devices, and thus obtain immediate responses to requests for answers, while also receiving immediate indications of errors in programming.

Modern systems have the capability of handling many terminal users concurrently and still use available time to process batch jobs in the normal fashion. The magnitude of the capability for this type of operation depends upon computer speed, storage size, auxiliary storage size and speed, the operating system used to manage and control these facilities, and the type and amount of terminal service to be offered. Time slicing is a common approach to allocating time for each user in the terminal system. See also **Time Slicing**.

Time sharing also is used in nonterminal systems for the purpose of sharing a portion of the system memory between jobs of different priority. This usually is called multiprogramming. In some control and data-acquisition systems, a portion of the main storage (a partition) is allocated to run nonprocess-related jobs (background jobs) in the conventional batch-processing manner. However, when the system is notified that a process-related program requires the partition, the background job is stored on auxiliary storage until the higher-priority program has been executed. The background job then is restored and resumed, if in the meantime, no other higher-priority job is waiting for service.

TIME SIGNAL. 1. An accurate signal marking a specified time or time interval. It is used primarily for determining errors of timepieces. Such signals are usually sent from an observatory by radio or telegraph.

2. In photography, a time indication registered on the film to serve as a time reference for interpretation of the date recorded on the film.

TIME SLICING. A technique that allows several users to employ a computer facility as though each had complete control of the machine. Several users can be serviced one at a time, unaware of each other, because of the relative speed between computer operation and human response. Essentially, time slicing is used by a software control system to control the allocation of facilities of a computer to tasks requesting service. The allocation basis is a fixed time interval. Each job is executed for the time period used in the time slice. The job is then temporarily stored on an auxiliary storage device (time sharing) or suspended (multiprogramming), while another job is being run. Each job, therefore, is run in an incremental fashion until complete. See also **Multiprogramming (Computer System)**.

TIME-STRATIGRAPHIC UNIT. This has been described as "a subdivision of rocks considered solely as the record of a specific interval of geologic time" (ACSN, 1961, art. 26). It is a material unit or body of strata based upon actual sections or sequences of rock, thus representing the preserved record of rocks formed during an arbitrary interval of finite geologic time, the time extending from the commencement to the ending of its deposition or intrusion. As stated by Hedberg (1976), a time-stratigraphic unit "provides us with the only available technique of determining approximate isochronous surfaces and thereby geographically extending approximate working boundaries for time-stratigraphic units." The magnitude of the unit is measured by the length of the time interval to which its rocks correspond, not by their thickness. The term *chronolith* is synonymous with time-stratigraphic unit and is not to be confused with *chonolith*.

TIME ZONE SYSTEM. See **Zone Time**.

TIMING BELT. A specially designed belt that provides a nonslip positive speed ratio between the driving and driven pulleys of an apparatus or machine. Timing belts are commonly used on numerically controlled machine tools and similar applications where light-weight, zero backlash, and positive drive are important to the servo operation. The belts also are used to drive the camshafts in some engines and for motor driven pumps, fans, and similar applications where quiet operation, long life, and minimum maintenance are required. Special materials for operation in hot oil or at very low temperatures are available.

A timing belt has an integral number of teeth (similar to gear teeth) molded on the inner surface. The pulleys carry grooves milled across the face to receive the belt teeth. Like a gear or chain drive, the belt provides an exact speed ratio corresponding to the ratio of the numbers of teeth on the pulleys.

The belts are molded of neoprene or similar materials in an endless loop having a flat backing strip with the teeth molded to shape on the inner belt surface. Molded within the backing strip are steel cables helically wound around the periphery of the belt for strength and stiffness in tension. The faces of the teeth are covered with a woven nylon fabric molded integrally with the belt.

Belt and pulley combinations are provided in a range of pitches varying from $\frac{1}{5}$ inch to $1\frac{1}{4}$ inch (spacing between teeth) and widths from $\frac{1}{4}$ inch to 5 inches. The corresponding range of power is from fractional horsepower to over 185 horsepower. Belts are available in a range of lengths permitting a wide range of shaft center distances. The advantages found in timing belt drives, as compared with gears, V-belts, and chains, are relatively low cost, light weight, low noise, zero backlash, and no requirement for lubrication. Timing belts provide a positive drive without high tension and have a long life as compared with V-belts.

TIMOTHY. See **Grasses**.

TIN. [CAS: 7440-31-5]. Chemical element, symbol Sn, at. no. 50, at. wt. 118.69, periodic table group 4, mp 231.97 °C (449.55 °F), bp 2,270 °C (4,118 °F), density 7.29 g/cm^3 (white tin at 15 °C (59 °F)), 5.77 (gray tin at 13 °C (55 °F)), 6.97 (liquid at mp). There are two allotropic forms of tin: (1) the more common soft white beta tin has a body-centered tetragonal crystal form, (2) the brittle gray alpha tin has a diamond-type cubic crystal form. The cubic form, α-tin, stable below 18 °C (64 °F), is an intrinsic

semiconductor, and is gray. At 161 °C (322 °F), white tin undergoes a transition to rhombic or γ-tin.

Tin is a silver-white metal with a bluish tinge, softer than zinc and harder than lead. It is malleable, ductile at 100 °C (212 °F); can be powdered at 200 °C (392 °F), and upon exposure to temperatures below 18 °C (64 °F), it crumbles to a grayish powder due to the "tin pest," which is caused by the transformation of white to gray tin (the reverse transformation may be brought about by heating gray tin to about 100 °C (212 °F)). When a bar of tin is bent a marked creaking sound is emitted due to the friction of the crystals. Tin: is not oxidized on exposure to air at ordinary temperatures; burns to stannic oxide when heated to high temperatures in air or oxygen; is soluble in HCl to form stannous chloride; is converted by concentrated HNO_3 into soluble beta-stannic acid; is soluble in aqua regia to form stannic chloride; is soluble in NaOH solution slowly to form sodium stannite and hydrogen gas; and reacts with chlorine to form volatile stannic chloride.

Tin is one of the world's most ancient metals. When and where it was discovered is uncertain, but evidence points to tin being used in 3200–3500 BC. Ancient bronze weapons and tools found in Ur contained 10–15 wt % tin. In 79 AD, Pliny described an alloy of tin and lead now commonly called solder. The Romans used tinned copper vessels, but tinned iron vessels did not appear until the fourteenth century in Bohemia. Tinned sheet for metal containers and tole (painted) ware made its appearance in England and Saxony about the middle of the seventeenth century. Although tinplate was not manufactured in the United States until the early nineteenth century, production increased rapidly and soon outstripped that in all other countries.

In most cases, tin is used on or in a manufactured material in small amounts, much out of proportion to the purpose it serves. Nevertheless, tin in some form has been associated with the economic and cultural growth of civilization. Food preservation and canning developed rapidly with the invention of tin-coated steel; transportation and high speed machinery became a reality with the invention of tin-base bearing metals; the casting of type metal was an important advance in printing technology; bronze alloys became weapons, tools, and architectural objects; tin alloys are used in organ pipes and bells; and telecommunications and electronic equipment depend upon the tin–lead soldered joint. In modern technology, new uses of tin include the plating of protective coatings, nuclear energy, plastics and other polymers, agriculture, biochemistry, electronic packaging, and glassmaking.

Tin has the largest number of naturally occurring isotopes ^{112}Sn, ^{114}Sn through ^{120}Sn, ^{122}Sn, and ^{124}Sn. Five radioactive isotopes have been identified ^{111}Sn, ^{113}Sn, ^{121}Sn, ^{123}Sn, and ^{125}Sn. With exception of ^{121}Sn, which has a half-life of about 5 years, the half-lives of the other isotopes are comparatively short, expressed in minutes and days. Tin occurs in the Earth's crust to the extent of about 40 grams/ton. It is estimated that a cubic mile of seawater contains about 15 tons of tin. First ionization potential 7.332 eV; second, 14.52 eV; third, 30.49 eV; fourth, 40.57 eV. Oxidation potential $Sn \rightarrow Sn^{2+} + 2e^-$, 0.406 V; $Sn^{2+} \rightarrow Sn^{4+} + 2e^-$, −0.14 V; $HSnO_2^- + 3OH^- + H_2O \rightarrow Sn(OH)_6^{2-} + 2e^+$, 0.96 V; $Sn + 3OH^- \rightarrow HSnO_2^- + H_2O + 2e^-$, 0.79 V. Electronic configuration $1s^2 2s^2 2p^6 3s^2 3p^6 3d^{10} 4s^2 4p^6 4d^{10} 5s^2 5p^2$.

Other important physical properties of tin are given under **Chemical Elements**.

Tin occurs in the earth's crust to the extent of 40 grams per metric ton and is present in the form of nine different minerals from two types of deposits. The most commercially significant ore is cassiterite [CAS: 1317-45-9] (tinstone), SnO_2. The more economically valuable deposits of cassiterite are heavily concentrated in bands and layers of varying thickness, in Malaysia, Thailand, Indonesia, and the People's Republic of China. Complex sulfidic ores, combinations of the sulfides of base metals and pyrites, are in lode deposits. These, economically significant only in Bolivia, are stannite [CAS: 12019-29-3], $SnS_2 \cdot Cu_2S \cdot FeS$; herzenbergite [CAS: 14752-27-3], SnS; teallite [CAS: 12294-02-9], $SnS \cdot PbS$; franckeite [CAS: 12294-04-1], $2SnS_2 \cdot Sb_2S_3 5PbS$; cylindrite [CAS: 12294-05-0, 59858-98-9], $Sn_6Pb_6Sb_2S_{11}$; plumbostannite, $2SnS_2 \cdot 2PbS \cdot 2(Fe,Zn)S \cdot Sb_2S_3$; and canfieldite [CAS: 12250-27-0], $4Ag_2S \cdot SnS_2$. The important tin-producing countries are Malaysia, Bolivia, Indonesia, Nigeria, Thailand, Zaire, and the People's Republic of China. Smaller quantities are produced in the United Kingdom, Burma, Japan, Canada, Portugal, Spain, and Australia. Tin is also normally present in natural waters, in soil, in marine organisms and animals, in the milk of lactating animals, in meteorites, in the tissues of animals, and in minor amounts in human organs.

Tin-mining methods depend on the character of the deposit. Primary deposits are embedded in underground granitic rock and recovery methods are complex. The more important secondary deposits are in the form of an alluvial mud in the stream beds and placers and the recovery is simpler than lode mining. Cassiterite is recovered from alluvial deposits by dredging, hydraulicking where a head of water permits it, jets and gravel pumps on level ground, or open-pit mining.

Gravel-pump mining is widely used in southeast Asia and probably accounts for 40% of the world's tin production. Powerful jets of water are directed onto the mine face to break down the tin-bearing soil, which is allowed to collect in a sump. A gravel pump in the sump elevates the watery mud to a wooden trough termed a palong in the trade. The palong has a gentle slope and as the ore flows down the slope, the tin oxide particles, which are 2.5 times heavier than sand, are trapped behind wooden slats or riffles. Periodically, the preliminary concentrates are collected and transferred to the dressing shed for final concentration. Hydraulicking and open-pit mining methods also involve gravity separation with water in palongs.

Dredging is mining with a floating dredge on an artificial pond in a placer. Chain buckets or suction cutters, digging at depths of 46 m, transfer the tin-bearing mud to revolving screens, hydrocyclons, jigs, shaking tables, classifiers, and similar equipment. The sand and dirt are removed in these preliminary roughing steps. The mineral is further beneficiated in dressing sheds on shore with modern techniques such as flotation, heavy-media separation, and electrostatic, magnetic, and spiral separators for the removal of associated minerals. Final concentrates ready for direct smelting contain 70–77 wt % tin, which is almost pure cassiterite.

Underground-lode deposits in Bolivia are located at very high altitudes, 4000–5000 m above sea level, whereas the lode deposits in Cornwall are ca 430 m below sea level. Access to the lodes is by shaft sinking or by adits, ie, passages driven into the side of a mountain, depending on the terrain. The ore is broken from the working face by blasting and drilling. Further crushing and grinding above-ground is necessary to produce the finely divided ore capable of being concentrated by the various gravity-concentration methods and mechanical separations commonly used for alluvial deposits.

Secondary tin is an important source of the metal. Tinplate scrap may be detinned electrolytically or chemically. The alkaline chemical process is the most widely used and involves a caustic solution, which contains an oxidizing agent to remove both tin and the underlying iron-tin alloy from the steel. The solution formed then is either (1) crystallized to form sodium stannate, (2) electrolyzed to recover tin metal, or (3) acidified with CO_2, H_2SO_4, or acidic gases to precipitate hydrated tin oxide. There are several secondary tin smelters in the United States, but only one primary smelter. The main primary tin smelters are located in the United Kingdom, Malaysia, and Thailand.

Uses. Not including former Soviet Bloc nations, world consumption of tin is in excess of 187,000 metric tons annually. Principal uses are: (1) tinplate, 35%; (2) solder, 24%; (3) bronze, 9%; (4) other alloys, 8%; (5) tinning, 4%; (6) chemicals, 5%; (7) other uses, 15%. In the United States, tin consumption in 1979 was: (1) tinplate, 29%; (2) solder, 29%; (3) bronze and brass, 14%; (4) chemicals, 8%; (5) other alloys, 9%; (6) tinning, 4%; (7) other uses, 7%. In the United States, the major portion of tinplate is used in the making of cans. The advantages of tin for cans and food-processing equipment include its nontoxic nature, resistance to corrosive attack by acids and other aqueous solutions, and when combined with other metals, strength.

Tin Plate. Tin coating may be applied to steel by (1) electroplating, usually as part of a high-speed, continuous process, or (2) by dipping cut sheets in a bath of molten tin. Electrolytic tin plate essentially is a sandwich in which the central core is strip steel. This core is thoroughly cleaned in a pickling solution prior to electroplating. The actual plating occurs as the strip moves through horizontal or vertical tanks containing electrolyte. The moving strip then is heated as it passes between high-frequency electric induction coils, whereupon the tin coating melts and flows to form a lustrous coat. The average thickness of tin on the end-product sheet is 0.00003

inch (0.0008 millimeter) on each side. A complex system of instrumentation is used to control process conditions and to inspect the moving sheet for any perforations in the plate. In hot-dip tinning, individual steel sheets are pickled and washed. A layer of hot palm oil is maintained on top of the molten tin bath to prevent oxidation of the molten tin by air and to prevent the molten tin from freezing too rapidly on the plate, thus providing a more even coating with a high luster.

Terne Plate. This is a sheet-steel product that is coated with an alloy of tin and lead. The coatings range from 50–50 mixtures of lead and tin to as low as 12% tin and 88% lead. Plate used for roofing normally is about 25% tin and 75% lead. In addition to roofing, terne plate is used in the manufacture of gasoline tanks for automotive vehicles, oil cans, and containers for solvents, resins, etc.

Tin-bearing solders are considered soft solders as contrasted with the hard solders which contain substantial quantities of silver. However, small quantities of silver are added to some tin solders to increase strength of the resulting joint and to adjust working temperature range. Antimony also is added in some cases for the latter purpose. Wiping solders usually have a tin content ranging from 35 to 40%. Solders used in automotive-body work require a wide plastic (working temperature) range. Solders with a low tin content (below 25%) are generally used. For very low-temperature melting, bismuth and cadmium also may be added to tin-lead solders.

Alloys. Tin is widely used as both a major and minor ingredient of alloy metals. These applications are summarized in Tables 1, 2, and 3. Phosphor bronzes (Table 3) actually contain very little phosphorus, ranging from 0.03 to 0.50%, and hence the alloys are poorly designated. Tin bronzes is the better term. High-silicon bronzes contain about 2.8% tin; low-silicon bronzes about 2.0% tin. Gun metals are tin bronze casting alloys with a 5–10% zinc content. Some wrought copper-base alloys contain tin: (1) Inhibited Admiralty metal, 1% tin; (2) manganese bronze, 1% tin; (3) naval brass, 0.75% tin, (4) leaded naval brass, 0.75% tin. See also **Copper**.

[a] Small amounts of zinc, lead, iron, antimony, and phosphorus also present.
[b] International Annealed Copper Standard.
[c] Free-cutting phosphor bronze.

Copper-nickel-tin alloys (UNS C72500, 2700, and 2900) are *spinodal*[1] materials that can be age hardened after forming. They combine tensile strengths as high as 1380 MPa (200×10^3 psi) with resistance to oxidation, stress relaxation, fatigue, and stress-corrosion cracking. For use in round-wire form, these alloys are challenging the traditional position held by phosphor bronzes for electronic leads, contact pins, and sockets. In flatwire form, they compete with beryllium copper for eyeglass frames, circuit boards, and electronic-contact clips. The alloys also have been used for rivets, self-threading screws, and a variety of cold-headed parts.

Tin Compounds. Tin, having valence of +2 and +4, forms stannous (tin(II)) compounds and stannic (tin(IV)) compounds. Tin compounds include inorganic tin(II) and tin(IV) compounds; complex stannites, $MSnX_3$, and stannates, M_2SnX_6, and coordination complexes, organic tin salts where the tin is not bonded through carbon, and organotin compounds, which contain one-to-four carbon atoms bonded directly to tin.

Of the large volume of tin compounds reported in the literature, possibly only ca 100 are commercially important. The most commercially significant inorganic compounds include stannic chloride, stannic oxide, potassium stannate, sodium stannate, stannous chloride, stannous fluoride, stannous fluoroborate, stannous oxide, stannous pyrophosphate, stannous sulfate, stannous 2-ethylhexanoate, and stannous oxalate. Also important are organotins of the dimethyltin, dibutyltin, tributyltin, dioctyltin, triphenyltin, and tricyclohexyltin families.

Inorganic Tin Compounds. Because of its amphoteric nature, tin reacts with strong acids and strong bases but remains relatively resistant to neutral solutions. A thin oxide film forms on tin exposed to oxygen or dry air at ordinary temperatures; heat accelerates this oxide formation. Tin is not attacked by gaseous ammonia even when heated. Chlorine, bromine, and iodine react with tin at normal temperatures, and fluorine reacts at 100 °C (212 °F), forming the appropriate stannic halides. Tin is easily attacked by hydrogen iodide and hydrogen bromide, but less readily by hydrogen chloride; it is weakly attacked by gaseous hydrogen fluoride, and it slowly dissolves in aqueous hydrochloric acid. Hot concentrated sulfuric acid reacts with tin, forming stannous sulfate, whereas dilute sulfuric acid reacts only slowly with tin at room temperature. Reaction of tin with dilute nitric acid yields soluble tin nitrates; in concentrated nitric acid, tin is oxidized to insoluble hydrated stannic oxide. No reaction occurs upon direct union of tin with hydrogen, nitrogen, or carbon dioxide.

If tin and sulfur are heated, a vigorous reaction takes place with the formation of tin sulfides. At 100–400 °C (212–752 °F), hydrogen sulfide reacts with tin, forming stannous sulfide; however, at ordinary temperatures no reaction occurs. Stannous sulfide also forms from the reaction of tin with an aqueous solution of sulfur dioxide. Molten tin reacts with phosphorus, forming a phosphide. Aqueous solutions of the hydroxides and carbonates of sodium and potassium, especially when warm, attack tin. Stannates are produced by the action of strong sodium hydroxide and potassium hydroxide solutions on tin. Oxidizing agents, eg, sodium or potassium nitrate or nitrite, are used to prevent the formation of stannites and to promote the reactions.

Stannic and stannous chloride are best prepared by the reaction of chlorine with tin metal. Stannous salts are generally prepared by double decomposition reactions of stannous chloride, stannous oxide, or stannous hydroxide with the appropriate reagents. Metallic stannates are prepared either by direct double decomposition or by fusion of stannic oxide with the desired metal hydroxide or carbonate. Approximately 80% of inorganic tin chemicals consumption is accounted for by tin chlorides and tin oxides.

Halides. The tin halides of the greatest commercial importance are stannous chloride, stannic chloride, and stannous fluoride. Tin halides of less commercial importance are stannic bromide [CAS: 7789-67-5], stannic iodide [CAS: 7790-47-8], stannous bromide [CAS: 10031-24-0], and stannous iodide [CAS: 10294-70-9].

[1] Spinodal structure is a fine homogeneous mixture of two phases that form by the growth of composition waves in a solid solution during suitable heat treatment. The phases of a spinodal differ in composition from each other and from the parent phase, but have the same crystal structure as the parent phase.

Stannous Chloride. Stannous chloride is available in two forms: anhydrous stannous chloride, $SnCl_2$, and stannous chloride dihydrate [CAS: 10025-69-1], $SnCl_2 \cdot 2H_2O$, also called tin crystals or tin salts. These forms are sometimes used interchangeably; however, where stability, concentration, and adaptability are important, anhydrous stannous chloride is preferred. Even after long storage, changes in the stannous tin content of anhydrous stannous chloride are extremely low. Physical properties of the tin chlorides are listed in Table 4.

TABLE 4. PHYSICAL PROPERTIES OF TIN CHLORIDES

Property	$SnCl_2$	$SnCl_2 \cdot 2H_2O$	$SnCl_4$	$SnCl_4 \cdot 5H_2O$
Mol wt	189.60	225.63	260.50	350.58
Mp, °C	246.8	37.7	−33	ca 56 dec
Bp, °C	623		114	
Density, at 25 °C, g/cm^3	3.95	2.63	2.23[a]	2.04

[a] At 20 °C.

Anhydrous stannous chloride, a water-soluble white solid, is the most economical source of stannous tin and is especially important in redox and plating reactions. Preparation of the anhydrous salt may be by direct reaction of chlorine and molten tin, heating tin in hydrogen chloride gas, or reducing stannic chloride solution with tin metal, followed by dehydration. It is soluble in a number of organic solvents (g/100 g solvent at 23 °C (73.4)): acetone 42.7, ethyl alcohol 54.4, methyl isobutyl carbinol 10.45, isopropyl alcohol 9.61, methyl ethyl ketone 9.43; isoamyl acetate 3.76, diethyl ether 0.49, and mineral spirits 0.03; it is insoluble in petroleum naphtha and xylene.

Anhydrous stannous chloride is used extensively in the plating industry, eg, in the high speed electrotinning of continuous strip steel by the halogen process involving an aqueous solution of stannous chloride and alkali–metal fluorides, in a variety of formulations in immersion tinning processes, and in tin alloy plating. See also **Electroplating**. The strongly reducing nature of this chloride has contributed to its commercial development and success. Established applications of this property include its use as an analytical reducing reagent, a reducing agent in inorganic and organic chemicals manufacture and in the photoleaching of dyes, and as a sensitizing agent for nonconductive surfaces before silver coating or other metallization processes. Originally, surface sensitization with stannous chloride solutions was used only on glass prior to silvering. It has come to be used to sensitize plastics prior to their electroless coating with metals, eg, nickel or copper.

Stannous chloride is also used as a food additive, for which use it has FDA GRAS approval. Other approvals include its use as a preservative for canned soda water, a color-retention agent in canned asparagus, and a component in food-packaging materials. It catalyzes a variety of organic reactions, eg, condensation, curing of resins and rubbers, esterification, halogenation, hydrogenation, oxidation, polymerization, hydrocarbon conversion, etc. Minor applications include the use of stannous chloride as an additive to drilling muds, an antisludge agent for oils, in tin coating of sensitized paper, and to improve the dyeing fastness of synthetic fibers, eg, polyamides. See also **Petroleum**.

Stannous Chloride Dihydrate. A white crystalline solid, stannous chloride dihydrate is prepared either by treatment of granulated tin with hydrochloric acid followed by evaporation and crystallization or by reduction of a stannic chloride solution with a cathode or tin metal followed by crystallization. It is soluble in methanol, ethyl acetate, glacial acetic acid, sodium hydroxide solution, and dilute or concentrated hydrochloric acid. It is soluble in less than its own weight of water, but with much water it forms an insoluble basic salt.

Stannic Chloride. Stannic chloride is available commercially as anhydrous stannic chloride, $SnCl_4$ (tin(IV) chloride); stannic chloride pentahydrate, $SnCl_4 \cdot 5H_2O$; and in proprietary solutions for special applications. Anhydrous stannic chloride, a colorless fuming liquid, fumes only in moist air, with the subsequent hydrolysis producing finely divided hydrated tin oxide or basic chloride. It is soluble in water, carbon tetrachloride, benzene, toluene, kerosene, gasoline, methanol, and many other

organic solvents. With water, it forms a number of hydrates, of which the most important is the pentahydrate. Although stannic chloride is an almost perfect electrical insulator, traces of water make it a weak conductor.

The main uses of stannic chloride are as a raw material for the manufacture of other tin compounds, especially organotins, and in the surface treatment of glass and other nonconductive materials, whereby deposition of stannic oxide from stannic chloride solutions onto the nonconductive substrate gives it strength, abrasion-resistance, and conductivity. Very thin stannic oxide films (less than 100 nm thick) are thus used to strengthen glassware for returnable and nonreturnable foodstuff bottles and jars and for restaurant and catering glasses, which are subject to rigorous use. Glass treated in this way can also be made considerably lighter, which is advantageous to packing, shipping, and handling. The process involves passing freshly formed glassware through an oven maintained in an atmosphere containing stannic chloride vapor. The chloride breaks down, leaving at the glass temperature a stannic oxide deposit on the glass surface. See also **Glass**.

Where electrical conductivity and optical transparency are required, thicker (greater than 1 μm) films of stannic oxide are necessary. Such treated glasses are used in low intensity lighting panels and display signs, fluorescent lights, electron-beam control in cathode-ray tubes, and deicing windshields in aircraft. The deposition of stannic oxide films on glass surfaces is accomplished by the decomposition of stannic chloride vapor at 500–600 °C and depositing it onto the glass surface or by spraying it from aqueous or mixed-organic solutions.

Stannic Chloride Pentahydrate. Stannic chloride pentahydrate [CAS: 10026-06-9] is a white, crystalline, deliquescent solid that is soluble in water or methanol and stable at 19–56 °C (66–133 °F). It is used in place of the anhydrous chloride where anhydrous conditions are not mandatory. It is easier to handle than the fuming anhydrous liquid form. The pentahydrate is prepared by dissolving stannic chloride in hot water, thereby forming the pentahydrate at a temperature above the melting point and crystallizing by cooling. The cake is broken into small lumps for packaging. A stannic chloride pentahydrate–ammonium bifluoride formulation for fireproofing wool is commercially available and used in New Zealand and Australia.

Stannous Fluoride. Stannous fluoride [CAS: 7783-47-3] (tin(II) fluoride), mol wt 156.7, mp 219.5 °C (427.1 °F), occurs as opaque, white, lustrous crystals, which are soluble in potassium hydroxide, fluorides, and water (31 g/100 g H_2O at 0 °C (32 °F), 78.5 g/100 g H_2O at 106 °C (222.8 °F)) and practically insoluble in methanol, ether, and chloroform. Dilute aqueous solutions hydrolyze unless stabilized with excess acid. The specific gravity of a saturated aqueous solution at 25 °C (77 °F) is 1.51. Commercially, stannous fluoride is produced by the reaction of stannous oxide and aqueous hydrofluoric acid or by dissolving tin in anhydrous or aqueous hydrofluoric acid. The principal commercial use of stannous fluoride is in toothpaste formulations and other dental preparations, eg, topical solutions, mouthwash, chewing gum, etc, for preventing demineralization of teeth.

Oxides

Stannous Oxide Hydrate. Stannous oxide hydrate [CAS: 12026-24-3], $SnO \cdot H_2O$ (sometimes erroneously called stannous hydroxide or stannous acid), mol wt 152.7, is obtained as a white amorphous crystalline product on treatment of stannous chloride solutions with alkali. It dissolves in alkali solutions, forming stannites. The stannite solutions, which decompose readily to alkali-metal stannates and tin, have been used industrially for immersion tinning.

Stannic Oxide. Stannic oxide tin(IV) oxide, white crystals, mol wt 150.69, mp > 1600 °C (2912 °F), sp gr 6.9, is insoluble in water, methanol, or acids but slowly dissolves in hot, concentrated alkali solutions. In nature, it occurs as the mineral cassiterite. It is prepared industrially by blowing hot air over molten tin, by atomizing tin with high pressure steam and burning the finely divided metal, or by calcination of the hydrated oxide. Other methods of preparation include treating stannic chloride at high temperature with steam, treatment of granular tin at room temperature with nitric acid, or neutralization of stannic chloride with a base.

In the ceramics and glass industries, stannic oxide is used for the production of opaque glasses; as an opacifier for glazes and, to a lesser extent, enamels for metals (eg, cast iron) as used in bathtubs, sinks, tile, and other sanitary ware; as a base for certain ceramic colors, eg, chrome–tin pink, vanadium–tin yellow, and antimony–tin blue; and as a component of ceramic capacitor dielectrics. More than 15 large glass-melting furnaces in the world use stannic oxide electrodes in the electromelting of lead glass. See also **Ceramics**. Other important uses of stannic oxide are as a putty powder for polishing marble, granite, glass, and plastic lenses and as a catalyst.

Metal Stannates. Many metal stannates of formula $M_nSn(OH)_6$ are known. The two main commercial products are the soluble sodium and potassium salts, which are usually obtained by recovery from the alkaline detinning process. They are also produced by the fusion of stannic oxide with sodium hydroxide or potassium carbonate, respectively, followed by leaching and by direct electrolysis of tin metal in the respective caustic solutions in cells using cation-exchange membranes. Another route is the recovery from plating sludges.

Potassium stannate, $K_2Sn(OH)_6$ (mol wt 298.93), and sodium stannate [CAS: 12058-66-1], $Na_2Sn(OH)_6$, mol wt 266.71, are colorless crystals and are soluble in water. The solubility of potassium stannate in water is 110.5 g/100 mL water at 15 °C (59 °F) and that of sodium stannate is 61.5 g/100 mL water at 15 °C. The solubility of sodium stannate decreases with increasing temperature, whereas the solubility of potassium stannate increases with increasing temperature. The solubility of either sodium or potassium stannate decreases as the concentration of the respective free caustic increases. Hydrolysis of stannates yields hydrated stannic oxides and is the basis of the Tin Sol solution, which is used to replenish tin in stannate tin-plating baths.

Although sodium stannate formed the basis for the first successful alkaline tin-electroplating bath, both stannates are used in these baths, with potassium stannate being favored in the United States. Potassium stannate is used for an alkaline tin-electroplating bath yielding higher cathode efficiencies and higher conductivities than any other alkaline bath. The stannates are also used in immersion tinning, particularly the immersion plating of aluminum pistons and other parts for the automotive industry, and in the electroplating of alloy coatings, especially tin–zinc and tin–copper alloys from mixed stannate–cyanide baths.

Other. Insoluble alkaline-earth metal and heavy metal stannates are prepared by the metathetic reaction of a soluble salt of the metal with a soluble alkali–metal stannate. They are used as additives to ceramic dielectric bodies. The use of bismuth stannate [CAS: 12777-45-6], $Bi_2(SnO_3)_35H_2O$, with barium titanate produces a ceramic capacitor body of uniform dielectric constant over a substantial temperature range. Other typical commercially available stannates are barium stannate [CAS: 12009-18-6], $BaSnO_3$; calcium stannate [CAS: 12013-46-6], $CaSnO_3$; magnesium stannate [CAS: 12032-29-0], $MgSnO_3$; and strontium stannate [CAS: 12143-34-9], $SrSnO_3$.

Salts. *Stannous sulfate* (tin(II) sulfate), mol wt 214.75, $SnSO_4$, is a white crystalline powder which decomposes above 360 °C (680 °F). Because of internal redox reactions and a residue of acid moisture, the commercial product tends to discolor and degrade at ca 60 °C (140 °F). It is soluble in concentrated sulfuric acid and in water (330 g/L at 25 °C (77 °F)). The solubility in sulfuric acid solutions decreases as the concentration of free sulfuric acid increases. Stannous sulfate can be prepared from the reaction of excess sulfuric acid (specific gravity 1.53) and granulated tin for several days at 100 °C (212 °F) until the reaction has ceased. Stannous sulfate is extracted with water and the aqueous solution evaporates *in vacuo*. Methanol is used to remove excess acid. It is also prepared by reaction of stannous oxide and sulfuric acid and by the direct electrolysis of high grade tin metal in sulfuric acid solutions of moderate strength in cells with anion-exchange membranes.

The main use for stannous sulfate is in tin plating. The sulfate bath is widely used commercially for general plating, especially barrel plating. Significant tin-plating processes involving stannous sulfate baths include flow melting, ie, momentarily melting the coating to attain a bright finish on tin or tin–lead alloy deposits, which is used primarily in the production

of printed circuit boards; bright-acid tin plating, which is used in finishing electrical contacts, radio chassis, domestic articles, and kitchen utensils; electrotinning steel strip by the vertical acid process, and liquor finishing, ie, immersion plating of steel wire with tin or copper–tin alloy prior to drawing.

Stannous Fluoroborate, $Sn(BF_4)_2$, is available only in solution, as the solid form has not been isolated. It is prepared by dissolving stannous oxide in fluoroboric acid or by direct electrolysis of tin metal in fluoroboric acid in cells with anion-exchange membranes. The commercially available 47-wt % solution is widely used in tin and tin–lead alloy plating, especially in the deposition of tin–lead solder alloys for the electronics industry. Stannous fluoroborate solutions are important in plating because of their good throwing and covering power and high solubility, which promote high rates of deposition. They are used in the tin plating of copper wire, backing of electrotypes, and barrel tin plating of components for subsequent soldering.

Stannous pyrophosphate, [CAS:15578-26-4], $Sn_2P_2O_7$, mol wt 411.32, sp gr 4.009 at 16 °C (60.8 °F), is an amorphous white powder, decomposing at above 400 °C. It is insoluble in water and soluble in concentrated mineral acids and sodium pyrophosphate. It is prepared from stannous chloride and sodium pyrophosphate, and used as a caries preventative in toothpaste and as a diagnostic aid in radioactive bone scanning and red-blood-cell labeling.

Health and Safety Factors. Inorganic tin and its compounds are generally of a low order of toxicity, largely because of the poor absorption and rapid excretion from the tissues of the metal. The acidity and alkalinity of their solutions make assessment of their parenteral toxicity difficult. U.S. daily intake of tin, which is mostly from processed foods, is 4 mg. Tin may be an essential trace element for the growth of the mammalian organism. Many inorganic tin compounds have been approved for human contact or use by the FDA. See also **Mineral Nutrients**.

Organotin Compounds. Five classes of organotin compounds are known: R_4Sn (tetraorganotins), R_3SnX (triorganotins), R_2SnX_2 (diorganotins), $RSnX_3$ (monoorganotins), and R_6Sn_2 (hexaorganoditins). Of commercial importance are those organotins where R is methyl, butyl, octyl, cyclohexyl, phenyl, or β- β-dimethylphenethyl (neophyl). The noncarbon-bonded anionic group is commonly halide, oxide, hydroxide, carboxylate or mercaptide.

It was not until the 1940s that the commercial potential of organotins was realized. Organotins first were used as stabilizers for poly(vinyl chloride), which is normally processed just below its decomposition temperature. The high biocidal activity of the triorganotins is one of the most applied areas of their usefulness. In addition, organotins are widely used as catalysts and curing agents and in the treatment of glass.

Tetraorganotin Compounds. These compounds are insoluble in water but are soluble in many organic solvents. Physical properties of typical tetraorganotin compounds are shown in Table 5.

The most important reactions which tetraorganotins undergo are heterolytic, ie, electrophilic and nucleophilic, cleavage and Kocheshkov redistribution. The tin–carbon bond in tetraorganotins is easily cleaved by halogens, hydrogen halides, and mineral acids:

$$R_4Sn + Br_2 \rightarrow R_3SnBr + RBr$$

$$R_3SnBr + Br_2 \rightarrow R_2SnBr_2 + RBr$$

$$R_4Sn + HCl \rightarrow R_3SnCl + RH$$

$$R_3SnCl + HCl \rightarrow R_2SnCl_2 + RH$$

The most widely utilized reaction of tetraorganotins is the Kocheshkov redistribution reaction, by which the tri-, di-, and in some cases the monoorganotin halides can be readily prepared:

$$R_4Sn + SnCl_4 \rightarrow 2R_2SnCl_2$$

$$R_2SnCl_2 + H_4Sn \rightarrow 2R_3SnCl$$

$$3R_4Sn + SnCl_4 \rightarrow 4R_3SnCl$$

$$R_4Sn + 3SnCl_4 \rightarrow 4RSnCl_3$$

The main use for tetraorganotin compounds is as (usually captive) intermediates for the tri-, di-, and monoorganotins. Application as Ziegler-Natta-type catalysts has been reported. See also **Olefin Polymers**.

Triorganotin Compounds. Physical properties of some typical triorganotin halides are listed in Table 6 and those of commercially important triorganotin compounds are listed in Table 7. The triorganotin halides are insoluble in water, except for $(CH_3)_3SnCl$ which is completely water soluble, but are soluble in most organic solvents. The fluorides are insoluble in most organic solvents because of their highly associated structure resulting from strong SnF–Sn interactions.

The utility of triorganotin chlorides and their application as starting materials for most other triorganotin compounds results from the ease of nucleophile displacement. They are generally prepared by Kocheshkov redistribution. Tribenzyltin chloride [CAS: 3151-41-5] is a unique example of a triorganotin chloride that can be prepared directly from the organic halide and tin metal.

Triorganotin compounds are widely used as industrial biocides, agricultural chemicals, wood preservatives, and marine antifoulants. The triorganotins that are most useful as biological control agents, in general, are the tributyltins, triphenyltins, and tricyclohexyltins. Tributyltin compounds, especially the oxide and benzoate, are used as antimicrobials and slimicides for cooling-water treatment and as hard-surface disinfectants. These and similar compounds have been used as laundry sanitizers and mildewcides to prevent mildew formation in the dried film of water-based emulsion paints. In most microbiocide applications, the tributyltin compound is used in conjunction with another biocide, usually a quaternary ammonium compound, to complement the activity of the organotin which is most effective against gram-positive bacteria.

Tricyclohexyltin hydroxide was introduced into the U.S. market by the Dow Chemical Company as Plictran. Plictran was originally recommended for the control of phytophagous (plant-feeding) mites on apples and pears. It is also registered in the United States and in many European and Asian countries for this use as well as for mite control on citrus, stone fruits, and hops. This product has since been joined in the market by similar-acting,

TABLE 5. PHYSICAL PROPERTIES OF TYPICAL TETRAORGANOTIN COMPOUNDS

competitive products marketed by Shell and Bayer. Other triorganotin compounds with significant agricultural uses are tricyclohexyltin hydroxide (Plictran, Dow Chemical), and hexaneophyldistannoxane (Vendex, Shell U.S.A.; Torque, Shell International Chemical).

Bis(tributyltin) oxide [CAS: 56-35-9] is widely used in Europe for the preservation of timber, millwork, and wood joinery, eg, window sashes and door frames. It is applied from organic solution by dipping or vacuum impregnation. It imparts resistance to attack by fungi and insects but is not suitable for underground use. An advantage of bis(tributyltin) oxide is that it does not interfere with subsequent painting or decorative staining and does not change the natural color of the wood. Eroding antifouling paints that are based on tributyltin acrylate [CAS: 13331-52-7] or methacrylate [CAS: 2155-70-6] copolymers with various organic acrylate esters as the combined toxicant and paint binder resin. Triorganotin compounds have also been used experimentally in controlled-release formulations to control the infective snail vector in the debilitating tropical disease schistosomiasis (bilharzia) and to control mosquitoes in stagnant ponds.

Diorganotin Compounds. Physical properties of some typical diorganotin compounds are shown in Table 8. The diorganotin chlorides, bromides, and iodides are soluble in many organic solvents and, except for dimethyltin dichloride, are insoluble in water.

Commercial grades of diorganotin carboxylates frequently have wider melting ranges because of the use of less pure grades of carboxylic acids in their manufacture which, for many applications, permits more facile handling of the liquids.

Diorganotin dichlorides are the usual precursors for all other diorganotin compounds; three primary methods of manufacture are practiced. Dibutyltin dichloride is manufactured by Kocheshkov redistribution from crude tetrabutyltin and stannic chloride and usually is catalyzed with a few tenths of a percent aluminum trichloride:

$$(C_4H_9)_4Sn + SnCl_4 \rightarrow 2(C_4H_9)_2SnCl_2$$

Many organic halides, especially alkyl bromides and iodides, react directly with tin metal at elevated temperatures. Methyl chloride reacts with molten tin metal, giving good yields of dimethyltin dichloride, which is an important intermediate in the manufacture of dimethyltin-based PVC stabilizers. Tin metal also reacts directly with a number of activated organic halides, including allyl bromide, benzyl chloride, chloromethyl methyl ether, and β-halocarboxylic esters and nitriles giving fair-to-good yields of diorganotin dihalides.

The largest single industrial application for organotin compounds is in the stabilization of PVC. Dialkyltin compounds are the best general-purpose stabilizers for PVC, especially if colorlessness and transparency are required. Commercial organotin stabilizers include the carboxylates, especially the maleates, laurates, and substituted maleates; the mercaptide, the mercaptoacid, and mercaptoalcohol ester derivatives; and the estertins, 2-carboalkoxyethyltin derivatives.

Sulfur-containing organotins impart excellent heat stability to PVC, but nonsulfur-containing organotins are used when resistance to light and weathering are required. The two main markets for organotin stabilizers are in the packaging and building industries. In the packaging industry, certain organotin stabilizers are used in PVC food packaging and drink containers. In the United States and Germany, dioctyltin maleate [CAS: 16091-18-2], dioctyltin bis(isooctylmercaptoacetate), and butylthiostannoic acid [CAS: 26410-42-4] are approved for use in PVC food packaging; in Germany, dimethyltin bis(isooctylmercaptoacetate), 2-carbobutoxyethyltin tris(isooctylmercaptoacetate) [CAS: 63438-80-2], and bis(2-carbobutoxyethyltin) bis(isooctylmercaptoacetate) are also approved. These uses reflect the low toxicity of these organotin stabilizers.

In the building industry, rigid PVC is stabilized with diorganotin carboxylates, especially dibutyltin maleate, for use in floorings and light fixture glazing and with diorganotin mercaptides and mercaptoacid esters for use in sidings, profiles, roofing, fencing, window frames, and piping. The dibutyltin, dimethyltin, and estertin sulfur-containing

TABLE 8. PHYSICAL PROPERTIES OF DIORGANOTIN COMPOUNDS

Compound	CAS Registry Number	Mp, °C	Bp, °C		d^{20}, g/cm^3

[a] To convert kPa to mm Hg, multiply by 7.5.
[b] At 25 °C.

derivatives are used for these nonfood applications as well as in PVC potable-water piping. Dibutyltin compounds as well as monobutyltins are used increasingly as esterification catalysts for the manufacture of organic esters used in plasticizers, lubricants, and heat-transfer fluids. See also **Plasticizers**. Dibutyltin and dioctyltin diacetate, dilaurate, and di-(2-ethylhexanoate) are used as catalysts for the curing of room-temperature-vulcanized (RTV) silicone elastomers to produce flexible silicone rubbers used as sealing compounds, insulators, and in a wide variety of other applications. Diorganotin carboxylates also catalyze the curing of thermosetting silicone resins, which are widely used in paper-release coatings.

Monoorganotins. The monoorganotin trihalides are strong Lewis acids and form complexes with ammonia, amines, and many other oxygenated organic compounds, eg, ethers. In many ways, they resemble acid chlorides. Monoorganotin halides are the basic raw materials for all other triorganotin compounds and are generally prepared by Kocheshkov redistribution from the tetraorganotin, eg, tetrabutyltin or the higher organotin halides:

$$R_4Sn + 3SnCl_4 \rightarrow 4RSnCl_3$$

$$R_2SnCl_2 + SnCl_4 \rightarrow 2RSnCl_3$$

Although generally less effective as PVC stabilizers than dialkyltin derivatives, monoalkyltin compounds added to the dialkyltin compounds in amounts of 5–20 wt % exert a synergistic effect on stabilizer effectiveness, preventing early yellowing. The use of monobutyltin trichloride in the hot-end coating of glass to improve the abrasion resistance and bursting strength of glass bottles has been patented, and the deposition process variables and product advantages have been described. Highly efficient utilization of tin is one of the main benefits.

Biochemical Aspects of Tin. Scientists at the University of Maryland have found that sediment microflora (from Chesapeake Bay sediments) can produce dimethyltin and trimethyltin species from inorganic Sn(IV) compounds. The results were consistent with a geocycle of tin proposed by Ridley et al. in 1977. The findings support the hypothesis that tin can be biotransformed in an estuarine environment.

Researchers J. Versieck and L. Vanballenberghe (University Hospital, Ghent, Belgium) have observed, "Tin has chemical properties offering potentials for a biological function. The element has a tendency to form truly covalent linkages as well as coordination complexes; hence, it was hypothesized that it could well contribute to the tertiary structure of proteins or other biologically important macromolecules, such as nucleic acids. The oxidation-reduction potential of $Sn^{2+} \leftrightarrows Sn^{4+}$ being at 0.13 V, well within the range of physiological oxidation-reduction reactions, it was also speculated that the element could function as the active site of metalloenzymes."

During the late 1960s, several experiments led to the conclusion that tin was indispensable for the growth of rats fed purified amino acid diets in trace-element-controlled isolators. However, no additional evidence for biological essentiality has been added since that time. Information on the tin content of foods is meager. Estimates have shown that the intake is less than 1 milligram per day. However, because of contamination from packaging, it has been estimated that this figure occasionally could rise to 50 mg/day. The aforementioned researchers have developed what appears to be a reliable method for determining tin in human blood serum by radiochemical neutron activation analysis.

TINAMIFORMES. An order of ground birds (*Aves*) with a compact form, a slender neck, a relatively narrow head, and a rather short beak which is slender and curves slightly downward. Their wings are short and hence their capacity for flight is poor. Their feet are strong, with only three well developed forward toes; the hind toe is located in a high position, being either retrogressed or absent. The tail is very short, and in a few species it is hidden under the tail coverts; this and the abundant rump feathering cause the rounded body shape. The length is 20–53 centimeters (7.9–21 inches), and the weight is 450–2300 grams (1–5 pounds).

They live in tropical parts of South America; in the north they live only slightly beyond the Tropic of Cancer (Zimttao in northwest Mexico), but in the south they are widely distributed in the temperate zone. They inhabit varied habitats: rainforest, thickets, bushland, tree steppes, and treeless grassland up to an altitude of 5,000 meters (16,405 feet).

With their beautiful, moving songs, their magnificent eggs, and their unusual family life it is unfortunate that they are so shy, which is partly because they are constantly hunted for their tasty meat. See also **Tinamous (Tinamidae)**.

TINAMOUS *(Tinamidae)*. In older natural history books, the description of the birds generally began with the ratites, including the rheas, ostriches, cassowaries, kiwis, and the extinct moas and elephant birds of Madagascar. Since these large, flightless birds have no keel on the sternum, which is otherwise characteristic of birds, they are known as flat-chested birds (ratites) in contrast to all the other modern birds, which are keel-breasted (*Carinatae*). Today we know that the ratites descended from flying, keel-breasted ancestors. The tinamous (*Tinamidae*) are a living primitive bird family which are close to the ancestral group of the ratites and particularly to the nandus (rheas). The tinamous used to be classified with gallinaceous birds, because externally they resemble guinea fowl. Because of their relationship to the ratites, they are today considered a separate order, *Tinamiformes*. See also **Tinamiformes**.

There are 9 genera with 43 species, divided into 2 subfamilies: (a) the Woodland Tinamous (*Tinaminae*) and (b) the Steppe-Tinamous (*Rhynchotinae*).

The Woodland Tinamous have connected nostrils in the middle of the beak or before it. There are 3 genera, which are distinguished by the back of their tarsometatarsus: (1) The genus Rough Taos (*Tinamus*) contains the following species: the Great Tinamou (*Tinamu major*) and Gray Tinamou (*Tinamus tao*); (2) Scaly Taos (*Nothocercus*): Bonaparte's Tinamou (*Nothocercus bonapartei*) and the Black-Capped Tinamou (*Nothocercus nigracapillus*); (3) the genus Smooth Tinamous (*Crypturellus*) has many species, among them the Little Tinamou (*Crypturellus soui*), the Variegated Tinamou (*Crypturellus variegatus*), the Brushland Tinamou (*Crypturellus cinnamomeus*), the Slaty-Breasted Tinamou (*Crypturellus boucardi*), and Tatupa (*Crypturellus tataupa*).

The Steppe-Tinamous have nostrils which are connected at the base of the beak. There are 6 genera: (1) the Red-Winged Tinamou with one species, the Red-Winged Tinamou (*Rhynchotus rufescens*); this bird is hunted in the pampas as a "partridge substitute;" (2) the Crested Tinamous (*Eudromia*); among them is the martineta Tinamou (*Eudromia elegans*; Fig. 1), which has no hind toe; (3) the Puna Tinamou (*Tinamotis pentlandii*; Fig. 1); (4) the Partridge Tinamous (*Nothoprocta*) comprise many species, among them the Ornate Tinamou (*Nothoprocta ornata*) and *Nothoprocta cinerascens*; (5) the Quail Tinamous (*Nothura*) comprise many species, among them the Spotted Tinamou (*Nothura maculosa*); (6) the Peacock Tinamous, with only one species (*Taoniscus nanus*), found in southeast Brazil and northeast Argentina; the upper tail coverts of this species are extended into a train.

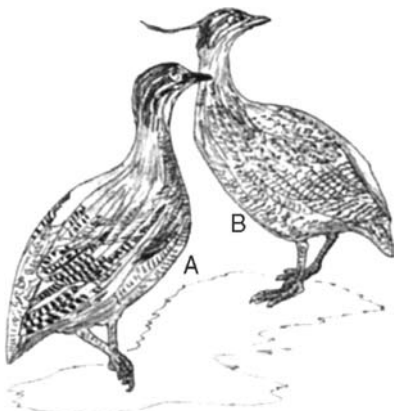

Fig. 1. Tinamous: (A) Puna (Tinamotis pentlandii), (B) Martineta (Eudromia elegans). (Sketch by Glenn D. Considine)

Walking or running, the tinamous move almost exclusively on the ground. When approached by man, they hide in thick ground cover or steal away unobserved. When they are hard-pressed in open country, they often crawl into holes which another animal has dug. Some species are very reluctant to fly. But when surprised by a larger animal or when followed too closely, they rise suddenly with loud frightening wing beats, and often they call. They disappear swiftly and alight in thick vegetation. The effectiveness of this escape behavior is evident from the fact that one of the largest species, the great tao, can still be found in forests in which men and dogs have exterminated all other large birds.

Tinamous eat mainly small fruits and seeds. They pick them from the ground or from the plants they can reach from the ground; sometimes they jump up about 10 centimeters (4 inches) to reach a particularly tempting fruit. Seeds with winglike appendages, which make swallowing difficult, are beaten against the ground or vigorously shaken in order to remove them. The tinamous also eat opening buds, tender leaves, blossoms, and even roots. For variety they catch insects and their larvae, worms, and, in moist places, mollusks. They swallow small animals whole; they first peck at larger ones, then shake them or beat them against the ground. When searching for food, they scatter fallen leaves and other ground cover aside with their beaks, but they do not scratch with their feet. When searching for worms or larvae in moist places, brushland tinamous and probably other species fling the earth aside with their beaks, digging 2–3 centimeters ($\frac{3}{4}$–1 inch) deep. Like many other birds, they swallow small stones and grains of sand. Those species living in deserts drink either very rarely or not at all.

Hearing the calls made by tinamous is one of the most unforgettable experiences. Although the calls or songs of many species are simple, the purity and softness of their tones are attained only by a few birds. In several species the songs sound like organ tones, while others are flutelike whistles or trills that have a melancholy quality. The tones of the song sometimes have the same pitch, but in some species they may rise, and in others they rise and fall again. In contrast to most tinamous, the male Bonaparte's

tinamou utters a rough crowing or barking call, which can be heard for several kilometers through the mountain forests. In some species, males and females can be readily distinguished by their calls. Tinamous sing mainly during the breeding season; they are noisiest in the early morning and late evening. When startled tinamous fly off or follow one another, they shriek or crow hoarsely.

Most adult tinamous live singly except during the reproductive season. The Martineta tinamous form strings of 6 to 30 or more birds. Reproductive behavior differs from that of most other birds. Only the males care for the eggs and young. So far no exception to this rule is known. In the few species that have been adequately studied, the males live in polygyny and the females in polyandry. A male in breeding condition attracts 2, 3 or even more females by continuously calling. They all lay their eggs in the same nest and then leave their incubation to the male. When the male has raised his young or has lost the eggs, he begins to call again and attracts new hens, which then supply him with another nest full of eggs. This breeding behavior has been observed in such different species as Bonaparte's tinamou, the brushland tinamou and the slaty-breasted tinamou. The variegated tinamou, however, cares for only a single egg.

The shiny tinamou eggs are among the most beautiful natural products known. They may be green, turquoise-blue, purple, wine-red, slate gray, or a chocolate color, and they often have a purple or violet luster. They are always uniformly colored without spots or blotches. Their shape is oval or elliptical.

Incubating male tinamous sit continuously on the eggs for many hours. In most species, they leave the clutch only once a day to look for food. These excursions are undertaken during the mornings or in the afternoon, depending upon the weather; they last from 45 minutes up to 4 or 5 hours.

Newly hatched tinamous are densely covered with long soft down which in some species is marked in dulled colors. On the first day after hatching, the male leads the young out of the nest, moving slowly and calling the young with repeated soft whistles or whining tones. On leaving the nest the chicks of the smaller tinamous are very delicate but move so skillfully and well-hidden through the dense vegetation that little is known about their lives after they leave the nest. They develop rapidly and soon differ little in color and size from the adults.

TINTOMETER. A type of colorimeter, in which the intensity of color, and hence the concentration of the colored substance in a colored solution, is determined by comparison with colored glass slides or standard solutions.

TISELIUS, ARNE W. K. (1902–1971). A Swedish biochemist who won the Nobel Prize for chemistry in 1948, for his research on electrophoresis and adsorption analysis, especially for his discoveries concerning the complex nature of the serum proteins. His work also involved virus isolation and synthesis of blood plasma. He earned degrees from the University of Uppsala and Princeton University, as well as a multitude of honorary degrees.

TISSUE. An aggregation of cells of characteristic form together with their intercellular matrix, specialized for the performance of some limited function or functions. All cells of the multicellular animal body take part in the formation of tissues, and tissues in turn are to a great extent incorporated in organs. The cells in a tissue may be alike, or several kinds may be present, and in some tissues the cells are supplemented by a conspicuous bulk of intercellular materials.

Animal tissues are divided into five classes: epithelial, muscular, nervous, connective, and vascular.

Plant tissues are: conducting, supporting, protective, food producing, food storage, and embryonic or meristematic.

TISSUE ENGINEERING. Within a biomedical context, the term "tissue engineering" points naturally to a central concept that is simple, powerful and intuitive: the creation of living tissues for therapeutic purposes. Tissue engineering (TE) represents the confluence of a complex array of pre-existing lines of work from three quite different domains: the worlds of clinical medicine, engineering, and science. Probably the first definition of tissue engineering was by Langer and Vacanti who stated it to be "an interdisciplinary field that applies the principles of engineering and life sciences toward the development of biological substitutes that restore, maintain, or improve tissue function". MacArthur and Oreffo defined tissue engineering as "understanding the principles of tissue growth, and applying this to produce functional replacement tissue for clinical use." A further description goes on to say that an "underlying supposition of tissue engineering is that the employment of natural biology of the system will allow for greater success in developing therapeutic strategies aimed at the replacement, repair, maintenance, and/or enhancement of tissue function." These more general definitions are driven in part by recent scientific progress with completely autologous approaches.

While the semi-official definitions of tissue engineering cover a broad range of applications, in practice the term has come to represent applications that repair or replace structural tissues (i.e., bone, cartilage, blood vessels, bladder, etc). These are tissues that function by virtue of their mechanical properties. A closely related (and older) field is Cell Transplantation. This field is concerned with the transplantation of cells that perform a specific biochemical function (e.g., a Bioartificial Pancreas, or a Bioartificial Liver). The term Regenerative Medicine is often used synonymously with Tissue Engineering, although those involved in Regenerative Medicine place more emphasis on the use of Stem Cells to produce tissues.

Accidents and diseases lead to devastating tissue losses and organ failures, which result in more than 8 million surgical operations each year in the United States alone. These problems convert to a national annual healthcare cost of approximately half trillion U.S. dollars. The state-of-the-art clinical therapies to tissue losses and organ failures can be categorized into three approaches, ie, transplantation, surgical reconstruction, and the use of prostheses. Each of these approaches has contributed to solving or alleviating the severity of these clinical problems, while all of them have serious limitations.

Organ transplantation became successful in the early 1960s because of the success of immunologic suppression in the clinical setting. Transplantation has saved, and is continuing to save, countless lives. This approach, however, is severely limited by the dearth of donor organs. For example, fewer than 3000 available donors are way shorter than the needs of approximately 30,000 Americans for liver transplants each year. Surgical reconstruction utilizes tissues harvested from the patient to rebuild a critically needed body part. The use of the patient's own tissue is advantageous in that it has a higher success rate resulting from the avoidance of immune rejection than using tissues from other sources. However, the need for second site of surgery, limited supply, inadequate size and shape, and the morbidity associated with donor site are all major concerns. In response to the shortages of needed tissues and organs, prostheses are developed to replace certain body parts for their structural and mechanical functions.

There are approximately 100,000 people in the United States with transplants, while there are more than 10,000,000 with biomedical implants. However, the prostheses are made from artificial materials, are not biologically functional, and are therefore subject to long-term complications and rejections.

In 2003, the NSF published a report titled "The Emergence of Tissue Engineering as a Research Field", which gives a thorough description of the history of this field. http://www.nsf.gov/pubs/2004/nsf0450/start.htm

Tissue engineering is a new approach to resolve the missing tissue and organ problems. There are three strategies in tissue engineering: (1) the use of isolated cells or cell substitutes to replace those cells that supply the needed function, including genetic or other manipulations before the cell infusion. (2) The delivery of tissue-inducing substances, such as growth and differentiation factors, to targeted locations. (3) Growing cells in three-dimensional (3-D) matrices (scaffolds) or devices, where cells can be either recruited from the host tissues *in vivo* or seeded (encapsulated) *in vitro.*

The advantage of the use of isolated cells is the simplicity. Cells are often directly injected into the targeted locations to avoid complex procedures and associated complications. The disadvantages include cell death and loss of function because cells need the right nutritional and substrate environment to grow and function. The success of using tissue-inducing substances is dependent on the economical large-scale production and purification of the bioactive molecules, and on the development of delivery systems that can deliver these molecules with the desired profiles. Certain gene therapy techniques can also be used for this approach. The above two approaches, ie, the use of isolated cells or tissue-inducing substances, are considered when the defects are very small and well contained. For engineering tissues of practical size scale and with predetermined 3-D structures, these two approaches are seriously limited. Therefore, the third approach, ie, growing cells in 3-D matrices (scaffolds) or devices, has become increasingly active.

Some of these matrices or devices are used to develop immobilized cell systems, either as implants or extracorporeal devices. The core of this technology is semipermeable membranes or matrices that have well-defined molecular weight or size cutoff. They serve as immunoprotective barriers to support cell growth and function, which allow nutrients, metabolic products, and wastes to diffuse through, but not immune cells or antibodies. These devices offer certain biological functions but are not living tissue/organ replacements. Some other 3-D matrices work as templates (called scaffolds) to guide cells to grow, synthesize biological molecules and extracellular matrix components, and facilitate the organization and formation of functional tissues and organs. After fulfilling the templating function, the scaffolds degrade and disappear, leaving nothing foreign to the biological system. See Fig. 1. There are many additional advantages in this approach. Patient-derived cells (stem cells or differentiated cells) or future universal cell sources (nonimmunogenic) can be used so that there will be minimum complication associated with immune rejections. These cells can be expanded *in vitro* to solve the donor shortage limitations. Any tissue/organ structure can be potentially mimicked by the scaffolding design. The engineered tissues will have the capacity of growing, modeling, and remodeling in concert with dynamic changes in physiological environment of the body. In this approach, biodegradable polymers (natural or synthetic) are the materials of choice. Polymers (or macromolecules) are currently used as scaffolds for nearly every tissue type including bone and other mineralized tissues. Besides polymers, only limited inorganic materials are used for certain mineralized tissue engineering research. Although growing cells on two-dimensional (2-D) substrates (such as petri dishes and culture plates) dates back centuries, designing 3-D scaffolds for tissue engineering is a new field, where polymer science and engineering play pivotal roles.

There are a few basic requirements that have been widely accepted for designing polymer scaffolds. First, the scaffold has to have high porosity and proper pore size. These pores allow cell seeding and migration to achieve the needed relative uniform distribution. The pores also provide the space for cell proliferation and neo tissue deposition. The pores also satisfy the needed mass transport requirements for nutrients, signaling molecules, metabolic products, and wastes. The porous structure should also allow for vascularization and innervation for sustained function of the regenerated tissues when implanted *in vivo*. High porosity is also beneficial because of the reduced polymer amount and its degradation products in the neo tissues, which can provoke unwanted inflammatory response from the host. Second, a high surface area (a.k.a. surface-to-volume ratio) is needed, which is the 3-D surface area of the porous scaffolds (not just the outside surface area). Many cell types are anchorage-dependent, ie, they can survive, grow, and function only when they are attached to an appropriate substrate. The high surface area provides cells with the sufficient area to attach, grow, and deposit neo tissue components. Third, biodegradability is generally required, and a proper degradation rate is needed to match the neo tissue formation. If the scaffold degrades too fast, it can collapse before the new tissue is formed so that it fails to serve as a 3-D guidance for the neo tissue organization. If the scaffold degrades too slowly, it remains for a prolonged time period after the neo tissue is formed and stabilized. It may hinder the new tissue replacement of the scaffold space, and may cause complications associated with long-term foreign body reactions. Fourth, the scaffold must have the needed mechanical integrity to maintain the predesigned tissue structure to serve the 3-D guidance. However, scaffolds are often not as mechanically strong as the tissues to be replaced because of the required high porosity for scaffolds. They usually serve the scaffolding purpose well as long as they can maintain the structural integrity under the cultivation or implantation conditions, while the goals are that the engineered tissues from the scaffolds are mechanically and biologically functional as their natural counterparts. Fifth, the scaffold should not be toxic to the cells (biocompatible). In addition to the polymer, the degradation products of the polymer should not be toxic to the cells, which is usually a more restricting requirement than for the polymer. Sixth, ideally the scaffold should positively interact with cells, including enhanced cell adhesion, growth, migration, and differentiated function. To achieve these positive cell–scaffold interactions, surface or bulk modifications of the polymer structure are often employed. Even drug, protein, or gene delivery techniques are often considered in the scaffold design.

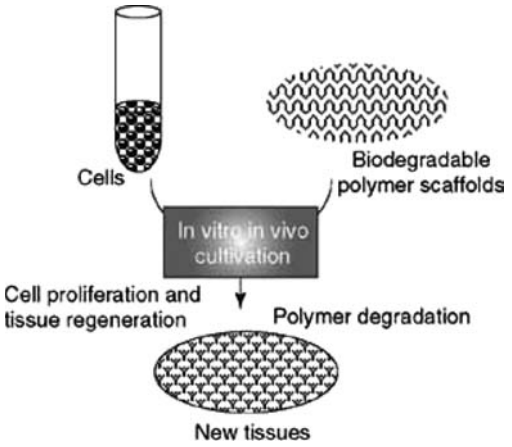

Fig. 1. Schematic diagram showing the tissue engineering concept. Scaffolding materials (temporary synthetic extracellular matrices) are designed, on which mammalian cells can grow to regenerate the needed tissue or organ in three dimensions (3-D). Because the scaffolds are biodegradable, they will resorb after fulfilling the template function and leave nothing foreign in the body.

Cells

Tissue engineering solves problems by using living cells as engineering materials. These could be artificial skin that includes living fibroblasts, cartilage repaired with living chondrocytes, or other types of cells used in other ways. Cells became available as engineering materials when scientists at Geron Corp. discovered how to extend telomeres in 1998. http://www.geron.com/. Before this, laboratory cultures of healthy, noncancerous mammalian cells would only divide a fixed number of times, up to the Hayflick limit.

From fluid tissues such as blood, cells are extracted by bulk methods, usually centrifugation or aspheresis.

From solid tissues, extraction is more difficult. Usually the tissue is minced, and then digested with the enzymes trypsin or collagenase to remove the cellular matrix that holds the cells. After that, the cells are free floating, and extracted using centrifugation or aspheresis.

Digestion with trypsin is very dependent on temperature. Higher temperatures digest the matrix faster, but create more damage. Collagenase is less temperature dependent, and damages fewer cells, but takes longer and is a more expensive reagent.

Autologous cells are obtained from the same individual to which they will be reimplanted. Autologous cells have the fewest problems with rejection and pathogen transmission, however in some cases might not be available. For example in genetic disease suitable autologous cells are not available. Also very ill or elderly persons, as well as patients suffering from severe burns, may not have sufficient quantities of autologous cells to establish useful cell lines. Moreover since this category of cells needs to be harvested from the patient, there are also some concerns related to the necessity of performing such surgical operations that might lead to donor site infection or chronic pain. Autologous cells also must be cultured from samples before they can be used: this takes time, so autologous solutions may not be very quick. Recently there as been a trend towards the use of mesenchymal stem cells from bone marrow and fat. These cells can differentiate into a variety of tissue types, including bone, cartilage, fat, and nerve. A large number of cells can be easily and quickly isolated from fat, thus opening the potential for large numbers of cells to be quickly and easily obtained. Several companies have been founded to capitalize on this technology, the most successful at this time being Cytori Therapeutics. http://www.cytoritx.com/.

Allogenic cells come from the body of a donor of the same species. While there are some ethical constraints to the use of human cells for *in vitro* studies, the employment of dermal fibroblasts from human foreskin has been demonstrated to be immunologically safe and thus a viable choice for tissue engineering of skin.

Xenogenic cells are those isolated from individuals of another species. In particular animal cells have been used quite extensively in experiments aimed at the construction of cardiovascular implants.

Syngeneic cells are isolated from genetically identical organisms, such as twins, clones, or highly inbred research animal models.

Primary cells are from an organism.

Secondary cells are from a cell bank.

Stem cells are undifferentiated cells with the ability to divide in culture and give rise to different forms of specialized cells. According the their source stem cells are divided into “adult” and “embryonic” stem cells, with the first class being multipont and the latter mostly pluripotent. While there is still a large ethical debate related with the use of embryonic stem cells, it is thought that stem cells may be useful for the repair of diseased or damaged tissues, or may be used to grow new organs.

Engineering Materials

Cells as found above are generally implanted or ’seeded’ into an artificial structure capable of supporting three-dimensional tissue formation. Such devices, usually referred to as scaffolds, serve at least one of the following purposes:

- Enhance structural properties
- Deliver biochemical factors
- Deliver or allow delivery of vital cell nutrients
- Exert certain mechanical and biological influences to modify the behaviour of the cell phase

To achieve the goal of tissue reconstruction, scaffolds must meet some specific requirements. A high porosity and an adequate pore size are necessary to facilitate cell seeding and diffusion throughout the whole structure of both cells and nutrients. Biodegradability is essential since scaffolds need to be absorbed by the surrounding tissues without the necessity of a surgical removal. The rate at which degradation occurs has to coincide as much as possible with the rate of tissue formation: this means that while cells are fabricating their own natural matrix structure around themselves, the scaffold is able to provide structural integrity within the body and eventually it will break down leaving the neotissue, newly formed tissue which will take over the mechanical load.

Many different materials (natural and synthetic, biodegradable and permanent) have been investigated. Most of these materials have been known in the medical field before the advent of tissue engineering as a research topic, being already employed as bioresorbable sutures. Examples of these materials are collagen or some linear aliphatic polyesters.

A commonly used synthetic material is PLA — polylactic acid. This is a polyester which degrades within the human body to form lactic acid, a naturally occurring chemical which is easily removed from the body. Similar materials are polyglycolic acid (PGA) and polycaprolactone (PCL): their degradation mechanism is similar to that of PLA, but they exhibit respectively a faster and a slower rate of degradation compared to PLA.

Scaffolds may also be constructed from natural materials: in particular different derivatives of the extracellular matrix have been studied to evaluate their ability to support cell growth. Proteic materials, such as collagen or fibrin, and polysaccharidic materials, like chitosan or glycosaminoglycans (GAGs), have all proved suitable in terms of cell compatibility, but some issues with potential immunogenicity still remains. Among GAGs hyaluronic acid, possibly in combination with cross-linking agents (e.g. glutaraldehyde, water soluble carbodiimide, etc.), is one of the possible choices as scaffold material. Funtionalized groups of scaffolds may be useful in the delivery of small molecules (drugs) to specific tissues.

Synthesis of Tissue Engineering Scaffolds

A number of different methods has been described in literature for preparing porous structures to be employed as tissue engineering scaffolds. Each of these techniques presents its own advantages, but none is devoid of drawbacks.

Textile Technologies. These techniques include all the approaches that have been successfully employed for the preparation of nonwoven meshes of different polymers. In particular nonwoven polyglycolide structures have been tested for tissue engineering applications: such fibrous structures have been found useful to grow different types of cells. The principal drawbacks are related to the difficulties of obtaining high porosity and regular pore size.

Solvent Casting and Particulate Leaching (SCPL). This approach allows the preparation of porous structures with regular porosity, but with a limited thickness. First the polymer is dissolved into a suitable organic solvent (e.g. polylactic acid could be dissolved into dichloromethane), then the solution is cast into a mold filled with porogen particles. Such porogen can be an inorganic salt like sodium chloride, crystals of saccharose, gelatin spheres or paraffin spheres. The size of the porogen particles will affect the size of the scaffold pores, while the polymer to porogen ratio is directly correlated to the amount of porosity of the final structure. After the polymer solution has been cast the solvent is allowed to fully evaporate, then the composite structure in the mold is immersed in a bath of a liquid suitable for dissolving the porogen: water in case of sodium chloride, saccharose and gelatin or an aliphatic solvent like hexane for paraffin. Once the porogen has been fully dissolved a porous structure is obtained. Other than the small thickness range that can be obtained, another drawback of SCPL lies in its use of organic solvents which must be fully removed to avoid any possible damage to the cells seeded on the scaffold.

Gas Foaming. A technique using gas as a porogen has been developed that overcomes the necessity of using organic solvents and solid porogens. First disc shaped structures made of the desired polymer are prepared by means of compression molding using a heated mold. The discs are then placed in a chamber where are exposed to high pressure CO_2 for several days. The pressure inside the chamber is gradually restored to atmospheric levels. During this procedure the pores are formed by the carbon dioxide molecules that abandon the polymer, resulting in a sponge like structure. The main problems related to such a technique are caused by the excessive heat used during compression molding (which prohibits the incorporation of any temperature labile material into the polymer matrix) and by the fact that the pores do not form an interconnected structure.

Emulsification/Freeze-drying. This technique does not require the use of a solid porogen like SCPL. First a synthetic polymer is dissolved into a suitable solvent (e.g. polylactic acid in dichloromethane) then water is added to the polymeric solution and the two liquids are mixed in order to obtain an emulsion. Before the two phases can separate, the emulsion is cast into a mold and quickly frozen by means of immersion into liquid nitrogen. The frozen emulsion is subsequently freeze-dried to remove the dispersed water and the solvent, thus leaving a solidified, porous polymeric structure. While emulsification and freeze-drying allows a faster preparation if compared to SCPL, since it does not require a time consuming leaching step, it still requires the use of solvents, moreover pore size is relatively small and porosity is often irregular. Freeze-drying by itself is also a commonly employed technique for the fabrication of scaffolds. In particular it is used to prepare collagen sponges: collagen is dissolved into acidic solutions of acetic acid or hydrochloric acid that are cast into a mold, frozen with liquid nitrogen then liophylized.

Liquid-Liquid Phase Separation. Similar to the previous technique, this procedure requires the use of a solvent with a low melting point that is easy to sublime. For example, dioxane could be used to dissolve polylactic acid, then phase separation is induced through the addition of a small quantity of water: a polymer-rich and a polymer-poor phase are formed. Following cooling below the solvent melting point and some days of vacuum-drying to sublime the solvent a porous scaffold is obtained. Liquid-liquid phase separation presents the same drawbacks of emulsification/freeze-drying.

CAD/CAM Technologies. Since most of the above described approaches are limited when it comes to the control of porosity and pore size, computer assisted design and manufacture techniques have been introduced to tissue engineering. First a three-dimensional structure is designed using CAD software, then the scaffold is realized by using ink-jet printing of polymer powders or through Fused Deposition Modeling of a polymer solution.

Conclusion

Just 15 years ago, Bob Langer and his colleague Joseph Vacanti pioneered a remarkable new process–growing human tissues in the laboratory. In 1987, Langer and Vacanti had difficulty in getting their work published; journal editors did not see any practical applications. Today the pair are acknowledged as the fathers of the field of TE.

Today, tissue engineered skin, the first so-called "neo-organ" approved by the U.S. Food and Drug Administration, comes to the aid of burn victims and patients with severe skin sores or ulcers. In the not-too-distant future, lab grown cartilage and bone could relieve arthritis sufferers, while blood vessels, cardiac valves and muscle tissue could save thousands of cardiovascular disease patients. Ultimately, custom-made hearts, livers, breasts, corneas, kidneys, bone marrow and bladders could offer elegant solutions to most life-threatening illnesses.

Glossary

Adhesion molecule/adhesion receptor — Any of a large variety of different cell-surface proteins and glycoproteins that mediate contact and adhesion of cells to one another and to the extracellular matrix. Some types of adhesion molecule bind to an identical molecule on the other cell whereas others bind to different receptor molecules. Examples include cadherin, integrin, and selectin.

Affinity — The strength of binding of two molecules, such as an antigen and its antibody or a hormone and its receptor.

Allograft (homograft) — A tissue or an organ transplant between individuals of the same species, but genetically nonidentical.

Angiogenesis — The promotion or development of blood vessels; an increase in vascularization.

Apoptosis — Cell death as a result of induction of an internal "suicide" program, and which is a normal and essential event in many developmental stages.

Assay — An experimental technique for measuring or quantifying a phenomena.

Autocrine — A growth factor or biologically active molecule produced by a cell, it acts locally to stimulate the same cell type in a tissue.

Autograft — A tissue or an organ transplanted into a new position within or on the same individual.

Bending — Deformation caused by transverse loading of a structure.

Bioabsorbable material — A material whose breakdown products are incorporated into normal physiologic and biochemical processes.

Biocompatible material — A material that can function in a biologic environment without known or significant detrimental effects on either the material or the living system.

Biodegradable material — A material that breaks down when placed in a biologic environment.

Biomaterial — A substance which is compatible with the physiology of the body; typically designed for use in tissue therapy and/or tissue engineering.

Bioresorbable material — A material that is broken down *in vivo* and removed from the implantation site.

Biomimetic — Able to replicate or imitate a body structure (anatomy) or function (physiology).

Bioreactor — A controlled artificial environment designed to promote life processes; often associated with culturing associated with tissue engineered systems.

Bone morphogenetic proteins (BMPs) — Important cell–cell signaling molecules first identified by their ability to induce cartilage and bone formation; growth factors often used to promote differentiation of osteogenic precursor cells into osteoblasts.

Chromogenic (colorimetric) assay — Experimental technique which relies on the generation and quantification of a colored product.

Collagen — One or all of a family of fibrous proteins of high tensile strength found throughout vertebrates, most abundant protein in mammals, major element of skin, bone, cartilage, teeth, blood vessels, etc. See also **Collagen**.

Compliance — The inverse stiffness (m/N); the motion caused by a load divided by that load.

Compression (force) — A force tending to squeeze or crush an object.

Connective tissue — A primary tissue with many different forms and functions, including support, storage, and protection. It is often recognized as distinct from other tissues due to its larger proportion of extracellular matrix. Examples include bone, muscle, cartilage, tendon, ligament, fat, and blood.

Cross-linking — The chemical or mechanical connection of adjacent polymer chains.

Cytokine — Typically defined as autocrine regulatory molecules, as well as cell-cell communication chemicals; generally restricted to immune cells, though functions vary widely.

Differentiation — In the general sense, the increasing specialization of organization of the different parts of an embryo as a multicellular organism develops from the undifferentiated fertilized egg. Referring to cells, the development of cells with specialized structure and function from unspecialized precursor cells, which occurs in embryonic development and in the subsequent replacement of certain types of cell from persisting unspecialized stem cells.

Diffusion — The free passage of molecules, ions, etc. from a region of high concentration to a region of low concentration.

Extracellular matrix — An intricate network of macromolecules occupying the spaces between the cells of multicellular animals. It is particularly important in the reinforcement of support tissues. Under the light microscope, it appears as a structureless mass of ground substance with embedded connective tissue fibers. The ground substance consists primarily of proteoglycans and glycoproteins, whereas the fibers consist mainly of fibrous proteins such as collagen. Depending on the relative quantities and type of its constituent macromolecules, the e.m. can display a number of forms, ranging from the calcified hard structures of bone and teeth to the transparent matrix of the cornea.

Genomics — Analysis of the entire genome (complete set of genes) of an organism; provides static information regarding the gene and protein composition of a cell. See also **Human Genome Project (The)**.

Glycoprotein — Any of a large class of proteins that contain carbohydrate in the form of chains of monosaccharide units attached to specific amino acid residues; common components of cell membranes and cellular secretions.

Ground substance — The non-living matrix of connective tissue.

Growth factors — Organic compounds other than those required as carbon and energy sources which are needed by many organisms for proper growth and development, and which may include vitamins, amino acids, purines, etc.; a general term for specific peptides or proteins that are released by certain cells and bind to specific cell membrane receptor sites to influence cells to divide or remain quiescent.

Growth plate (epiphyseal plate) — A cartilaginous structure composed of proliferating chondrocytes (cartilage cells) that produces a large extracellular matrix, which serves as a template for bone formation.

Haversian canal — Freely anastomosing channels within cortical (dense) bone containing blood vessels, lymph vessels, and nerves.

Homograft. See allograft.

Hydroxyapatite. Naturally occurring mineral [$Ca_{10}(PO_4)_6(OH)_2$] found as the major inorganic constituent of bone matrix.

Insulin-like growth factors (IGF) — Peptides that behave similarly to insulin and stimulate cell proliferation.

In vivo — An event or process occurring naturally or spontaneously within a living organism.

In vitro — An event or process occurring outside of the living organism or natural system; usually referring to artificial experimental systems such as cultures, cell-free extracts, etc.

Isograft — A tissue or an organ transplanted between genetically identical individuals.

Material property — Any physical characteristic of an object's substance, for example, heat conduction, diffusivity, thermal expansion, and melting point, that is independent of the object's structure and geometry.

Matrix — An intricate network of natural or synthetic fibers that aids in the reinforcement and development of tissues by supplying a scaffold on which cells may grow, migrate and proliferate.

Mechanical property — A subset of material properties that relates stresses to strains.

Mitogen — An agent that stimulates DNA production and cell division.

Moment of inertia — Resistance of a geometric shape to deformation; solely a function of geometry, independent of material properties.

OPC1 — Immortalized osteogenic precursor cells derived from human fetal bone; cells able to differentiate into osteoblastic (bone forming) cells *in vitro*.

Ossification — Formation of bone, replacement of cartilage by bone.

Osteoblast — Bone-forming cell that secretes the bone matrix.

Osteocalcin — A small, bone-specific protein that is produced by the osteoblast and may play a role in osteoclast recruitment.

Osteoclast — Large, multinucleate cell that destroys bone or any other matrix during bone formation and remodeling.

Osteocyte — Non-secreting, non-dividing cell derived from an osteoblast, found in calcified bone; active in bone mineral homeostasis.

Osteogenesis — Process of producing bone tissue.

Osteoid — Collagenous material secreted by bone cells (osteoblasts) and which forms the basis of bone, the uncalcified bone matrix.

Osteon bone — Type of bone composed of overlapping cylinders (osteons) each comprised of concentric layers (lamellae), the collagen fibers of each layer running at right angles to the next, surrounding a central canal (Haversian canal).

Osteoporosis — A decrease in bone mass per unit volume of normally mineralized bone.

Paracrine — Local action of (such as growth factors) that are produced by one cell on another cell type within the same tissue.

Phenotype — The expression of structure, function, or behavior of an organism or cell.

Platelet-derived growth factor (PDGF) — Glycoprotein growth factor that stimulates cell proliferation and chemotaxis in cartilage, bone, and many other cell types after being produced by mesenchymal cells or released by platelets during clotting.

Polymer — A generic term used to describe a very long molecule consisting of structural units and repeating units connected by covalent chemical bonds. The key feature that distinguishes polymers from other molecules is the repetition of many identical, similar, or complementary molecular subunits in these chains. These subunits, the monomers, are small molecules of low to moderate molecular weight, and are linked to each other during a chemical reaction called polymerization.

Porosity — Ratio of void (or fluid) volume to apparent (total) volume of a porous material.

Proteomics (Cellular) — A large-scale study of proteins; it reflects the dynamic situation of a cell, providing information regarding the rate of expression and regulation of individual cell proteins.

Resilience — The capacity of a strained material to recover its size and shape after a deforming load is removed.

Scaffold — A three-dimensional biocompatible construct (may be seeded with cells) that serves as a temporary implantable tissue; generally fated to biodegrade and be replaced by natural tissue.

Stem cell — Undifferentiated cell in embryo or adult which can undergo unlimited division and give rise to one or several different cell types. In adults, an undifferentiated cell from which some renewable tissues (blood, skin, etc.) are formed.

Stiffness — Resistance of a structure to a deformation.

Strength — Maximum resistance to strain before mechanical failure begins.

Tension — A force tending to elongate an object; a pull.

Torsion — Deformation caused by twisting (torquing) of a shaft.

Tropic — An influence of one cell or tissue on the direction of movement or outgrowth of another.

Vascularization — The process of infiltration of blood vessels; regarded as a critical support for the health and maintenance of living tissue.

Viscous — A property of a fluid that offers resistance to flow; for example, frictional drag.

TITANITE. Titanite or sphene is a calcium titanium nesosilicate mineral, $CaTiSiO_5$. Trace impurities of iron and aluminium are invariably present. Also commonly present are rare earth metals including cerium and yttrium. Titanite, which is named for its titanium content, occurs as translucent to transparent, reddish brown, gray, yellow, green, or red monoclinic crystals. These crystals are typically sphenoid (from the Greek *sphenos*, meaning wedge) in habit and are often twinned. Possessing a subadamantine tending to slightly resinous lustre, titanite has a hardness of 5.5 and a weak cleavage. Its specific gravity varies between 3.52 and 3.54. Titanite's refractive index is 1.885–1.990 to 1.915–2.050 with a strong birefringence of 0.105 to 0.135 (biaxial positive). Titanite is a source of TiO_2 used in pigments and is admired as a gemstone when suitably free of flaws. Titanite occurs in metamorphic rocks such as gneiss and schists and also in granular limestones and granite. Transparent specimens are noted for their strong trichroism, the three colors presented being dependent on body colour. Owing to the quenching effect of iron, sphene

exhibits no fluorescence under UV. Some titanite has been found to be metamict.

Notable occurances include Gilget, Pakistan; Mt Vesuvius, Italy; Kola Penn., Russia; Ontario, Canada and New York and California, USA.

TITANIUM. [CAS: 7440-32-6]. Chemical element, symbol Ti, at. no. 22, at. wt. 47.9, periodic table group 4, mp 1,650–1,670 °C (3,002-3,038 °F), bp 3,287 °C (5,949 °F), density 4.507 g/cm^3 (20 °C (68 °F). Below 885 °C (1,625 °F), elemental titanium has a hexagonal closepacked crystal structure; above this temperature, it has a body-centered cubic crystal structure. Compact titanium is a white metal, when cold it is brittle and may be powdered, but at red heat may be forged and drawn into wire. Titanium exhibits some passivity in air due to formation of coatings of oxide or nitride. At 610 °C (1,130 °F), titanium reacts with oxygen to form titanium dioxide; at 800 °C (1,472 °F), it reacts with nitrogen to form titanium nitride. Upon heating with chlorine, the metal forms titanium tetrachloride. Cold, dilute H_2SO_4 readily dissolves the metal to form titanous sulfate. Hot, concentrated H_2SO_4 yields titanic sulfate. The first commercial uses date back to 1860 when ferrotitanium was used as an alloying element in steel and a bit later as a deoxidizer in the production of steel. There are five natural isotopes of the metal ^{46}Ti through ^{50}Ti, with ^{48}Ti being the most abundant (73.8% natural abundance). Eleven radioisotopes have been characterized with the most stable being ^{44}Ti with a half-life of 63 years, ^{45}Ti with a half-life of 184.8 minutes, ^{51}Ti with a half-life of 5.76 minutes, and ^{52}Ti with a half-life of 1.7 minutes. All of the remaining radioactive isotopes have a half-life less than 33 seconds and the majority of these have a half-life less than half a second. The isotopes of titanium range in atomic weight from 39.99 amu (^{40}Ti) to 57.966 amu (^{58}Ti). The primary decay mode before the most abundant stable isotope, ^{48}Ti, is electron capture and the primary mode after is beta emission. The primary decay products before ^{48}Ti are element 21 (scandium) isotopes and the primary products after are element 23 (vanadium) isotopes. Titanium is relatively abundant, ranking 9th in the list of chemical elements occurring in the Earth's crust. Titanium ranks 35th among the elements in terms of content in seawater, with an estimated 5 tons of titanium per cubic mile (1.1 kilograms per cubic kilometer) of seawater. First ionization potential 6.83 eV; second, 13.60 eV; third, 27.6 eV; fourth, 44.66 eV. Oxidation potential $Ti + 2H_2O \rightarrow TiO_2 + 4H^+ + 4e^-$, 0.95 V; $Ti \rightarrow Ti^2 + 2e^-$, 1.75 V; $Ti^{2+} \rightarrow Ti^{3+} + e^-$, 0.37 V. Electronic configuration $1s^22s^22p^63s^23p^63d^24s^2$.

Other physical properties of titanium are given under **Chemical Elements**.

Titanium (Latin *Titans*, Earth or the first sons of Gaia) was discovered in England by Reverend William Gregor in 1791. He recognized the presence of a new element in ilmenite, and named it *menachite*. At around the same time, Franz Joseph Muller also produced a similar substance, but could not identify it. The element was independently rediscovered several years later by German chemist Martin Heinrich Klaproth in rutile ore. Klaproth confirmed it as a new element and in 1795 he named it for the Latin word for Earth (also the name for the Titans of Greek mythology).

The metal has always been difficult to extract from its various ores. Pure metallic titanium (99.9%) was first prepared in 1910 by Matthew A. Hunter by heating $TiCl_4$ with sodium in a steel bomb at 700–800 °C (1,292-1,472 °F) in the Hunter process. Titanium metal was not used outside the laboratory until 1946 when William Justin Kroll proved that titanium could be commercially produced by reducing titanium tetrachloride with magnesium in the Kroll process which is the method still used today.

In 1950–1960s the Soviet Union attempted to corner the world titanium market as a tactic in the Cold War to prevent the American military from utilising it. In spite of these efforts, the U.S obtained large quantities of titanium when a European company set up a front for the U.S. foreign intelligence agencies to purchase it.

Occurrence and Production. Titanium metal is not found unbound to other elements in nature but the element is the ninth most abundant element in the Earth's crust (0.63% by mass) and is present in most igneous rocks and in sediments derived from them (as well as in living things and natural bodies of water). Titanium mineral occurs in nature as ilmenite, $FeTiO_3$; rutile, tetragonal TiO_2; anatase, tetragonal TiO_2; brookite, rhombic TiO_2; perovskite, $CaTiO_3$; sphene (titanite), $CaTiSiO_5$; and geikielite, $MgTiO_3$. Ilmenite is by far the most common, although rutile has been an important source of raw material. Although some deposits of anatase and perovskite are rich enough to be of commercial interest, the abundance and availability of high grade deposits of ilmenite and rutile have postponed the development of these minerals. See also **Ilmenite**; and **Rutile**.

This metal is found in meteorites and has been detected in the sun and in M-type stars. Rocks brought back from the moon during the Apollo 17 mission are composed of 12.1% TiO_2. Titanium is also found in coal ash, plants, and even the human body.

The principal titanium mineral, ilmenite, is found in either alluvial sands or hard-rock deposits. After concentrating, the titanium ore color is black. This is the black sand often found concentrated in bands along sandy beaches. The density of this concentrate is ca 4–5 g/cm^3. The concentrate is processed to either pigment-grade TiO_2 or metal. The titanium metal is won from the ore in a physical form called sponge, a name derived from its appearance. The sponge is consolidated to an ingot and further processed to mill products in a manner similar to steel. In metallic form, titanium has a dull silver luster and an appearance similar to stainless steel.

Titanium ore bodies are uniformly distributed throughout the continents of the world. They occur either as hard-rock deposits, magnetic in origin, or as secondary placer deposits. The titanium oxide contained in known deposits of ilmenite is close to 1 billion metric tons, whereas only about 50 million metric tons of titanium oxide in rutile are known to exist. The largest known reserves of titanium are in Canada and China.

The commercial production of titanium metal involves the chlorination of rutile (TiO_2) in the presence of coke or other form of carbon. The most important chemical reaction involved is the resulting $TiCl_4$ ("tickle") is purified by distillation and chemical treatments and subsequently reduced to titanium sponge using either the Kroll process (mg) or Hunter process (Na).

Ore-Concentrate Refining. The TiO_2 content of ore concentrates determines further processing steps. High grade ore such as rutile, synthetic rutile, or slag from Richard's Bay is refined to pigment-grade TiO_2 via chlorination. Lower grade ore is processed via the sulfate route. The chlorination process, commercialized by Du Pont in the early 1960s, which produces a better quality pigment, requires less processing energy than the sulfate process (1800 kWh/t compared to 2500 kWh/t), and has less waste discharge. The sulfate process produces approximately six tons of waste per ton of TiO_2, whereas only one ton of waste is produced through the chloride process. However, high grade ore is required for the latter process, ie, TiO_2 content >70%, with <1% MgO and 0.2% CaO, because ores that have high MgO and CaO can clog the chlorinator. Environmental problems have forced the industry either to shut down sulfate plants or to install expensive pollution-control equipment. Because of the shortage of high grade TiO_2 reserves, the pigment industry must adapt the ore to the chloride process. The trend has been towards ore beneficiation. Ore containing 50–60% TiO_2 content is beneficiated by partial reduction, then leached with sulfuric or hydrochloric acid to yield a concentrate containing >90%TiO_2, the so-called synthetic rutile.

Sulfate Process. In the sulfate process, ilmenite ore is treated with sulfuric acid at 150–180 °C (302–356 °F):

$$5H_2O + FeTiO^3 + 2H_2SO_4 \rightarrow FeSO_4 \cdot 7H_20 + TiOSO_4$$

The undissolved solids are removed and the liquid is evaporated under vacuum and cooled. The precipitated $FeSO_4 \cdot 7H_2O$ is filtered and the filtrate concentrated to ca 230 g/L. Heating to 90 °C hydrolyzes titanyl sulfate to insoluble titanyl hydroxide.

$$TiOSO_4 + 2H_2O \rightarrow TiO(OH)_2 \downarrow + H_2SO_4$$

To ensure the rutile crystal form, seed crystals are added, otherwise anatase is obtained. The precipitate is thoroughly washed using water

and sulfuric acid to remove all traces of discoloring elements, eg, iron, chromium, vanadium, and manganese. The $TiO(OH)_2$ is finally calcined at 1,000 °C (1,832 °F) to TiO_2.

Chloride Process. In the chloride process, a high grade titanium oxide ore is chlorinated in a fluidized-bed reactor in the presence of coke at 925–1010 °C (1,697–1,850 °F):

$$TiO_2 + 2C + Cl_2 \rightarrow 2CO + TiCl_4$$

$$\Delta G_{1,300\,^\circ C(2,372\,^\circ F)} = -125 \text{ kJ}(30 \text{ Kcal})$$

The volatile chlorides are collected and the unreacted solids and nonvolatile chlorides are discarded. Titanium tetrachloride is separated from the other chlorides by double distillation. Vanadium oxychloride, $VOCl_3$, which has a boiling point close to $TiCl_4$, is separated by complexing with mineral oil, reducing with H_2S to $VOCl_2$, or complexing with copper. The $TiCl_4$ is finally oxidized at 985 °C to TiO_2 and the chlorine gas is recycled

Tetrachloride-Reduction Process. Titanium tetrachloride for metal production must be of very high purity. Titanium tetrachloride for metal production is prepared by the same process as described above, except that a greater effort is made to remove impurities, especially oxygen- and carbon-containing compounds.

Magnesium-Reduction (Kroll) Process. This process was developed in 1946 by William Justin Kroll. In the 1990s and early 2000s, nearly all sponge is produced by the magnesium reduction process.

$$TiCl_4(g) + 2\ Mg(l) \rightarrow Ti(s) + 2\ MgCl2(l)$$

$$\Delta G_{900\,^\circ C(1,652\,^\circ F)} = -301 \text{ kJ}(-72 \text{ kcal})$$

TiCl4 (g) is metered into a carbon-steel or 304 stainless-steel reaction vessel that contains liquid magnesium. An excess of 25% magnesium over the stoichiometric amount ensures that the lower chlorides of titanium ($TiCl_2$ and $TiCl_3$) are reduced to metal. The highly exothermic reaction ($\Delta H_{900\,^\circ C}$ (1, 652 °F) = −420 kJ/mol (−100 kcal.mol) is controlled by the feed rate of $TiCl_4$ at ca 900 °C. The reaction atmosphere is helium or argon. Molten magnesium chloride is tapped from the reactor bottom and recycled using conventional magnesium-reduction methods, including L. G. Farben, Alcan, and USSR VAMI cells. The product, the so-called sponge, is further processed to remove the unreacted titanium chlorides, magnesium, and residual magnesium chlorides. After purification, the sponge is crushed, screened, dried, and placed in air-tight, 23-kg (51-lb) drums to await consolidation. The energy required to convert $TiCl_4$ to sponge, which is ready for further processing by the leaching routes, is ca 37 kWh/kg of sponge, of which ca 97% is required for magnesium production.

Other Reduction Processes. A number of alternating processes have been evaluated for sponge production, including electrolytic, molten salt and plasma processes and while but none of these have yet reached commercial status a promising "reverse electrolytic" approach is at the pilot plant stage.

Sponge Consolidation. The next step is the consolidation of the sponge into ingot. The crushed sponge is blended with alloying elements or other sponge. Consumable electrodes are produced by welding 45–90-kg (39-198 lb) sponge compactions (electrode compacts) in an inert atmosphere, and then double-vacuum-arc-remelted (VAR). A portion of the elemental sponge compacts are often replaced with bulk scrap. The ingots are ca 71–91-cm dia (28-36 in dia) and long enough to weigh 4.5 to 9.0 t. The double melt, included in aerospace specifications, is required for thorough mixing of alloying elements, scrap, and titanium sponge, and for improving yields because vaporization of volatiles during the first melt leaves a rough, porous surface. The double melt removes residual volatiles such as Mg, $MgCl_2$, Cl_2, and H_2. Triple melts are specified for critical applications such as rotating components in gas turbine engines. The third melt allows more time to dissolve high melting point inclusions that infrequently occur. This is often referred to as rotating quality titanium.

Uses. The major uses for titanium are in various alloys, although unalloyed titanium finds some application. Titanium alloys are classified as alpha, alpha-beta, or beta, determined by the phases present in the alloy at room temperature. The alpha alloys usually result when the main elements present are the alpha stabilizers, e.g., oxygen, nitrogen, hydrogen, and carbon. Alpha-beta alloys and beta alloys contain increasing amounts of beta stabilizers, mainly vanadium, molybdenum, iron, chromium, manganese, tantalum, and niobium (columbium). The alpha-beta class of alloys normally has great room-temperature strength and may be heat treated. The annealed beta alloys show poor thermal stability over about 230 °C (446 °F), but do have good formability and weldability. The beta alloys may be age heat treated wherein some alpha phase is precipitated and this results in a very high room-temperature strength. The complexity of titanium alloys is brought about by the fact that the element is allotropic and undergoes a phase transformation at about 885 °C (1,625 °F), changing from one crystalline form to another as mentioned at the start of this entry. The variations in strength and percent elongation for the three major types of alloys and for pure titanium are given in Table 1.

TABLE 1. TITANIUM ALLOYS

Alloy	Tensile Strength psi	Tensile Strength mpa	Yield Strength psi	Yield Strength mPa	Percent Elongation
Pure titanium					
High purity (99.9%)					
Annealed	34,000	237	20,000	138	54
Commercial purity (99.0%)	79,000	545	63,000	435	27
Alpha alloy					
Ti-5Al-2.5 Sn					
Annealed	125,000	863	120,000	828	18
Alpha-*beta alloy*					
Ti-6Al-4V					
Annealed	135,000	932	120,000	828	11
Heat treated	170,000	1173	150,000	1035	7
Beta alloy					
Ti-3Al-13V-11Cr					
Heat treated	180,000	1242	170,000	1173	6

Classification of alloys by application:
Airframe Alloys
Ti-75A, Ti-SAl-2.5Sn, Ti-6Al-6V-2Sn, Ti-6Al-4 V, Ti-7Al-4Mo, Ti-4Al-3Mo-IV, Ti-8Mn, Ti-13V-11Cr-3Al
Engine Alloys
Ti-8Al-1Mo-IV, Ti-SAl-2.5Sn, Ti-6Al-4V, Ti-6Al-2Sn-4Zr-2Mo, Ti-6Al-2Sn-4Zr-6Mo
Corrosion-resistant Alloys
Ti-35A, Ti-50A, Ti-65A, Ti-0.2Pd, Ti-2Ni

Many diversified applications have been found for titanium and its alloys. Moreover, the number of these applications tends to increase steadily as greater production and improved processes reduce costs. At the present time, titanium is still an expensive material and is only used where its light weight, high strength, and corrosion resistance justify its cost. Aeronautical and missile design engineers find titanium and its alloys to be materials whose light weight and high strength, particularly at elevated temperatures (600 °C), give them many applications in aircraft and missile construction. About 99% of all titanium materials are used in these fields.

Titanium and its alloys are widely used in compressor blades, turbine disks and many other forged parts of the jet engine. Here they offer resistance to high temperature, as well as weight-saving. The latter quality is increasing their use in the structural airplane parts, ranging from engines and air frames to skin and fastenings. Titanium sheet finds application in shroud assemblies, cable shrouds and ammunition tracks. Titanium alloy sheet is formed into ribs for use as stiffeners, as well as fuselage frames and bulk heads. Other uses of titanium in aircraft include channel sections, flat rubbing strips, landing gear doors, hydraulic lines, baffles, tail cones,

longerons, etc. Other uses of titanium alloys include bulk heads, ducts, fire walls, etc.

The light weight of titanium and its alloys, coupled with their corrosion resistance, has brought them into use in ships, especially naval ships. Here many investigations show the important advantages of the metal and its alloys as wet exhaust muffles for submarine diesel engines, and as meter disks, and heat exchanger tubes which offer improved service for widespread use in salt water. Military applications of titanium extend from cannon and guided missiles to light-weight armor-plate for tanks. These materials offer other weight savings in other parts of military vehicles, such as piston rods and transmissions, which may extend to the transportation industries generally.

Throughout the chemical industry, titanium is used extensively both in plant and in laboratory. Among important present-day applications are heat exchangers, autoclave heads, autoclave coils for cooling and heating, chemical processing racks, and valves and tanks where corrosion resistance is necessary.

Advancements in Titanium Technology. Increasingly, titanium alloys are competing with nickel-base alloys on the basis of cost, strength, and corrosion resistance. The alloy Ti-3Al-2.5 V, for example, is finding expanded use in the process industries because of its resistance to mildly reducing chloride environments.

Authorities in the field do not believe that the demand for titanium in the aerospace industry will be adversely affected by the increasing use of polymer-matrix composites in airframes and engines. Titanium has been replaced outright by composite materials in only a few aerospace applications. In those instances, the primary considerations have been weight reduction and "stealth" characteristics. By contrast, titanium has been selected instead of composites for several applications where the primary considerations have been titanium's superior stiffness and toughness as well as its multidirectional strength characteristics. Titanium also has gained favor because of its compatibility with composites. An example of this compatibility is found in titanium-aluminide foils. These are used to fabricate honeycomb structures. Fiber-reinforced alpha 2 titanium aluminide-matrix composites are fabricated by consolidating a foil/fiber/foil layup, using hot isostatic processing. The reinforcements are carbon-coated silicon-carbide continuous fibers.

Near-Net-Shape Processing. Even greater use of titanium in aircraft has been limited because of its relatively high cost (as compared with aluminum, by a factor of $10\times$ to $20\times$) and also because of its lower machinability. Gains are being made by titanium on both of these counts, however, by initially making titanium parts very close to the shape and dimensions of the desired end product (near-net-shape or NNS). These gains have been made through advanced titanium processing techniques and include precision casting, hot isostatic pressing, blended elemental (BE) powder techniques, and precision forging.

Increasingly, titanium alloys are competing with nickel-based alloys on the basis of cost, strength, and corrosion resistance.

Titanium Diboride. TiB_2 cermet is an extremely hard material. For several years, there was no successful process for depositing the material on parts for achieving wear resistance. A process was introduced by Montreal Carbide Co. in 1990, however, that deposits microspheres of TiB_2 in a metallic matrix. Using a conventional plasma-spray technique, a series of cermet coatings, in which the ceramic phase is finely and uniformly dispersed, yields a wear-resistant surface. TiB_2 is synthesized during spraying by a reaction between powders of titanium-bearing alloys and boron-bearing alloys. Due to the rapid solidification, the TiB_2 crystals that form are finely dispersed in a metallic matrix, which originated from the alloys used in the process.

Health and Safety. The titanium industry is extremely concerned over environmental, health and safety issues relating to all aspects of the production of titanium. In fact, under the auspices of the Trade Organization "The International Titanium Association" (ITA) there is a safety committee which acts in an advisory role to the world-wide titanium industry. www.titanium.org/.

Titanium and its corrosion products are nontoxic. A safety problem does exist with titanium powders, grindings, turnings, and some corrosion products that are pyrophoric. Powders can ignite at about 2,500 °C (4,532 °F) and should be handled in small quantities at room temperature in electrically grounded, nonsparking equipment made from materials, such as monel, aluminum, and stainless steel. Grindings and turnings should be stored in a closed container and not left on the floor. Smoking must be prohibited in areas where titanium is ground or turned. If a fire occurs, it must be extinguished with a Class-D extinguisher, specially used against metal fires. Dry common salt can also be used to smother a fire. Water or other liquids must not be used as they could react with the titanium and release hydrogen. The larger the surface area, the more pyrophoric the titanium powder. When titanium equipment is being worked on, all flammable and corrosive products must be removed and the area well ventilated. A pyrophoric corrosion product has been observed in environments of dry Cl2 gas and in red-fuming nitric acid. The concerns mentioned above also apply to the transportation of finely divided powder, grindings or turnings, however there are no such concerns with solid titanium.

Titanium is one of the least toxic meterials and is essentially benign to the human body, which in combination with excellent mechanical properties has led to use in medical implants such as hip joints and knees.

Titanium Compounds, Inorganic. Titanium is the first member of the *d*-block transition elements. Its electron configuration is [Ar] $4s^2 3d^2$, and successive ionization potentials are 6.83, 13.57, 27.47, and 43.24 eV. Its technologically important chemistry is predominantly that of oxidation states (II), (III), and (IV), in order of increasing importance. Ti(II) and Ti(III) compounds are readily oxidized to the tetravalent state by air, water, and other oxidizing agents. The energy for the removal of four electrons is so high that the Ti^{4+} ion does not itself have a real existence, and compounds of Ti(IV) are generally significantly covalent. Titanium, capable of utilizing the 3*d* shell, forms a large group of addition compounds in which the Ti is coordinated by donor atoms such as oxygen, sulfur, or chlorine.

The titanium compounds of greatest technological importance are titanium dioxide, the predominant white pigment. Approximately 90% of this usage is as a white pigment, placing TiO_2 as the second highest valued inorganic chemical consumed in the world. Titanium esters, eg, titanium isopropoxide, and derived compounds, are used for applications such as structuring agents in paint; titanium metal, which has excellent corrosion resistance and a high strength–weight ratio; and barium titanate, an important electroceramic. See also **Titanium Dioxide**.

The first recorded use of titanium dioxide as a white pigment was in 1908, when A. J. Rossi, a French metallurgist and chemist, prepared a relatively pure TiO_2, mixed the material with salad oil, and brushed out the mixture. Rossi had come to the United States in the late 1800s and developed methods to produce titanium alloys for the iron-and-steel industry. Work continued on the development of titanium compounds used as pigments, and in 1916, the Titanium Pigment Company was formed in Niagara Falls, New York.

During the same time period, the Norwegian government appointed a commission to investigate the commercial uses of extensive titaniferous magnetites and ilmenite deposits in the southwest coast of Norway. Although initially directed at smelting these ores for iron, the investigations lead to the development of titanium dioxide pigments. By 1912, production of composite pigments was begun at Fredrikstad, Norway.

All four of the common halogens form tetrahalides of titanium, $TiCl_4$ being a liquid at ordinary temperatures, while TiF_4, $TiBr_4$, and TiI_4 are solids. They are readily hydrolyzed, yielding as end products TiO_2 and the hydrogen halide, in the case of $TiCl_4$ an intermediate addition product of the type $H_2O \cdot TiCl_4$ is considered to be formed. This is in accordance with the behavior of $TiCl_4$ and $TiBr_4$ as Lewis acids to form such unstable adducts, not only with water, but with oxygen-function organic compounds. Likewise, titanium chelates are formed with oxygen donor compounds such as acetylacetone.

The dihalides of titanium, formed by reduction of the tetrahalides, are vigorous reducing agents and unstable; $TiCl_2$ is inflammable in air. The trihalides, though more stable than the dihalides, are effective reducing agents. Ti(III) occurs in aqueous solutions as $Ti(H_2O)_6^{3+}$.

Normal oxyacid salts of titanium are unknown, but many basic salts, formulated as stated above, in terms of TiO^{2+}, though more or less hydrated, have been prepared.

Titanium Borides. Five phases of titanium boride have been reported. TiB_2 [CAS: 12405-65-35], Ti_2B [CAS: 12305-68-9], TiB [CAS: 12007-08-8], Ti_2B_5 [CAS: 12447-59-5], and TiB_{12} [CAS: 51311-04-7]. The most important of these is the diboride, TiB_2, which has a hexagonal structure and lattice parameters of $\alpha = 302.8$ pm and $c = 322.8$ pm. Titanium diboride is a gray crystalline solid. It is not attacked by cold concentrated hydrochloric or sulfuric acids, but dissolves slowly at boiling temperatures. It dissolves more readily in nitric acid/hydrogen peroxide or nitric acid/sulfuric acid mixtures. It also decomposes upon fusion with alkali hydroxides, carbonates, or bisulfates.

The applications of titanium diboride depend on such properties as its hardness, electrical conductivity, and ability to be wetted by metals. The actual values of these properties attained in sintered bodies depend on the grain structure and degree of densification and, ultimately, on both the fabrication method and the quality of the starting powder. In monolithic form, sintered titanium diboride can be used as a strong but lightweight armor. It is an important constituent of cermets, eg, composites based on TiB_2–TiC–Fe mixtures show excellent performance as cutting tools for aluminum alloys. Titanium diboride also shows excellent wettability and stability in liquid metals, eg, liquid aluminum, and many tons of the powder are used in the production of vacuum metallizing boats, eg, TiB_2, AlN, and BN composites. These are resistance-heated to about 1400 °C and used for the continuous evaporation of aluminum to produce thin metal films. The use of titanium diboride as an inert solid cathode, which would replace the molten aluminum cathode in aluminum reduction refining cells, has been proposed. See also **Thin Films**.

Titanium Carbide. Titanium carbide [CAS: 12070-08-05], TiC, has the fcc, NaCl structure in which the carbon atoms can be regarded as occupying the octahedral interstices in a slightly expanded cubic close-packed arrangement of titaniums. The system is stable from $TiC_{1.0}$ to $TiC_{0.47}$, ie, ca 50% of the carbon sites can be vacant. As the carbon content is reduced, the lattice parameter ($\alpha = 432.8$ pm) and density decrease. From $TiC_{0.47}$ to $TiC_{0.08}$, TiC and Ti phases coexist; below $TiC_{0.08}$, only the α- Ti phase is present. Titanium carbide also forms solid solutions with TiO and TiN. Sintered titanium carbide is light gray when fractured but can be polished to a silver gray. The maximum melting point in the Ti–C system is 3067 °C for $TiC_{0.8}$, that of $TiC_{1.0}$ is slightly lower. The boiling point of titanium carbide is 4,800 °C (8,672 °F). Titanium carbide is resistant to aqueous alkali except in the presence of oxidizing agents. It is resistant to acids except nitric acid, aqua regia, and mixtures of nitric acid with sulfuric or hydrofluoric acid.

Titanium carbide may also be made by the reaction at high temperature of titanium with carbon; titanium tetrachloride with organic compounds such as methane, chloroform, or poly(vinyl chloride); titanium disulfide [CAS:12039-13-3] with carbon; organotitanates with carbon precursor polymers; and titanium tetrachloride with hydrogen and carbon monoxide.

The primary commercial applications of titanium carbide are in wear-resistant components and cutting tools. Titanium carbide is added to alumina-based cutting tools to give improved thermal conductivity and hence improved resistance to thermal shock, as well as mechanical performance, such as strength, hardness, and toughness, compared with pure alumina ceramics.

Titanium-Nitrogen Compounds. Titanium nitride [CAS: 25583-20-4] has the cubic NaCl structure, but the structure is stable over a wide range of either anion or cation deficiency ($TiN_{0.42}$, $\alpha = 421$ pm; $TiN_{1.0}$, $\alpha = 423.5$ pm). The nitride is a better conductor of electricity than titanium metal. It becomes superconductive at 1.2–1.6 K. Titanium nitride has a density of 5213 kg/m^3 and melts at 2950 °C. Thermodynamic data are given in Table 4. The powder, usually described as chocolate-brown, is actually bluish black when sufficiently fine. The ease of sintering depends on particle size. Sintered titanium nitride is a bronze color and can be polished to a golden lustre.

TiN is used in cutting tools and wear parts, often in conjunction with TiC. Thus, the thermal conductivity, strength, toughness, and hardness of alumina-based cutting tools are improved by adding titanium carbide and titanium nitride at ca 30%. Because of its excellent electrical conductivity, TiN can be used as an additive to confer electrical conductivity on silicon nitride and sialon ceramic components. As a result, these can be shaped by spark erosion instead of by costly diamond grinding. Surface treatment of metals, often by chemical vapor deposition, as well as tungsten carbide cutting inserts, is widely employed to form a wear-resistant, low friction, titanium nitride surface layer.

Titanium Nitrate. Titanium nitrate [CAS: 13860-02-1], $Ti(NO_3)_4$, is a white powder, mp 58 °C (136 °F), in which the titanium achieves a coordination number of eight by being surrounded by four bidentate nitrate groups. It is stable in a sealed tube at room temperature, is less sensitive to moisture than titanium tetrachloride, and does not fume in air but reacts vigorously with water, liberating nitrogen oxides. It may be prepared by prolonged reaction of N_2O_5 on titanium tetrachloride at −60 to −20 °C (−76 to −4 °F). This produces an intermediate compound that decomposes on warming in the presence of excess nitrogen dioxide to form NO_2Cl and titanium nitrate. A more recent patent describes the production of titanyl nitrate by electrolysis of titanium tetrachloride or titanyl chloride. Other titanium nitrogen compounds that have been described include titanous amide [CAS: 15190-25-9], $Ti(NH_2)_3$, titanic amide [CAS: 15792-80-0], $Ti(NH)_2$, and various products in which amines have reacted with titanium tetrachloride.

Titanium Oxides. The properties of lower oxides of titanium are summarized in Table 2.

TABLE 2. PROPERTIES OF THE LOWER OXIDES OF TITANIUM

Property	TiO	Ti_2O_3	Ti_3O_5
Color	Golden yellow	Violet	Blue-black
Density, kg/m^3	4888	4486	421(0)
Melting point, °C	1737	2127	
Structure	fcc	Hexagonal	Monoclinic
Lattice parameters, pm			
a	417	515.5	975.2
b		515.5	380.2
c		1316.2	944.2
Solubility			
HF[a]	Dissolves rapidly	Dissolves	
HCl[b]	Slow attack	No action	
H_2SO_4[b]	Slow attack	Slow attack	
HNO_3[b]	Surface attack	No action	
NaOH[b]	Slow attack	No action	

[a] Hot 40 wt %.
[b] Hot concentrated.

Titanium Monoxide. Titanium monoxide [CAS: 12137-20-1], TiO, has a rock-salt structure but can exist with both oxygen and titanium vacancies. For stoichiometric TiO, the lattice parameter is 417 pm, but varies from ca 418 pm at 46 atom % to 416_2 pm at 54 atom % oxygen. Apparently, stoichiometric TiO has ca 15% of the Ti and O sites vacant. At high temperatures (>900 °C (1,652 °F)), these vacancies are randomly distributed; at low temperatures, they become ordered. Titanium monoxide may be made by heating a stoichiometric mixture of titanium metal and titanium dioxide powders at 1,600 °C (2,912 °F).

Titanium Sesquioxide. Ti_2O_3 has the corundum structure. At room temperature it behaves as a semiconductor having a small (0.2 eV) band gap. At higher temperatures, however, it becomes metallic. This is associated with marked change in the mean Ti–Ti distance. As with TiO, titanium sesquioxide, Ti_2O_3, may be made by heating a stoichiometric mixture of titanium metal and titanium dioxide powders at 1,600 °C (2,912 °F) under vacuum in an aluminum or molybdenum capsule.

Trititanium Pentoxide. Trititanium pentoxide, Ti_3O_5, may be made by the reduction of titanium dioxide by hydrogen at 1300 °C. The low temperature form is monoclinic. Above 177 °C, Ti_3O_5 has a distorted pseudobrookite structure, which can be stabilized at lower temperatures by small amounts of iron.

Hydrated Titanium Oxides. Hydroxides of Ti(II) (black) and Ti(III) (brown) are precipitated when an alkali metal hydroxide is added to a solution of the corresponding salt. These precipitates, though difficult to purify, are powerful reducing agents and readily oxidize in air to form a hydrated titanium dioxide.

Hydrolysis of solutions of Ti(IV) salts leads to precipitation of a hydrated titanium dioxide. The composition and properties of this product depend critically on the precipitation conditions, including the reactant concentration, temperature, pH, and choice of the salt. At room temperature, a voluminous and gelatinous precipitate forms. This has been referred to as orthotitanic acid [CAS: 20338-08-3] and has been represented by the nominal formula $TiO_2 \cdot 2H_2O$ ($Ti(OH)_4$). The gelatinous precipitate either redissolves or peptizes to a colloidal suspension in dilute hydrochloric or nitric acids. If the suspension is boiled, or if precipitation is from hot solutions, a less-hydrated oxide forms. This has been referred to as metatitanic acid [CAS: 12026-28-7], nominal formula $TiO_2 \cdot H_2O$ ($TiO(OH)_2$). The latter precipitate is more difficult to dissolve in acid and is only soluble in concentrated sulfuric acid or hydrofluoric acid.

Titanium Dioxide. Titanium dioxide [CAS: 13463-67-7] occurs in nature in three crystalline forms: anatase [CAS: 1317-70-0], brookite [CAS: 12188-41-9], and rutile [CAS: 1317-80-2]. These crystals are essentially pure titanium dioxide but contain small amounts of impurities, such as iron, chromium, or vanadium, which darken them. Rutile is the thermodynamically stable form at all temperatures and is one of the two most important ores of titanium. Large deposits of anatase-bearing ore occur in Brazil.

Titanium Compounds, Organic. Organic titanium compounds are materials having a covalent bond between titanium and another atom that is also bonded to a carbon-based group. Titanium tetrachloride [CAS: 7550-45-0], $TiCl_4$, the basic raw material from which organic titanate compounds are made, is readily converted to tetraisopropyl titanate, TYZOR TPT [546-68-9], by the Nelles process. This ester can be converted by alkoxy exchange (transesterification) to a wide variety of tetraalkyl titanates, sold commercially worldwide. The tetraalkyl titanates react with other ligands and chelating agents, eg, glycols, β-diketones and ketoesters, α-hydroxycarboxylic acids, and alkanolamines, to give complexes having properties significantly different from the starting materials. These complexes are also important items of commerce. See also **Chelates and Chelation**; and **Glycol**.

True organometallic compounds having a titanium–carbon bond are prepared from $TiCl_4$ by reaction with main-group organometallics, such as organomagnesium, sodium, or lithium reagents. Most simple C–Ti bonds are very unstable. The predominant exceptions are bis(cyclopentadienyl)titanium dichloride [CAS: 1271-19-8] and its analogues. Many organometallics and complexes of trivalent titanium are stable at room temperature, but most are attacked by oxygen and moisture. Organic derivatives of divalent titanium are much less common. Titanium(II) and titanium(0) are potent reducing agents.

Titanium alkoxides (titanate esters) are superb catalysts for esterification, transesterification, and cross-linking of ester-containing resins and epoxides. Water-soluble titanium chelates are widely used in cross-linking (gelling) of dilute polysaccharide solutions, which are used in oil-field fracturing fluid applications. Titanium's great affinity for oxygen atoms is reflected in its bonding to oxide surfaces, such as glass and plastic, to yield a scratch-resistant oxide coating. Titanates are also used to cross-link silicone resins and as curing agents for wire coatings. Titanates are also used to cross-link silicone resins and as curing agents for wire coatings. Titanates disperse pigments and often help bond resins to fillers and reinforcement agents, eg, fiber glass.

TITANIUM DIOXIDE. [CAS: 13463-67-7], TiO_2, formula weight 79.90, variously colored, depending upon source, but white when purified and sold in commerce. Decomposes at about 1,640 °C (2,984 °F) before melting, density 4.26 g/cm^3, insoluble in H_2O, soluble in H_2SO_4 or alkalies. Titanium dioxide is a very high-tonnage material and is the principal white pigment of commerce. The compound has an exceptionally high refractive index, great inertness, and a negligible color, all qualities that make it close to an ideal white pigment.

Titanium dioxide occurs in nature in three crystalline forms: anatase [CAS: 1317-70-0], brookite [CAS: 12188-41-9], and rutile [CAS: 1317-80-2]. These crystals are essentially pure titanium dioxide but contain small amounts of impurities, such as iron, chromium, or vanadium, which darken them. Rutile is the thermodynamically stable form at all temperatures and is one of the two most important ores of titanium. Large deposits of anatase-bearing ore occur in Brazil.

Anatase and rutile are produced commercially, whereas brookite has been produced by heating amorphous titanium dioxide, which is prepared from an alkyl titanate or sodium titanate [CAS: 12034-34-3] with sodium or potassium hydroxide in an autoclave at 200–600 °C (392-1,112 °F) for several days. Only rutile has been synthesized from melts in the form of large single crystals. More recently, a new polymorph of titanium dioxide, TiO_2 (B), has been demonstrated, which is formed by hydrolysis of $K_2Ti_4O_9$ to form $H_2Ti_4O_9 \cdot H_2O$, followed by subsequent calcination/dehydration at 500 °C (932 °F). Crystallographic information on the different forms of titanium dioxide is summarized in Table 1.

It is accepted that, at normal pressures, rutile is the thermodynamically stable form of titanium dioxide at all temperatures. Calorimetric studies have demonstrated that rutile is more stable than anatase and that brookite and TiO_2(ii) have intermediate stabilities, although the relative stabilities of brookite and TiO_2(ii) have not yet been defined. The transformation of anatase to rutile is exothermic, eg, 12.6 KJ/mol, although lower figures have also been reported. The rate of transformation is critically dependent

TABLE 1. DIFFERENT FORMS OF TITANIUM DIOXIDE

Property	TiO_2 (B)	Anatase	Brookite	Rutile	α-PbO_2 form

on the detailed environment and may be either promoted or retarded by the presence of other substances. For example, phosphorus inhibits the transformation of anatase to rutile.

The commercially important anatase and rutile both have tetragonal structures; consequently, the values of physical properties such as refractive index and electrical conductivity depend on whether these are being measured parallel or perpendicular to the principal, ie, *c*, axis. However, in most applications, this distinction is lost because of random orientation of a large number of small crystals. It is thus the mean value that is significant.

Both anatase and rutile are broad band gap semiconductors in which a filled valence band, derived from the O 2*p* orbitals, is separated from an empty conduction band, derived from the Ti 3*d* orbitals, by a band gap of ca 3 eV. Consequently the electrical conductivity depends critically on the presence of impurities and defects such as oxygen vacancies. For very pure thin films, prepared by vacuum evaporation of titanium metal and then oxidation, conductivities of have been reported. For both single-crystal and ceramic samples, the electrical conductivity depends on both the state of reduction of the TiO_2 and on dopant levels.

Two major processes are used for producing raw titanium dioxide pigment: (1) the sulfate process, a batch process accounting for over half of current production, introduced by European makers in the early 1930s; and (2) the chloride process, a continuous process, introduced in the late 1950s and accounting for most of the new plant construction since the mid-1960s. The sulfate process can handle both rutile and anatase, but the chloride process is limited to rutile.

In the sulfate process, ilmenite (45–60% TiO_2) or a slag rich in titanium (70% TiO_2) obtained from electric smelting of ilmenite, is the feedstock. The raw materials first are digested: $FeTiO_3 + 2\ H_2SO_4 \rightarrow FeSO_4 + TiO \cdot SO_4 + 2\ H_2O$. In a second step, the concentrated liquor is nucleated, diluted with H_2O, and boiled until nearly all of the titanium has precipitated out in the form of flocculated titanium dioxide (anatase) hydrate: $TiO \cdot SO_4 + 2H_2O \rightarrow TiO_2 \cdot H_2O + H_2SO_4$. After filtering, the cake is leached under reducing conditions to remove residual iron. Conditioning agents are added, after which the hydrate is dried and calcined in a rotary kiln at approximately 900 °C: $TiO_2 \cdot H_2O \rightarrow TiO_2 + H_2O$. The conditioning agents usually consist of a phosphate and a potassium salt, as well as zinc, antimony, and aluminum compounds. The purpose of these additions is to improve the final properties of the pigment, including color, photochemical stability, and dispersibility, as well as to catalyze the formation of rutile from the anatase hydrate.

In the chloride process, the feedstock must be high in titanium and low in iron. Mineral rutile (95% TiO_2) is best suited, but leucoxene (65% TiO_2) can be used. See also **Brookite**. An economical conversion of ilmenite for use as a chloride process feedstock has not been developed to date. The ore is mixed with coke and chlorinated at about 900 °C in a fluidized bed. The principal product is titanium tetrachloride, but other impurities including iron also are chlorinated and thus must be removed by selective condensation and distillation. Up to this point, the process is similar to that of producing titanium metal as described under **Titanium**. Normally, the first stage in the preparation of pure titanium dioxide is repeated distillation of titanium tetrachloride. A number of different routes may then be followed, the choice depending on the use for which the titanium dioxide is required.

Hydrolysis in aqueous solution precipitates hydrated titanium dioxide which, after washing and drying, can be calcined at 800 °C (1,472 °F) to remove water and residual Cl. This method has been the basis of producing titanium dioxide of 99.999% purity. If retaining a high specific surface area is important, it may be convenient to reduce the residual Cl content by Sohxlet extraction rather than calcination. For many electroceramic uses, the millability of the product is as important as the absolute purity. A number of process variants designed to modify particulate morphology have been described. Titanium dioxide with silica, magnesium, and iron contents as low as can be achieved by converting the initial hydrous titanium dioxide precipitated from $TiCl_4$ into the double oxalate [CAS: 10580-02-06] $(NH_4)_2[TiO(C_2O_4)_2]$, recrystallizing this from methanol, and then forming the oxide by calcination. Alternatively, the titanium tetrachloride may be converted into an alkoxide, eg, the often-used titanium isopropoxide [CAS: 546-89-9] (isopropyl titanate), which is then hydrolyzed, washed, and dried. The hydrolysis products have a well-defined spherical morphology but may retain considerable amounts of organic residues.

A high purity titanium dioxide of poorly defined crystal form (ca 80% anatase, 20% rutile) is made commercially by flame hydrolysis of titanium tetrachloride. This product is used extensively for academic photocatalytic studies (70). The gas-phase oxidation of titanium tetrachloride, the basis of the chloride process for the production of titanium dioxide pigments, can be used for the production of high purity titanium dioxide, but, as with flame hydrolysis, the product is of poorly defined crystalline form unless special dopants are added to the principal reactants.

Nonpigment Uses. Welding electrodes, used in shielded metal-arc welding, consist of a mild steel or stainless-steel core wire coated with a flux layer. The TiO_2 is used as a fluxing agent, slag former, and shade modifier in the electrode, with other minerals performing gas shielding, fluxing, and extrusion aid functions. There are many different types of electrodes produced for different applications. The electrodes are classified by the American Welding Society, www.aws.org/ and other worldwide organizations relating to their strengths and uses. Certain electrodes can be used for flat and horizontal welds and others only for flat-welding applications. The electrodes have special properties and formulations, depending on their applications. Certain fluxes are produced with high

sodium and iron oxide levels; others with low potassium or hydrogen levels, or high titanium and sodium mixes. The flux coverings dictate the application of the electrode, its tensile strength, and whether they can be applied with alternating current or direct current. The composition of the electrode flux covering determines the performance of the electrode and the soundness of the weld. The thickness of the flux cover varies from 10 to 55% of the diameter of the electrode. These coverings are usually applied by extrusion of the flux onto the core wire using a blend of sodium and potassium silicate solution as the binder. Stainless-steel core wires require different coverings because of reactivity.

The ultimate formulation, involving the use of different minerals, will produce different arcs. Some yield a semiglobular viscous slag that allows welding of joints with a poor "fit." Others are used at higher welding currents due to their low cellulose content and high refractory material content, ensuring more specialized welding. Use of electrodes containing more potassium permits the use of low open-circuit voltage, which is a common application for welding sheet materials.

Rutile, or a TiO_2 substitute, is consumed in the flux covering, in the range of 30–55%, depending on the grade. Welding electrode manufacturers prefer natural rutile or leucoxene, because the product is crystalline and contains higher concentrations of TiO_2. Ilmenite and synthetic rutile (SR) are also being considered as a feedstock, but because of the porous nature of the (SR), more silicates are required to ensure effective extrusion of the flux. Also, because natural rutile is in short supply, some specialized welding rod flux coverings contain untreated anatase TiO_2 pigments. Synthetic rutile is also more red in color than natural rutile; therefore, some carbon-black pigment has to be added to match the color of the "natural" electrodes. This is more for cosmetic than physical purposes since the color does not affect the welding properties of the electrode.

Stainless-steel electrodes have different impurity criteria than do mild steel electrodes. Here the Cr and Ni contents are critical. Iron must also be kept under control to prevent a slight "running" problem in vertical down welding. Some adjustments of the flux formulations have to be made to prevent this problem from occurring.

Mild steel electrodes are sensitive to sulfur and phosphorous levels. These will affect the strength of weld metal. In certain applications the sulfur also makes the weld brittle, and phosphorus can cause pitting of the welds. Particle size is important. A uniform, but fine, particle size is required to ensure even covering of the electrode. The stainless industry require a product that is minus 70 Tyler mesh.

The traditional ceramic applications of titanium dioxide are in vitreous enamels, thread guides for the fibers industry, and electroceramics. In enamels used on steel and cast iron, titanium dioxide makes up part of the raw-material batch and dissolves during frit smelting. As the enamel cools and fuses to its substrate, the titanium dioxide recrystallizes and confers both improved opacity and acid resistance. To avoid color effects, elements such as tungsten and niobium must be carefully controlled. For ease of handling, it is convenient to use a coarse grade of TiO_2. Thread guides for the fiber industry are made by firing anatase or rutile at ca 1,300 °C (2,372 °F) to produce a dense ceramic that can be polished to allow easy drawing of the fiber over the guides during spinning.

In the rubber and leather industries, a small quantity of TiO_2 incorporated into the finished product imparts a high degree of whiteness while permitting most of the natural properties of the rubber or leather to be retained.

The fact that TiO_2 is chemically and biologically inert means that it can be used for cosmetics, soap, pharmaceuticals, and certain types of foodstuffs, where whiteness is considered to be important for marketing reasons. TiO_2 is finding increasing use as a uv-A and uv-B absorber in sunscreens.

TiO_2 can be used as a single-crystal electrode for the electrolysis of water to produce hydrogen, and this may well become the basis for important applications of TiO_2 if hydrogen fuel cells become accepted for powering vehicles, submarines, spacecraft, etc. TiO_2 has also been used in thermistors to measure temperature changes at elevated temperatures or in difficult environments.

Pigmentary Titanium Dioxide. The most important commercial use of titanium dioxide is as a white pigment in a wide range of products, including paint, plastics, paper, and inks. Because of its opacifying properties, TiO_2 is used not just in whites but to opacify colored systems also. Titanium dioxide is the predominant white pigment both because of its high refractive index and because technology has been developed to allow the right size range and the necessary chemical purity. See also **Inks**; **Paint Architectural**; and **Paints and Coatings**.

In order to appear white, a pigment must have minimal optical absorption at visible wavelengths. For titanium dioxide, this in turn requires high chemical purity; in particular, transition-metal impurities must be eliminated as far as possible. Because titanium dioxide pigments do not significantly absorb visible light, their opacity derives from their ability to scatter light. Light scattering by particles depends on their refractive index. A measure of the effect of refractive index on opacity can be achieved by using a simplified form of an equation introduced by Fresnel, which gives the reflectivity, R, of a coating by

$$R = \frac{(n_p - n_m)^2}{(n_p + n_m)^2}$$

where n_p is the refractive index of the pigment and n_m the refractive index of the medium in which the pigment is dispersed. This is 1 for air and typically ca 1.5 for an alkyd paint resin. Hence, the higher the value of the pigment refractive index, the higher its potential opacity. Both anatase and rutile are used as white pigments, and scatter light more efficiently than other oxides. Because of its higher refractive index, rutile has a higher opacity than anatase and is more widely used. Anatase is, however, used for many specialized applications, eg, in paper and in fibers, where the lower abrasivity of anatase causes less wear on thread guides and other spinning equipment. In order to realize the maximum scattering power, the pigment particles must be of the correct size, ie, light-scattering is a function of $d\lambda$, where d is the diameter of the scattering particle and λ the wavelength in a particular medium of the light. Maximum scattering of visible (400–700 nm) light occurs for pigment particles of ca 300 nm and the scattering efficiency decreases rapidly as the particle size varies from the optimum. This decrease is by about 60% for particles twice the optimum size. Therefore careful control of particle size is necessary. Two further desirable properties are that titanium dioxide is nontoxic and that its density (ca 4000 kg/m^3) is sufficiently low as not to cause excessively rapid settling of the pigment particles in paint. Although titanium dioxide does not absorb visible light, it is a strong absorber of uv radiation. In paints opacified with titanium dioxide, the pigment protects the organic film-forming molecules from photochemical degradation by solar uv. However, absorption of UV by TiO_2 can lead to the generation of hydroxyl radicals, which cause the pigment to act as a photocatalyst. The net effect of the pigments on the uv stability, ie, the durability, of a paint is a balance between the protective and photocatalytic effects. In order to ensure that the actual effect is beneficial, the photocatalytic effect of the pigment is minimized by coating the pigment with hydrous oxides, eg, silica and alumina, during manufacture. This coating treatment is also applied to facilitate good pigment dispersion in the medium of application. Good dispersion ensures that the pigment scatters light efficiently and does not contribute to any surface roughness that would otherwise reduce the gloss of, eg, the final paint.

Surface Coatings. Although white pigments are used in virtually all types of surface coatings, their principal use is in liquid paints (because they are more highly pigmented than most other surface coatings) and to an increasing extent, powder coatings.

Surface coatings in which TiO_2 is used are generally categorized according to their end-use applications. A list of the types of surface coating that make up the major markets for TiO_2 is given in Table 2.

In the United States, TiO_2 pigments for surface coatings are frequently classified according to the ASTM D476-84 standard. This standard defines four types of TiO_2:

Type I: Anatase, free chalking
Type II: Rutile, medium chalk resistance for low-pigment-volume-concentration) (PVC) coatings
Type III: Rutile, medium chalk resistance for medium/high PVC coatings
Type IV: Rutile, highly chalk-resistant

[a] IBMA.

All anatase pigments are classified under Type I and have a minimum of 94% TiO_2. Type II rutile pigments have some degree of surface treatment to enhance their dispersibility and their weatherability. They have a minimum of 92% TiO_2. Types III and IV pigments generally have greater amounts of surface treatments to further improve their weatherability characteristics. Each grade specifies a minimum TiO_2 level of 80%.

In Europe, the grading system is defined by the International Standard ISO 591-1977 (1985), which is somewhat different from the ASTM standard. The ISO standard divides TiO_2 pigments into two Type A anatase grades, and three Type R rutile grades:

Grade A1 is uncoated anatase pigment; Grade A2 is the coated type. Grade R1 is basically an uncoated grade, that is, made with little or no posttreatment. Grades R2 and R3 are increasingly surface treated, with the majority of rutile pigment production currently falling into the R2 category.

Plastics. The plastics industry is the largest user of TiO_2 after the surface coatings industry, consuming approximately 20% of the world's production of the pigment. TiO_2 itself represents over 65% of the colorants used by the plastics industry.

In their unpigmented state most plastics are either clear or at least somewhat translucent. Except in a few cases, the translucence is due to the various additives incorporated into the pure resins to modify their properties and make them more suitable for their intended end-use applications.

Plastics applications can be divided into two very large and diverse groups: those in which the material is used in a transparent or translucent condition, and those in which complete opacity is required, either for esthetic or practical reasons.

As in the case of surface coatings, it has long been established that the most cost-effective white pigment for the majority of plastics is TiO_2 because of its many excellent properties. An additional property of TiO_2 pigments — dispersibility — is critically important in plastics because uniform dispersion of the pigment within the plastic matrix is needed to impart maximun opacity without causing a loss of physical or optical properties. Organic surface treatments on the TiO_2 pigments are utilized to facilitate their dispersion in the viscous molten plastic resin. It is believed that TiO_2 currently accounts for over 90% of the inorganic pigments used in plastics. This figure excludes extenders, or fillers, large tonnages of which are used in certain plastics applications, such as flooring, to lower the cost of the final product.

Because of the many pigment properties involved in the use of pigments in plastics, there are a large number of TiO_2 grades marketed for use in the plastics industry. Some TiO_2 producers offer many different grades, covering most possible applications and suggesting more than one grade for many applications to give the formulator a wide degree of flexibility in selecting pigments for specific end-uses. Other producers offer only a few grades to the plastics industry that are designed to cover most plastics applications. See also **Plastics**.

Paper. Although the use of TiO_2 in paper far exceeds that used in coatings for paper and paperboard, the quantities going into coatings have increased greatly in the late 1990s. In North America, TiO_2 accounts for about 4% of the total tonnage of fillers used; in Europe, the amount is less than 1%. Because TiO_2 costs 10–15 times as much as the other inorganic fillers, the value of the TiO_2 used by the paper industry is roughly equivalent to that of all other fillers combined. Worldwide, about 12% of TiO_2 production goes into the paper industry. See also **Paper**; and **Papermaking and Finishing**.

In printing papers, which are derived from highly refined and high-strength pulps, the major criterion for TiO_2 pigments is opacity, especially since double-sided color printing is often used. In writing papers and carton boards, the major criterion is whiteness.

Coatings for paper and paperboard are widely and extensively used. Generally a coating consists of a binder, additives, and pigment. Although traditionally, low-cost natural products such as starch and casein were used as binders, synthetic polymeric resins have played an increasing role in their formulation. Additives for paper coatings have much the same function as they do in surface coatings; they are used as levelers, defoamers, rheology modifiers, dispersing aids, and other agents. Fillers often make up as much as 70–90% of the dry weight of the coatings. Most of the filler is kaolin clay and varieties of calcium carbonate. Calcium carbonate is added to impart whiteness to a coating. In coatings for applications in which opacity and brightness of are of prime concern, small amounts of TiO_2 are added to the fillers.

Anatase TiO_2 has traditionally been used in coatings because of its lower cost, and, since it is softer than rutile pigments, anatase pigments may cause less abrasive wear on papermaking machines. In the late 1990s, however, rutile has made major inroads into the coatings market. In those applications in which an optical brightener has been added, however, anatase is preferred.

Laminated papers are used to manufacture both high- and low-pressure decorative Formica-type laminates. A high pressure laminate is a construction consisting of 8–10 layers of resin impregnated paper converted by heat and pressure into a plasticlike material. The face is a translucent sheet of textured or untextured melamine resin treated paper. The second layer is the printed pattern (often wood grain) or colored sheet, which is also melamine resin impregnated. The remaining sheets are phenolic resin impregnated kraft filler papers. The sandwich construction is heated to a temperature in excess of 265 °C (509 °F) and compressed to pressures as high as 82.6×10^3 Pa (1200 psi) for a period of 60–90 min to convert the sandwich to a printed, textured rigid plastic laminate. High-pressure laminates are typically used for horizontal surfaces experiencing wear and abrasion such as counter tops and furniture wear surfaces.

TiO_2 pigments are used to impart brightness and opacity to the face papers in the laminate construction and often to impart opacity to the entire construction. Pigment loadings will vary considerably according to the base papers used — their color, weight, composition, and other variable factors. The whiter the paper, the greater the loading of pigment. Rutile pigments are used exclusively in paper laminates. Loadings for the whitest face papers can be as much as 50% of the furnish, and as low as 20% for the entire laminate construction.

Anatase TiO_2 has traditionally been more widely used than rutile for most filler or paper stock applications for opacity, with the exception of resin-bonded laminate papers and waxed papers. The preference for the anatase form grew from the fact that it has a lower specific gravity and is therefore better retained at the wet end of the paper machine and that it imparts a cold blue white appearance instead of the yellow cast imparted by rutile. Also, the anatase crystal is softer than rutile and is less abrasive of rollers, calendars, and other paper-contacting components of papermaking machinery. However, over the years Du Pont has developed applications technology to overcome rutile's shortcomings, and rutile has

steadily grown in paper stock because of its superior opacity compared to anatase. Presently, more than half the TiO_2 used in paper stock is rutile.

In coatings, however, rutile is much more widely used because its brightness and opacity is superior to that of anatase in most coatings applications. It is almost always used in conjunction with other fillers such as clays. If, however, the coating or the paper is formulated to contain optical brighteners, anatase may be preferred because it absorbs less uv radiation than rutile, thus leaving more uv available for the optical brighteners. Also, rutile TiO_2 tends to floculate fluorescent whitening agents in some paper-coating formulations. Fluorescent whitening agents are often used as optical brighteners.

Printing Inks. A small but important market for TiO_2 is in printing inks. Although carbon black is the major pigment used in the manufacture of printing inks, decorative printing would be much less vividly rendered and less attractive without the use of TiO_2. The use of TiO_2 in printing inks has much in common with its use in surface coatings. Thus, printing inks may be considered a highly specific type of surface coating, but with several significant differences. Most of these arise from the fact that ink films are generally much thinner than those of surface coatings. See also **Inks**.

Synthetic Fibers. TiO_2 is widely used as a delusterant for a number of synthetic fibers. Its presence in small amounts (1–2%) helps to diffuse the intrinsic high-gloss appearance of many such fibers. This enables them to take on an appearance more like that of the natural fibers, most of which have a more or less dull surface. The presence of TiO_2 also increases the whiteness and opacity of the fibers and decreases the tendency of some fibers towards translucency.

Ceramics. There are a number of applications for TiO_2 in ceramics. In most of these, TiO_2 is utilized for its chemical properties rather than as a white pigment. In some applications, TiO_2 is used to produce a white hue in a ceramic glaze. In the manufacture of certain types of glass, the high refractive index of TiO_2 is utilized for its effect on the overall refractive index of the glass. TiO_2 has long been used in the preparation of vitreous (porcelain) enamels for coating glass, aluminum, steel, cast iron, and other materials. In this application, it reacts with the other components of the feedstock mixture, including borax, feldspar, quartz, fluorspar, soda, and metal oxides.

Relatively coarse grades of TiO_2 are made for enameling, and it is important that the concentrations of tungsten and niobium in the feedstock be minimized because even small traces of these elements discolor the enamel. The inclusion of TiO_2 in the feedstock mixture improves its resistance against acid attack and enhances opacity, thus making it possible to use thinner coats of enamel and thereby reducing the risk of flex-induced cracking. Enamels of this type are used for domestic appliances, road signs, sanitarywares, and other applications.

Because of its unique photocatalytic properties, TiO_2 is widely used in electroceramics, such as for the manufacture of miniature ceramic capacitors. For this purpose, high-purity rutile-type TiO_2 is pressed into the required shape, then heated until the particles sinter at 1,400–1,450 °C (2,552-2,642 °F). On a worldwide basis, growth in electroceramics has more than offset a decline in enameling usage, so that overall there has been slight growth in TiO_2 consumption in the ceramics industry.

See also **Titanium**.

TIT *(Aves, Passeriformes)*. A small insect-eating bird of agile habits and friendly nature, exemplified by the chickadees, *Penthestes*, and titmice, *Baeolophus*, of North America. They are chiefly birds of the northern hemisphere, but the group is represented in the Australian region. The colors of most species are quiet, ranging from white to black through bluish grays, relieved by a limited amount of buff or chestnut. The blue tit, *Parus caeruleus*, and the azure tit, *P. cyanus*, of the Old World, however, are much more brightly colored, as their names imply.

In North America some species of chickadee is to be found in almost every locality, while titmice occur in the far west and in the states east of the Mississippi.

These species are usually fearless, and although they have no reputation as singers their cheery calls are always welcome. In the winter, they visit feed boxes readily, and they soon become accustomed to close observation if the observer avoids sudden movements. See also **Chickadee**.

TITEL. See **Antelope**.

TITRATION COULOMETER. See **Coulometer**.

TITRATION (Potentiometric). This analytical method is based in principle upon the Nernst equation, which may be written in the form

$$E = E^0 - \frac{0.059}{n} \log \frac{A_{ox}}{A_{red}}$$

where E is the measured electromotive force, E^0 is the standard value of the electromotive force (electrode potential) when the substances of the electrochemical reaction are in their standard states, n is the valence change (change in number of electrons per mole of the reactants) and the A-terms are the activities of the oxidized and reduced forms of the reactants. See also **Activity Coefficient**. Activities are proportional to concentrations, so that the concentration of one of the reactants may be determined if that of the other is known. Thus the concentration of Cu^{2+} ions in a solution could be found by use of an electrode of metallic copper (unstrained metals are assumed to be at unit activity). Or the concentration of Cl^- ions in a solution could be found by use of an electrode of (insoluble) silver chloride AgCl deposited on an electrode of metallic silver. Or the concentrations in a solution containing two ions in different states of oxidation, such as Fe^{2+} and Fe^{3+}, could be found by the use of an inert electrode, such as one of platinum. The three reactions and corresponding forms of Nernst's equation (using the approximation of substituting concentrations for activities) are:

$$Cu^0 \rightleftharpoons Cu^{2+} + 2e^-$$

$$E = E^0 - \frac{0.0591}{2} \log c_{Cu^{2+}}$$

$$Ag^+ + Cl^- \rightleftharpoons AgCl \downarrow$$

$$E = E^0 - (0.0591) \log K_{sp} + (0.0591) \log c_{Cl-}$$

(where K_{sp} is the solubility product of AgCl)

$$Fe^{2+} \rightleftharpoons Fe^{3+} + e^-$$

$$E = E^0 - (0.0591) \log \frac{c_{Fe^{3+}}}{c_{Fe^{2+}}}$$

In constructing an electric cell for potentiometric titrations it is necessary, of course, to use a second electrode to complete the circuit, in addition to the measuring electrodes (commonly called *indicator electrodes*) described above. Ideally the second electrode would be a hydrogen electrode which (as explained in the entry on electrode potential) is the standard reference electrode for which the potential, in equilibrium with its ions, is defined as zero. Since it is awkward to use, other electrodes of known potential, such as the calomel electrode or the glass electrode, are commonly used as reference electrodes. The arrangement of the apparatus is as shown in Fig. 1.

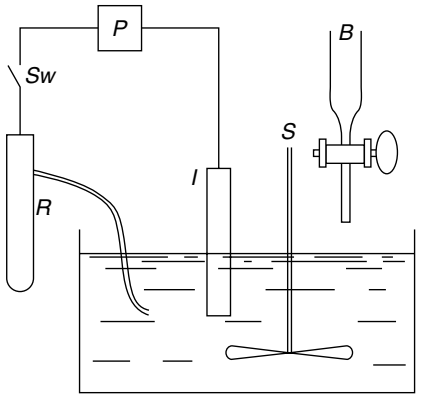

Fig. 1. Apparatus for potentiometric titration: (*R*) reference electrode; (*I*) indicating electrode; (*P*) potentiometer; (*B*) burette; (*S*) stirrer; (*Sw*) switch.

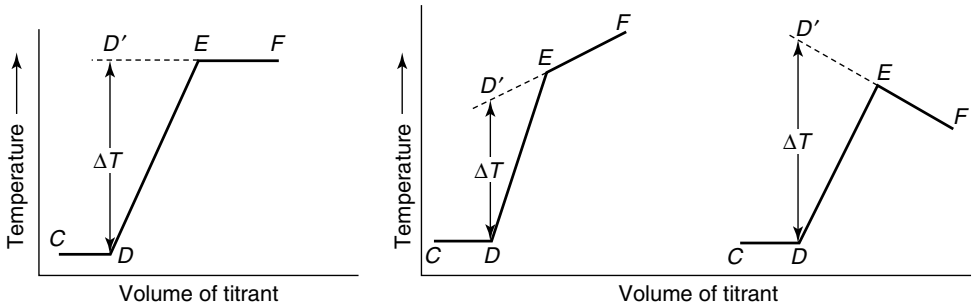

Fig. 1. Thermometric curves for an exothermic reaction (ideal).

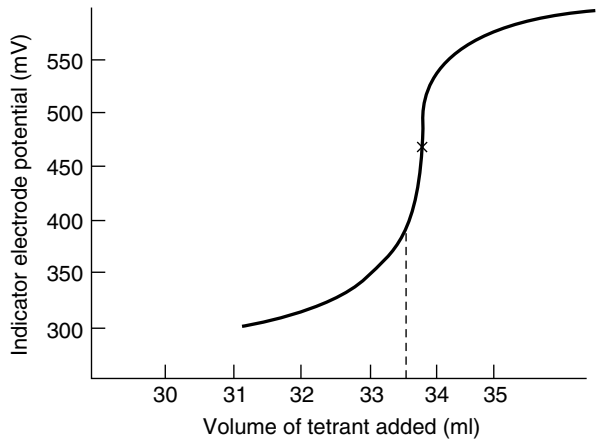

Fig. 2. Potentiometric titration curve.

The procedure in a potentiometric titration is to determine the potential of the indicator electrode after each addition of the titrating solution. This is done by closing the switch in the circuit shown in Fig. 1 just long enough to read the potential on the sensitive measuring device used, such as a potentiometer or vacuum tube voltmeter. Of course, very small additions of titrant are made as the expected endpoint is approached. Then the readings of potential are plotted against volume of titrant added, as shown in Fig. 2. Reactions suitable for determination by this method show sharply defined endpoints as pictured in the figure. To correspond to the true stoichiometric endpoint, certain conditions should be met, including reversibility of the reaction and allowing time for the electrodes to reach equilibrium before closing the switch to read the potential difference. While the description given was on the basis of titration with zero current drawn from the electrodes between readings, there is also a method in which a small constant current is drawn, not large enough to affect their potentials, but serving to eliminate some of the sources of error in the null method.

Types of titrations for which potentiometric methods of determining endpoints are particularly useful including titrations of halide mixtures, of various metals, of alkaloids, in non-aqueous solvents, and various titrations with oxidizing agents, such as permanganate, dichromate, iodate, and ceric sulfate.

TITRATION (Thermometric). This technique consists of the detection and measurement of the change in temperature of a solution as the titrant is added to it, under as near adiabatic conditions as possible. Experimentally, the titrant is added from a constant-delivery burette into the titrate (solution to be titrated) which is contained in an insulated container such as a Dewar flask. The resultant temperature-volume (or time) curve thus obtained is similar to other titration curves, e.g., acid-base, in that the end point of the reaction can be readily ascertained. Since all reactions involve a detectable endothermic or exothermic enthalpy change, the technique has potentially wide application in analytical chemistry, especially in those cases where other more common methods are not applicable.

Several idealized thermometric titration curves for an exothermic reaction are given in Fig. 1. A titration curve in which the titrant and the titrate are at the same initial temperature is illustrated in (a). The actual titration is preceded by a blank run, *CD*, in which no titrant is added to the titrate. At *D*, titrant is added, causing the temperature of the titrate to rise rapidly, reaching a maximum value at *E*. Beyond *E*, additional titrant causes no further change in the temperature of the titrate, hence, the horizontal excess reagent line, *EF*. The temperature rise of the titrate (and titration vessel), ΔT, is obtained by determining the vertical distance between the excess reagent line, ED', and *CD*. In curve (b), the conditions of the titration were identical to those of (a) except that the titrant was at a higher temperature than the titrate, hence, the sloping excess reagent line, *EF*. For curve (c), conditions were also identical to the above except that the titrant was at a lower temperature than the titrate. The excess reagent line, *EF*, thus slopes in an opposite direction to that of curve (b). For an endothermic reaction, the curves would be identical to the above except that the temperature changes would be in an opposite direction.

TOAD. See **Frogs and Toads**.

TOAD BUG *(Insecta, Hemiptera).* A small broad bug found on the muddy shores of ponds and streams. It is peculiarly like a toad in appearance and habits, capturing insects as prey and burrowing at times. Only a few species are known.

TOADSTOOL. See **Agarics**; **Basidiomycetes**; and **Fungus**.

TOBACCO WORM *(Insecta, Lepidoptera).* The caterpillar of a large sphinx moth, *Protoparce sexta*, which eats the leaves of tobacco, tomato, and other plants. The moth is gray with a row of six orange spots on each side of the abdomen and the larva is green, about 3 inches (7.5 centimeters) long, with a stout horn near the caudal end of the body. Its sides are marked with oblique whitish lines.

Crop rotation as prescribed for the region involved, and dusting with lead arsenate (see also **Lead**), are effective methods of control on large fields. The larvae are so easily seen when they become large enough to cause severe damage that hand picking is effective on truck crops of smaller extent.

Tobacco is attacked by other caterpillars, hence the term tobacco worm is not always restricted to this form.

TOCOPHEROLS. See **Vitamin E**.

TODD, ALEXANDER ROBERTUS (1907–1997). A. R. Todd was a Scottish organic chemist and Nobel Prize winner who elucidated the structure of nucleotides.

Todd was born in Glasgow and read chemistry at its university before taking a doctorate on bile acids (1931) at the university of Frankfurt and a second doctorate on the synthesis of anthocyanins (1933) under R. Robinson at Oxford. In 1934 he began work on the structure and successful synthesis of vitamin B_1 in the Medical Chemistry Department at Edinburgh University, which he completed at the Lister Institute of

Preventive Medicine in London in 1936. At Manchester University, where he headed the Department of Chemistry between 1938 and 1944, he worked on vitamin E and the constituents of cannabis. He was Head of Chemistry at Cambridge University from 1944. A statesman of science, he was knighted in 1954 for his government service, and made a life peer in 1962. He was President of the Royal Society 1975–1980. The "Todd Report" (1968) made important recommendations on the modernization of medical education. See also **Robinson, Robert (1885–1975)**.

Todd was awarded the Nobel Prize for Chemistry in 1957 for his elucidation of the structures and syntheses of nucleosides, nucleotides and their coenzymes, as well as the related problems of their phosphorylation. This work was a necessary preliminary to the elucidation of the structure of DNA by James Watson and Francis Crick in 1952. Todd also worked extensively on adenosine triphosphate, vitamin B_{12} and other natural products, including plant and insect pigments. A towering physical presence in organic chemistry, he was nicknamed "Lord Todd Almighty'." He was married to Alison Dale, daughter of the physiologist, Sir Henry Dale. See also **Crick, Francis Harry Compton (1916–2004)**; **Dale, Henry Hallett (1875–1968)**; **Vitamin B_{12} (Cobalamin)**; and **Watson, James Dewey (1928–Present)**.

TODOROKITES. Calcium-bearing manganese oxides found in terrestrial manganese ore depositions, in weathering products of manganese-bearing rocks, and in some manganese nodules. It is quite soft with a Mohs hardness of 1.5 and a specific gravity of 3.49–3.82. Todorokites are, in many instances, principal constituents of manganese nodules. Host copper and nickel within the modules is potentially of economic importance. Knowledge of todorokites is important for understanding how nodules form and how they concentrate transition elements from ocean waters. See **Ocean Resources (Mineral)**. It was discovered in 1934 in the Todroki mine, Hokkaido, Japan.

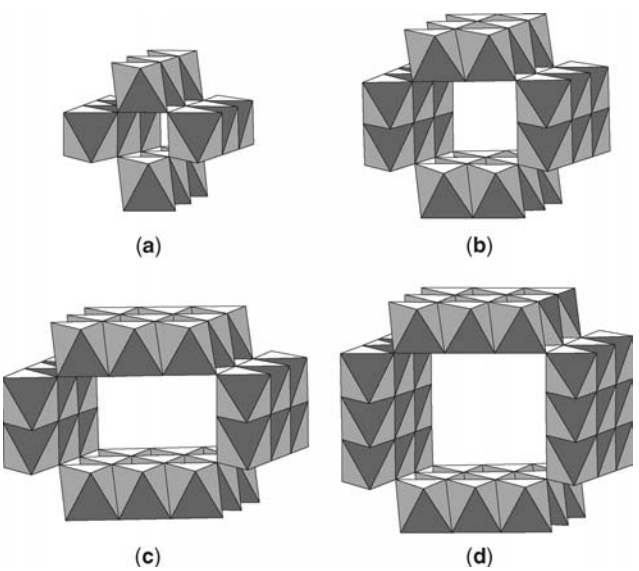

Fig. 1. Diagram of various manganese oxide tunnel structures. The common smallest unit of the structures is a $[Mn^{+3}, Mn^{+4}]O_6$ octahedron. The octahedra are edge linked to form long chains that are corner linked to form the framework of tunnel minerals: (**a**) 1×1, pyrolusite, (**b**) 2×2, hollandite, (**c**) 2×3, romanechite and (**d**) 3×3, todorokite. The larger tunnel structures (hollandite, romanechite, todorokite) can accommodate large cations and water. There are many more possible tunnel structures and those with a common dimension (for instance the double chain sides of hollandite and romanechite) can intergrow on a unit cell level. As far as is now known, todorokite occurs only as an intergrowth of differently sized tunnel structures that have a triple chain in common (3×2, 3×3, 3×5, 3×6, etc.) The 3×3 structure is the most prevalent. (*Source: S. Turner.*)

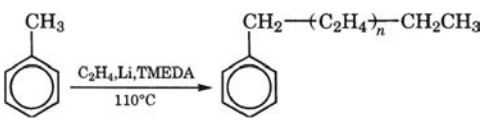
Formerly believed to be a single phase, todorokite was discredited as a mineral by the International Mineralogical Association Commission on New Minerals and Mineral Names in 1970 when evidence was submitted showing it to be a complex mixture of several compounds. As reported by Turner and Buseck (1981), many mineralogists felt the decision was incorrect since recognizable x-ray diffraction patterns could be produced from todorokite collected from widespread deposits. X-ray patterns have not been adequate for structure determination. Further confusion is caused by the variable morphology of todorokite, which appears fibrous in some samples and platy in others. Todorokite material appears to have a range of related structures. High-resolution transmission electron microscopy reveals that terrestrial todorokites consist of tunnel structures of previously unreported dimensions and that these tunnel structures are intergrown coherently on a unit cell scale. As shown in Fig. 1, many types and degrees of disorder are evident. The widespread presence of disorder explains prior confusion with x-ray diffraction patterns and hence the difficulty to relate x-rays studies with specific structures. Turner and Buseck suggested a revised nomenclature of tunnel manganese oxides. This is described in *Science*, **212**, 1024–1027 (1981).

TODY. See **Kingfishers and Other Coraciiformes**.

TOLUENE. Toluene, [CAS: 108-88-3], C_7H_8, is a colorless, mobile liquid with a distinctive aromatic odor somewhat milder than that of benzene. The name toluene derives from a natural resin, balsam of Tolu, named for a small town in Colombia, South America. Toluene was discovered among the degradation products obtained by heating this resin. Prior to World War I, the main source of toluene was coke ovens. At that time, trinitrotoluene (TNT) was the preferred high explosive and large quantities of toluene were required for its manufacture. Petroleum became the source for toluene with the advent of catalytic reforming and the need for large quantities of toluene for use in aviation fuel during World War II. Since then, manufacture of toluene from petroleum sources has continued to increase, and manufacture from coke ovens and coaltar products has continued to decrease.

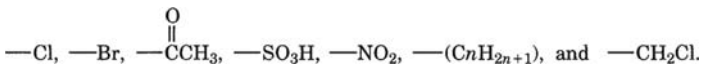
Toluene is generally produced along with benzene, xylenes, and C_9-aromatics by the catalytic reforming of C_6–C_9 naphthas. There have been, ca 1997, recent technological developments to produce benzene, toluene, and xylenes from pyrolysis of light hydrocarbons C_2–C_5, LPG, and naphthas. See also **Xylenes and Ethylbenzene**. About 85–90% of the toluene produced annually in the U.S. is not isolated, but is blended directly into the gasoline pool as a component of reformate and of pyrolysis gasoline.

Derivatives are formed by substitution of the hydrogen atoms of the methyl group, by substitution of the hydrogen atoms of the ring, and by addition to the double bonds. Substitutions on the methyl group are generally high-temperature, free-radical reactions. Thus, chlorination at ca 100 °C, or in the presence of uv or other free-radical initiators, successively gives benzyl chloride, benzal chloride, and benzotrichloride. See also **Benzaldehyde**; and **Benzoic Acid**. With oxygen in the liquid phase, particularly in the presence of a catalyst, good yields of benzoic acid are obtained. In the presence of alkali metals, toluene is alkylated. With a lithium catalyst and a chelating compound, telomers are obtained with ethylene.



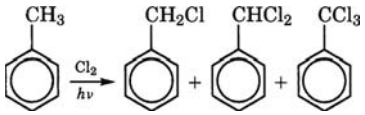
Additions to the double bonds results from both free-radical and catalytic reactions, e.g., chlorination at 0 °C and hydrogenation. Usually, all

three double bonds react. Substitution of the ring hydrogen atoms by electrophilic attack takes place with the same reagents that react with benzene. Some of the common groups with which toluene can be substituted directly include



Under the same conditions, toluene reacts more rapidly than benzene. These reactivities and the related selectivity to the ortho and para positions can be explained in terms of the inductive effect of the methyl group. Toluene requires substitution by strongly negative groups, such as NO_2, to react with anions.

Substitution Reactions on the Methyl Group. The reactions that give substitution on the methyl group are generally high temperature and free-radical reactions. Thus, chlorination at ca 100 °C, or in the presence of ultraviolet light and other free-radical initiators, successively gives benzyl chloride, benzal chloride, and benzotrichloride.



This oxidation reaction which yields benzoic acid is another example of this type of reaction.

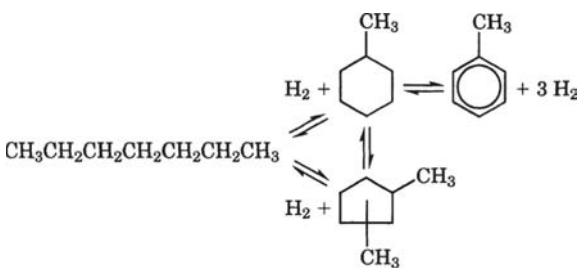
In the presence of alkali metals such as potassium and sodium, toluene is alkylated with ethylene on the methyl group to yield, successively, normal propylbenzene, 3-phenylpentane, and 3-ethyl-3-phenylpentane.

In the formation of π-complexes with electrophiles such as silver ion, hydrogen chloride, and tetracyanoethylene, toluene differs from either benzene or the xylenes by a factor of less than two in relative basicity.

Properties. Physical and thermodynamic properties are given in Table 1. Toluene forms azeotropes with many hydrocarbons and most alcohols that boil in a similar range; all are minimum-boiling azeotropes. Toluene, water, and alcohols frequently form ternary azeotropes.

Because of the high electron density in the aromatic ring, toluene behaves as a base both in the formation of charge-transfer π-complexes and in the formation of sigma complexes. When only π-electrons are involved, toluene behaves much like benzene and xylene. When σ-bonds and complexes are involved, toluene reacts much faster than benzene and much slower than xylenes.

Manufacture and Processing. The principal source of toluene is catalytic reforming of refinery streams. This source accounts for ca 79% of the total toluene produced. An additional 16% is separated from pyrolysis gasoline produced in steam crackers during the manufacture of ethylene and propylene. The reactions taking place in catalytic reforming to yield aromatics are dehydrogenation or aromatization of cyclohexanes, dehydroisomerization of substituted cyclopentanes, and the cyclodehydrogenation of paraffins. The formation of toluene by these reactions is shown.



Of the main reactions, aromatization takes place most readily and proceeds ca 7 times as fast as the dehydroisomerization reaction and ca 20 times as fast as the dehydrocyclization. Hence, feeds richest in cycloparaffins are most easily reformed.

Because catalytic reforming is an endothermic reaction, most reforming units comprise about three reactors with reheat furnaces in between to minimize kinetic and thermodynamic limitations caused by decreasing temperature. There are three basic types of operations, i.e., semiregenerative, cyclic, and continuous. In the semiregenerative operation, feedstocks and operating conditions are controlled so that the unit can be maintained on-stream from 6 mo-2 yr before shutdown and catalyst regeneration. In cyclic operation, a swing reactor is employed so that one reactor can be regenerated while the other three are in operation. Regeneration, which may be as frequent as every 24 h, permits continuous operation at high severity. Since ca 1970, continuous units have been used commercially. In this type of operation, the catalyst is continuously withdrawn, regenerated, and fed back to the system.

The composition of aromatics centers on the C_7- and C_8-fraction, depending somewhat on the boiling range of the feedstock used. Most catalytic reformate is used directly in gasoline. That part which is converted to benzene, toluene, and xylenes for commercial sale is separated from the unreacted paraffins and cycloparaffins or naphthenes by liquid–liquid extraction or by extractive distillation.

Proper choice of feedstocks and use of relatively severe operating conditions in the reformers produce streams high enough in toluene to be directly usable for hydrodemethylation to benzene without the need for extraction. Toluene is recovered from pyrolysis gasoline, usually by mixing the pyrolysis gasoline with reformate and processing the mixture in a typical aromatics extraction unit. Yields of pyrolysis gasoline and the toluene content depend on the feedstock to the steam-cracking unit. Pyrolysis gasoline is hydrotreated to eliminate dienes and styrene before processing to recover aromatics.

TABLE 1. PHYSICAL PROPERTIES OF TOLUENE

Property	Value
molecular weight	92.14
melting point, K	178.15
normal bp, K	383.75
critical temperature, K	591.80
critical pressure, MPa[a]	4.108
critical volume, L/(g · mol)	0.316
critical compressibility factor	0.264
acentric factor	0.262
flash point, K	278
autoignition temperature, K	809
GAS PROPERTIES, 298.15 °K	
H_f, kJ/mol[b]	50.17
G_f, kJ/mol[b]	122.2
C_p, J/(mol · K)[b]	104.7
H_{vap}, kJ/mol[b]	38.26
H_{comb}, kJ/mol[b]	−3734
viscosity, mPa · s(= cP)	0.00698
flammability limits, in air[c], vol%	
lower limit at 1 atm	1.2
upper limit at 1 atm	7.1
LIQUID PROPERTIES, 298.15 °K	
density, L/mol	9.38
C_p, J/(mol · K)[b]	156.5
viscosity, mPa · (= cP)	0.548
thermal conductivity, W/(m · K)	0.133
surface tension, mN · m(= dyn/cm)	27.9
SOLID PROPERTIES	
density at 93.15 °K, L/mol	11.18
C_p at 178.1 K, J/(mol · K)[b]	90.0
heat of fusion at 178.15 °K, kJ/mol[b]	6.62

[a] To convert MPa to psi, multiply by 145.
[b] To convert J to cal, divide by 4.184.
[c] At 101.3 kPa (1 atm).

Recent technological developments have centered on high temperature pyrolysis of light hydrocarbons C_2 to C_5, LPG, and naphtha to form aromatics in higher yields. Conversions were traditionally low because they were accompanied by a high degree of degradation to carbon and hydrogen. Recent improvements include modification of the thermal cracking process to produce higher yields of liquid products rich in aromatics and the extension of the catalytic hydroforming process to promote oligomerization and dehydrocyclization of the lower olefins. The common core of these developments is the use of shape-selective zeolite catalysts to promote the various reactions.

Specifications, Standards, and Quality Control. Toluene is marketed mostly as nitration and industrial grades. The generally accepted quality standards for the grades are given by ASTM D841 and D362, respectively.

Purity of toluene samples as well as the number, concentration, and identity of other components can be readily determined using standard gas chromatography techniques.

Health and Safety Factors. Permissible exposure limits established by the U.S. Department of Health and Human Services and the U.S. Department of Labor are summarized below, with the more restrictive levels proposed by NIOSH.

	OSHA, mg/m^3 (ppm)	NIOSH, mg/m^3 (ppm)
average during 8-h shift (TWA)	752 (200)	376 (100)
not to exceed	1129 (300)	
except for 10-min average (TLV)	1181 (500)	752 (200)

Toluene generally resembles benzene closely in its toxicological properties; however, it is devoid of benzene's chronic negative effects on blood formation.

Uses. About 90% of the toluene generated by catalytic reforming is blended into gasoline as a component of $>C_5$ reformate. The octane number ($R+M/2$) of such reformates is typically in the range of 88.9–94.5, depending on severity of the reforming operation. Toluene itself has a blending octane number of 103–106, is exceeded only by oxygenated compounds such as methyl *tert*-butyl ether, ethanol, and methanol.

Toluene is a valuable blending component, particularly in unleaded premium gasolines. Although reformates are not extracted solely for the purpose of generating a high octane blending stock, the toluene that is co-produced when xylenes and benzene are extracted for use in chemicals, and that exceeds demands for use in chemicals, has a ready market as a blending component for gasoline.

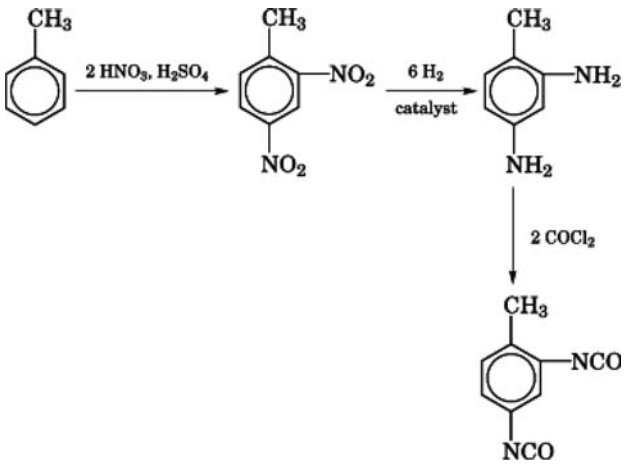
Toluene is converted to benzene by hydrodemethylation either under thermal or catalytic conditions. Benzene produced from this source generally supplies 25–30% of the total benzene demand. The feedstock is usually extracted toluene, but some reformers are operated under sufficiently severe conditions or with selected feedstocks to provide toluene pure enough to be fed directly to the dealkylation unit without extraction.

Toluene is more important as a solvent than either benzene or xylene. Solvent use accounts for ca 14% of the total U.S. toluene demand for chemicals. About two-thirds of the solvent use is in paints and coatings; the remainder is in adhesives, inks, pharmaceuticals, and other formulated products utilizing a solvent carrier. Use of toluene as solvent in surface coatings has been declining, primarily because of various environmental and health regulations. It is being replaced by other solvents.

Potential Uses. Because much toluene is demethylated for use as benzene, considerable effort has been expended on developing processes in which toluene can be used in place of benzene to make directly from toluene the same products that are derived from benzene. Such processes both save the cost of demethylation and utilize the methyl group already on toluene. Most of this effort has been directed toward manufacture of styrene. An alternative approach is the manufacture of *para*-methylstyrene by selective ethylation of toluene, followed by dehydrogenation. Resins from this monomer are expected to displace polystyrene because of price and performance advantages.

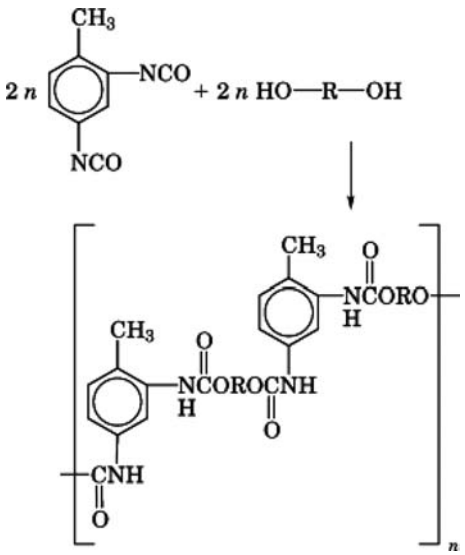
Derivatives

Toluene Diisocyanate. Toluene diisocyanate is the basic raw material for production of flexible polyurethane foams. It is produced by the reaction in which toluene is dinitrated, the dinitrotoluene is hydrogenated to yield 2,4-diaminotoluene, and this diamine in turn is treated with phosgene to yield toluene 2,4-diisocyanate.

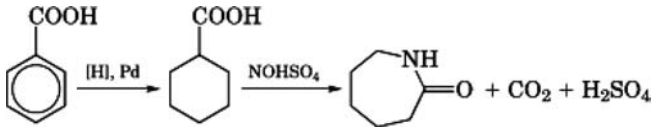


Polyurethane foams are formed by reaction with glycerol; with poly(propylene oxide), sometimes capped with poly(ethylene oxide) groups; with a reaction product of trimethylolpropane and propylene oxide; or with other appropriate polyols. A typical reaction sequence is shown below, in which HO−R−OH represents the diol. If a triol is used, a cross-linked product is obtained.

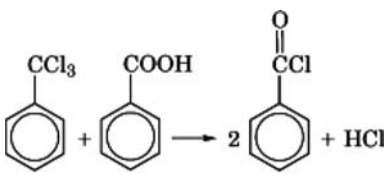
Water, in small amount, reacts with the diisocyanate to generate carbon dioxide, and amine and is used most frequently as the foaming agent.



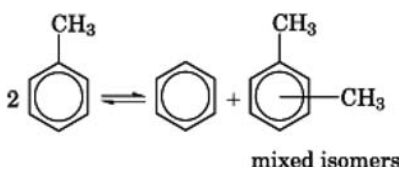
Benzoic Acid. Benzoic acid is manufactured from toluene by oxidation in the liquid phase using air and a cobalt catalyst. Typical conditions are 308–790 kPa (30–100 psi) and 130–160 °C. The crude product is purified by distillation, crystallization, or both. Yields are generally >90 mol%, and product purity is generally >99%.



Benzyl Chloride. Benzyl chloride is manufactured by high temperature free-radical chlorination of toluene. The yield of benzyl chloride is maximized by use of excess toluene in the feed. More than half of the benzyl chloride produced is converted by butyl benzyl phthalate by reaction with monosodium butyl phthalate. The remainder is hydrolyzed to benzyl alcohol, which is converted to aliphatic esters for use in soaps, perfume, and flavors. Benzyl salicylate is used as a sunscreen in lotions and creams. By-product benzal chloride can be converted to benzaldehyde, which is also produced directly by oxidation of toluene and as a by-product during formation of benzoic acid. By-product benzotrichloride is not hydrolyzed to make benzoic acid but is allowed to react with benzoic acid to yield benzoyl chloride.



Disproportionation to Benzene and Xylenes. With acidic catalysts, toluene can transfer a methyl group to a second molecule of toluene to yield one molecule of benzene and one molecule of mixed isomers of xylene.



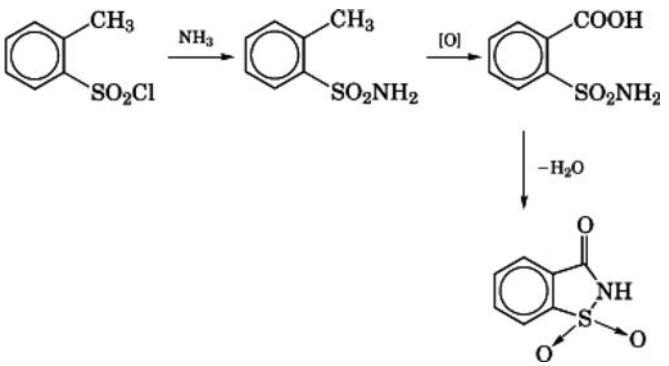
This disproportionation is an equilibrium reaction. Disproportionation generates benzene from toluene and at the same time takes full advantage of the methyl group to generate a valuable product, i.e., xylene. Economic utility of the process is strongly dependent on the relative values of toluene, benzene, and the xylenes.

Vinyltoluene. Vinyltoluene is used as a resin modifier in unsaturated polyester resins. Its manufacture is similar to that of styrene; toluene is alkylated with ethylene, and the resulting ethyltoluene is dehydrogenated to yield vinyltoluene.

Toluenesulfonic Acid. Toluene reacts readily with fuming sulfuric acid to yield toluene–sulfonic acid. By proper control of conditions, *p*-toluenesulfonic acid is obtained. The primary use is for conversion, by fusion with NaOH, to *p*-cresol. The resulting high purity *p*-cresol is then alkylated with isobutylene to produce 2,6-di-*tert*-butyl-*p*-cresol (BHT), which is used as an antioxidant in foods, gasoline, and rubber. Mixed cresols can be obtained by alkylation of phenol and by isolation from certain petroleum and coal–tar process streams.

Benzaldehyde. Annual production of benzaldehyde requires ca 6,500–10,000 t ($2–3 \times 10^6$ gal) of toluene. It is produced mainly as by product during oxidation of toluene to benzoic acid, but some is produced by hydrolysis of benzal chloride. The main use of benzaldehyde is as a chemical intermediate for production of fine chemicals used for food flavoring, pharmaceuticals, herbicides, and dyestuffs.

Toluenesulfonyl Chloride. Toluene reacts with chlorosulfonic acid to yield both *o*- and *p*-toluenesulfonyl chlorides. The ortho isomer is converted to saccharin.



The para isomer is used for preparation of specialty chemicals. Annual toluene requirements are ca 6500 t (2×10^6 gal).

TOMOGRAPHIC EXPERIMENT USING RADIATIVE RECOMBINATIVE IONOSPHERIC EUV AND RADIO SOURCES (TERRIERS) MISSION. See **Space Science Missions: Sun**.

TONE. See **Musical Sound**.

TONE CONTROL. The control for regulating the frequency response of an audio amplifier. In its most common form as found in most radio receivers it consists of a capacitor in series with a variable resistance shunted across the circuit at some point. Since such a combination passes high frequencies more easily than low values, the high frequencies will be attenuated, the degree being determined by the setting of the variable resistance and the impedance of the circuit to which the tone control is connected. Thus by varying the resistance more or less attenuation may be given the high frequencies, and the effect is as if the bass response were being varied. In more elaborate tone controls, separate bass and treble controls are provided, thus allowing a balanced control of the response.

TONGUE (Anatomy). An organ associated with the floor of the oral cavity, usually projecting or protrusile. The true tongue is a vertebrate structure, occurring in all classes above the fishes. It is made up largely of voluntary muscle fibers, so distributed that it can be protruded and withdrawn and swung in every possible direction. It arises embryonically from the floor of the anterior part of the pharynx, extending forward into the oral cavity.

The tongue is used in man and other species for the manipulation of foods in chewing, and in some of the amphibians, reptiles and birds it aids in capturing food, usually by adhesion. In man it is an important organ of speech, aiding in the modulation of sounds produced by the larynx.

The word is sometimes applied to the radula of the snails and to parts of the insect mouth, but only from superficial similarity with the true tongue of the vertebrates.

TONGUE SOLE. See **Flatfishes**.

TONKA BEAN. See **Bean**.

TONOMETER. A tonometer is an instrument used by eye care professionals to measure the intraocular pressure of a patient's eye. This pressure measurement is an important part of every eye examination because an increase in pressure may signal the onset of glaucoma, a sight-threatening disease. Pressure is measured in millimeters of mercury, and, as a general guideline, pressure above 21 millimeters is considered to be elevated pressure, though not all persons with that reading have glaucoma.

The most popular tonometry test is with the noncontact tonometer, often referred to as the "air-puff" test. The patient looks through a machine as it blows a gentle puff of air at the eye. This puff of air flattens the cornea slightly in order to give the pressure reading. The machine is gas pressurized and does not require direct contact with the eye.

Another form of tonometry, and one of the most accurate, is the contact tonometer, an instrument that looks like a pen. When using the contact tonometer, numbing eye-drops are administered, and then the tip of the tonometer touches the eye and measures the pressure.

An applanation tonometer, measures the force required to flatten a small area of central cornea. A topical anesthetic and fluorescein dye, are instilled before the measurement is taken. One type of applanation tonometer attaches to a slit lamp, another is hand-held.

The Schiotz tonometer measures the amount the cornea is indented by a fixed weight that artificially raises the pressure. It is a simple, portable instrument, but is considered to be somewhat less accurate than other types of measuring devices. See also **Glaucoma**.

Vision Rx, Inc., Elmsford, NY

TOOTH. 1. A hard structure projecting from the wall of the mouth or the anterior part of the alimentary tract (digestive system) and used for grasping and breaking up food. Teeth vary from the chitinous projections on the radula of mollusks to the complex structures of the vertebrates. Chitinous teeth of annelid worms, located on the walls of the pharynx, are also known as jaws.

Vertebrate teeth are formed of two layers of hard materials over a living papilla, the pulp, which contains blood vessels and nerves. They form in the embryo from ingrowths of the outermost layer of the body, the ectoderm, associated with masses differentiated in the middle layer, the mesoderm. The mesoderm forms the dental papilla and around its outer surface, except at the end that is to remain connected with the body, lays down a layer of dentine. This material is similar to bone in composition but not in minute structure. It is harder, contains less organic matter than bone, and is the ivory of commerce. The ectodermal cap over the dental papilla develops into an enamel organ and deposits a layer of enamel on the dentine. Enamel is made up of minute prisms and is the hardest substance produced by the animal body, containing only 2–4% organic matter. When the tooth takes its place in the jaw in the process of eruption the enamel organ is destroyed, hence no more of this substance can be produced. Dentine may be deposited later in life, however, encroaching on the pulp cavity.

The teeth of sharks are the most primitive vertebrate teeth. They are formed like the placoid scales of the body, with a principal point and sometimes smaller supplementary points, and are superficially attached in rows on the jaws. Both scales and teeth contain dentine covered with enamel.

In other fishes and amphibians teeth are distributed in various parts of the oral cavity and are associated with the bones of the jaws and skull. In reptiles and mammals they are limited to the jaws and are seated in sockets (alveoli) in the bones by means of a third hard substance, cementum, deposited between the dentine of the roots and the bone of the jaw.

Primitive teeth are simple conical structures. In mammals this type persists only in the canines. The other teeth are sharp-edged incisors, broad molars with projecting cusps on the apposed surfaces, and premolars of intermediate form. The premolars of man are also called bicuspids. An assemblage of teeth of these kinds, variously specialized for cutting, tearing and holding, and grinding and crushing, is known as a heterodont dentition, and is the fundamental plan of dentition in the mammals. The various forms of teeth are the basis of specialization in different groups of mammals for the use of limited types of food. Thus species that depend on plant tissues have greater need of crushing teeth while carnivorous forms need cutting teeth for their tougher food. The molars of the former are broad and are so folded that the worn apposed (occlusal) surfaces show alternating bands of dentine, enamel, and cementum in patterns characteristic of the kind of animal. In the elephants these materials form transverse ridges. The incisors of grazing animals are also flattened, forming clipping, rather than cutting, teeth. The canines are reduced or lacking. In carnivores the incisors are greatly reduced, the canines are highly developed, and the molars are sharp-edged. Molars of the two jaws work together like the blades of shears. Some mammals, notably certain anteaters, have lost all trace of teeth.

The tusks of various animals are greatly elongated teeth projecting from the jaws for use in fighting and digging. They are usually devoid of enamel. Those of the elephants are upper incisors and in early growth are provided with enamel tips. Those of walruses and swine are canines. Single tusks of elephants weighing almost 200 pounds (90.7 kilograms) have been recorded but the average is less than 100 pounds (45.4 kilograms). These tusks provide the finest ivory.

Some teeth grow constantly as they are worn away, while others attain a fixed form within a short period and still others undergo a partial compensation for wear. The incisors of rodents are of the first type. These chisel-like teeth wear away in gnawing but are constantly renewed by growth at their bases to preserve a uniform length. The molars and premolars of horses are elevated in the jaws by lengthening of the roots, but the amount available for use during the life of the animal is regulated by the height of the crown at the initial formation of the tooth. Human teeth assume a fixed form. The only compensation for wear is the partial filling in of the pulp cavity by the deposition of dentine.

A compensation for breakage and wear is also found in the replacements that occur in lower vertebrates. Mammals normally have no more than two sets, milk and permanent, and once the permanent teeth of adult life have assumed their functional positions in the jaws, loss through accident is permanent. Rarely a third set of teeth develops.

The word tooth also denotes:

2. The interlocking projections at the hinged edges of the valves of the bivalve molluscan shell.

3. Tooth-like projections on a hard structure or on the surface of the body of an animal.

TOPAZ. The mineral topaz is a silicate of aluminum and fluorine corresponding to the formula $Al_2SiO_4(F, OH)_2$. It is orthorhombic and its crystals are mostly prismatic terminated by pyramidal and other faces, the basal pinacoid being often present. Massive varieties are known. It has an easy and perfect basal cleavage, hence for this reason gems or fine specimens should be handled with care to avoid developing cleavage flaws. The fracture is conchoidal to uneven; hardness, 8; specific gravity, 3.4–3.6; luster, vitreous; color, of typical topaz, wine or straw-yellow but may be colorless, white, gray, green, blue or reddish-yellow; transparent to translucent. When heated, yellow topaz often becomes a reddish pink.

Topaz is found associated with the more acid rocks of the granite and rhyolite type and may occur with fluorite and cassiterite. Topaz comes from many localities, a few of which are: the former U.S.S.R. in the Urals and the Ilmen Mountains; the Czech Republic and Slovakia, Saxony, Norway, Sweden, Japan, Brazil and Mexico. In the United States, topaz has been found in Oxford County, Maine; Carroll County, New Hampshire; Fairfield County, Connecticut; El Paso and Chaffee Counties, Colorado; and in Texas, Utah and California.

The name *topaz* is derived from the Greek meaning to seek. It was the name of an island in the Red Sea that was difficult to find, and from which a yellow stone, now believed to be a yellowish-olivine, was obtained in ancient times. In the Middle Ages, any yellow stone was called topaz, but now the name is properly applied only to the species here described.

TOPEX/POSEIDON MISSION. See **Space Science Missions: Earth**.

TOPOCENTRIC. Of measurements or coordinates, referred to the position of the observer on the Earth as the origin.

TOPOCHEMICAL REACTION. Any chemical reaction that is not expressible in stoichiometric relationships. Such reactions are characteristic of cellulose; they can take place only at certain sites on the molecule where reactive groups are available, i.e., in the amorphous areas or on the surfaces of the crystalline areas.

TOPOGRAPHICAL MAPPING. Topographical mapping consists of representing on a map the physical features of a given section of land, by showing thereon contours or hachures representing the elevation, and noting various other physical features by conventionalized signs. Thus trees, streams, marshes, and roads may be part of a topographic survey. The method of topographic surveying and mapping of large areas consists of establishing points for horizontal and vertical control, and surveying the adjacent area from these points by the use of leveling, stadia, or the plane table.

TOPOLOGICAL GROUP (or Continuous Group). A group for whose elements a topology is defined in such a way that the group operations (formation of product and of inverse) are continuous. Thus, the set of real numbers forms a topological group if the group operation is given by addition and the distance between two numbers by the absolute value of their difference. Consider, e.g., the (one-parameter) group of rotations of the Euclidean plane given by the elementary formulas

$$X = x\cos\theta - y\sin\theta, \quad Y = x\sin\theta + y\cos\theta$$

corresponding to the group of matrices

$$\begin{pmatrix} \cos\theta, & -\sin\theta \\ \sin\theta, & \cos\theta \end{pmatrix}$$

depending on the parameter θ. If we now define two matrices as being close together if every element of one is close to the corresponding element of the other (see under **Topology**), then it is clear that multiplication of matrices is continuous, i.e., that if $A = A(\theta_1)$ is a fixed matrix and $B = B(\theta_1)$ is a variable one, then small changes in B will produce only small changes in AB.

Most groups which occur in applications are either finite or are topological groups, and often express the symmetry of a given system. Most useful is the full linear group of all $n \times n$ real or complex matrices and certain distinguished subgroups such as the special linear group, the orthogonal group, etc.

TOPOLOGICAL SPACE. An abstract set with a structure based on the notion of nearness sufficient for the study of the limit concept.

A topological space is a set X along with a collection $\mathcal{J}$ of distinguished subsets of X called *open* sets which satisfies: (1) each x in X is contained in some open set, (2) the intersection of two open sets is open, and (3) the union of a subcollection of open sets is open.

A subset K of X is said to be *closed* if the complement $X - K$ is open. The intersection of a collection of closed sets is closed and the smallest closed set containing a subset M of X is called the *closure* of M and is denoted by $\overline{M}$. A point x is said to be an *accumulation* or *limit point* of a set M if x is in the closure of the set obtained by deleting x from M.

It is usually assumed that a topological space has additional separation properties. In particular, a topological space is said to be a *Hausdorff space* if distinct points are contained in disjoint open sets.

Most of the familiar examples of topological spaces are metrizable. See also **Metric Space**. Not all topological spaces are metrizable, however.

A sequence $x_1, x_2, x_3, \ldots$ of points in a topological space is said to converge to a point x if for every open set U containing x, there exists an integer N so that for every $n > N$ the point x_n is in U. The notion of sequential convergence can be used to provide an alternate definition of metrizable topological spaces in terms of accumulation points but a more general notion of convergence is necessary for general topological spaces.

A mapping f between topological spaces X and Y is said to be continuous if for each point x in X and open set U in Y containing $f(x)$, there is an open subset V of X so that the image of V is contained in U. A continuous mapping can bend, can twist, and can change lengths, angles and shapes but cannot tear or break. If the mapping f is also one-to-one, and onto itself, and the inverse of f is continuous, then f is said to be a *homeomorphism* or a *topological transformation*. The mapping $f(x) = \tan x$ is a homeomorphism between the open interval $(-\pi/2, \pi/2)$ and the real line. Topological spaces are said to be homeomorphic if there exists a homeomorphism between them. A property of a space is said to be a *topological property* if every homeomorphic copy also possesses it. Being a Hausdorff space is a topological property, while being a triangle is not.

A topological space is said to have a property *locally* if some open set about each point has this property. For example, a space is said to be *locally Euclidean* if each point is contained in an open set which is homeomorphic to an open subset of Euclidean space. If in a locally Euclidean space overlapping open sets match up properly, the space is said to be a *manifold*.

Usually, the collection of possible states of a physical system possess a natural topology, that is, there is a notion of two systems being "close." Further, the collection of all states having a given energy forms a submanifold.

R.G. DOUGLAS, State University of New York at Stony Brook, Stony Brook, NY

TOPOLOGY. A branch of mathematics which studies the *topological properties* of figures. See Fig. 1 on p. 153. Although certain topological problems had been studied previously, the subject reached maturity in this century and has become a separate field of study.

Two basic problems in topology can be stated very generally as follows: (1) Given topological spaces X and Y, when are they homeomorphic? (2) Given subsets A of X and B of Y and a continuous mapping f from A to B, when does there exist a mapping F from X to Y which agrees with f on A? Questions as general as these have complete answers only in very special cases.

An example of the first problem is obtained by considering a circle, a square, a triangle, and a figure-eight; any two of the first three are homeomorphic, while the latter is homeomorphic to none of the others. An example of the second problem is obtained by considering two simple

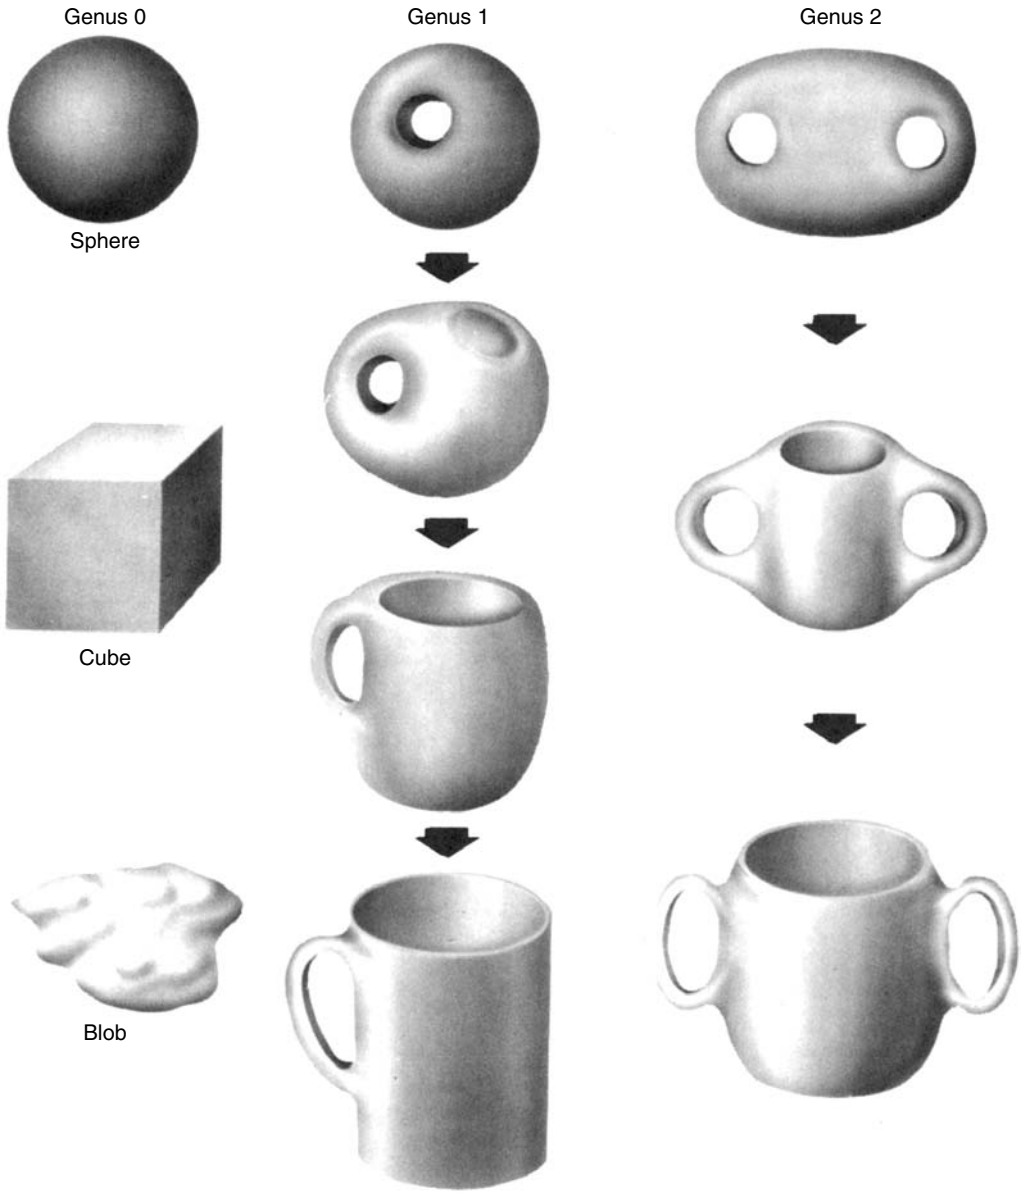

Fig. 1. Topological transformation. The sphere, cube, and blob are basically the same topologically and all of Genus 0. The doughnut typifies Genus 1 and can be transformed into innumerable shapes and still retain the topological basic features of Genus 1. Similarly a Genus 2 surface can be transformed into many different shapes. One may envision all of the foregoing from a plastic substance, such as clay. The principal differences between the classes are (0) no hole; (1) one hole; (2) two holes.

loops (non-self-intersecting) in the plane; the loops are homeomorphic and the *Jordan curve theorem* states that there exists a homeomorphism on the plane which extends this mapping. This implies, in particular, that a simple loop separates the plane into an inside region and an outside. On the other hand, if the similar problem is considered in three-space with one loop being knotted and the other with no knot, then the loops are homeomorphic, but the homeomorphism between them can not be extended to a homeomorphism on three-space.

Topology is composed of several branches. *General topology* is the study of the most abstract topological spaces and is related to certain parts of functional analysis. *Point-set topology* is the study of arbitrary subsets of Euclidean spaces, mainly of dimensions two, three and four. *Differentiable topology* is the study of manifolds with sufficient additional structure to define the notion of differentiable mapping between such manifolds. The most important examples of *differentiable manifolds* are Euclidean n-space and the Euclidean n-sphere, which consists of all points in $n+1$-space at distance one from the origin.

Combinatorial topology is the study of geometric objects by decomposing them into simpler objects (simplexes) which are adjoined to each other in a regular way. A triangle is decomposed into three line segments or 1-simplexes. *Algebraic topology* is the study of topology using algebraic methods. There are many natural ways of associating with a topological space some algebraic object such as a group so that homeomorphic spaces have isomorphic groups. The first problem mentioned has a negative answer in case the groups associated with the spaces X and Y are not isomorphic. See also **Four-Color Map Theorem**.

R.G. DOUGLAS, State University of New York at Stony Brook, Stony Brook, NY

TOPSOIL. See **Soil**.

TORBERNITE. An ore of uranium with the composition, $Cu(UO_2)_2(PO_4)_2 \cdot 8-12H_2O$, green, radioactive, tetragonal, and isomorphous with autunite. Occurring in tabular crystals or in foliated form, the mineral is commonly a secondary mineral.

As a radioactive mineral, torbernite has some significance as an ore of uranium. Its rich color and distinctive crystals make it a sought after collectors mineral, as well. However, torbernite, like other hydrated

minerals, suffers from loss of water molecules. This loss of water from the mineral leads to an alteration of all torbernite specimens into its psuedomorph, meta-torbernite. In fact, some collector's sites assert than any torbernite specimen more than a few years old should be considered fully transitioned to meta-torbernite.

TORNADO. A tornado is a violent rotating column of air reaching to the ground from a storm cloud in the shape of a condensation funnel created and maintained by strong inflowing winds. The spinning winds can attain extremely high speeds, which present great risk to property and life on the ground and in the air. When the humidity is high enough, the tornado funnel is made visible by the circulation of condensed water vapor, and although the flow of air is inward and upward, the cloud within the low-pressure funnel is seen to extend downward from the cloud base.

The origin of tornadoes is often associated with well-developed thunderstorm cells on cold fronts, for example, at the gust-front boundary where an advancing mass of cold air overruns and displaces pre-existing warmer humid air. Within a cell, a strong persistent updraft of warm moist air is maintained as air enters the forward right flank at low altitude. As the air ascends, it is forced to turn because of the variation of wind speed with height (known as vertical wind shear) and because of its proximity to a downdraft of drier cold air. By this means, the buoyant warm updraft acquires rotation in an anticlockwise sense as it undergoes local stretching in the vertical. The spinning, spiraling effect gradually extends along the length of the updraft, and the speed of rotation or "twisting" increases as the effective column diameter diminishes.

Just as water exits from a bath more efficiently by spinning down the plug hole, so the humid rising air is carried more effectively through the cloud cell in the form of a spinning updraft. Another way of expressing it is by recognizing that the tornado's high wind speeds are the result of convergence because angular momentum has to be conserved. A parallel analogy is the way in which an ice skater increases his or her rate of spin (thereby providing a convergence of mass) by drawing in the arms. The upward flow of air in the tornado being greater and faster than inflow at the base ensures a reduced pressure for the rotating updraft.

When the column is seen extending visibly beneath the cloud base as a funnel cloud, it is because water vapor is condensing into its outer sheath because of falling pressure and temperature. Eventually, given enough time and a high enough rate of spin and stretching, the tornado's funnel lengthens to the ground, and with it come the high-speed, potentially damaging winds. By contrast, winds in the limited area at the middle of a tornado funnel are light, if not approaching calm in the epicenter, as with the eye of a tropical storm or hurricane.

In the most intense storms, known as supercells, winds in the lowest three kilometers of the atmosphere veer strongly with height and produce, relative to a horizontal axis, vorticity of the inflow toward the updraft before tilting into the vertical and becoming a fiercely spinning column of air. At the same time, in such meteorological conditions, a mesocyclone can develop in which the entire cumulonimbus, often 10 kilometers across, rotates with a strong sustained updraft.

Most continents have regions where conditions for tornado formation are more likely to develop. In the United States, across a broad zone from Nebraska to Texas and Oklahoma, violent tornadoes develop more frequently than elsewhere. This region has been named "tornado alley". In this zone, cold dry air moving south and east from across the Rockies meets warm moist air from the Gulf of Mexico, especially in late spring and summer when the general conditions are optimum. On some remarkable occasions, more than a hundred tornadoes have been recorded in a day, not only in the United States but also in the British Isles. In the United States on April 3–4, 1974, within sixteen hours in thirteen states from Georgia to the Canadian border, there were 148 tornadoes, of which 48 caused 315 deaths. In Britain, on November 21, 1981, as many as 105 tornadoes broke out in five-and-a-half hours as a cold front crossed a comparatively small part of England from north-west to south-east. The country with the highest number of reported tornadoes per unit area is England, whose area corresponds roughly with Oklahoma, but many of the Oklahama's tornadoes are more violent. Holland is another small country reporting a very high frequency of tornadoes per unit area. The part of the United States with the highest number of tornadoes per unit area is central Oklahoma.

Tornadoes of North America and Europe have been studied the most, especially since 1970. In the United States and Europe, two tornado windspeed scales have come into use. There is the international decimal T-Scale, which ranges from 0 to 9 and is a simple development of the 200-year old Beaufort windspeed scale, and there is the American F-Scale, with its shorter span from 0 to 5 (Table 1). In the severest tornadoes, wind speeds have been known to approach 130 meters per second or 300 miles per hour. The strongest known tornadoes for the United States and for Europe are T10 or F5 on these scales. Tornado tracks commonly range from a few dozen to a few hundred meters in diameter but can be up to 5 or more kilometers (3 or more miles) wide. Lengths of tornado tracks exceeding one hundred kilometers are known, especially for the United States.

TABLE 1. FUJITA SCALE (OR F SCALE)

F0 (weak)	40–72 mph, light damage
F1 (weak)	73–112 mph, moderate damage
F2 (strong)	113–157 mph, considerable damage
F3 (strong)	158–206 mph, severe damage
F4 (violent)	207–260 mph, devastating damage
F5 (violent)	261–318 mph, (rare) incredible damage

Some tornadoes form out to sea as strong waterspouts (q.v.), which sometimes cross the coast, so a waterspout may become a tornado as the twisting funnel moves from sea to land (and vice-versa). A recent powerful and well-documented example is that of Selsey on the south coast of Britain on the night of January 7–8, 1998. When the waterspout made landfall, it carved a trail of damage one kilometer wide through the town as it damaged hundreds of buildings in the space of ten minutes. See also **Fronts and Storms**; and **Whirlwind**.

TOROIDAL COORDINATE. A curvilinear coordinate system closely related to bipolar coordinates. If the traces of the surfaces in that system are taken in the XY-plane as two families of mutually orthogonal circles, then rotation of the circles about the Z-axis forms a family of spherical surfaces and a family of anchor rings. The toroidal coordinate surfaces are then taken as: (1) spherical, with centers on the Z-axis at a distance of $\pm a \cot \xi$ from the origin and with radii of $a \csc \xi$, $\xi = \text{const.}$; (2) anchor rings with radii of $a \coth \eta$ for the axial circles and circular cross sections of radii $a \operatorname{csch} \eta$, $\eta = \text{const.}$; (3) planes through the Z-axis, $\psi = \text{const.}$, where $\psi = \tan^{-1} y/x$. These coordinates are related to rectangular coordinates by the equations

$$x = r \cos \psi, \quad y = r \sin \psi$$

$$r = \frac{a \sinh \eta}{\cosh \eta - \cos \xi}; \quad z = \frac{a \sinh \xi}{\cosh \eta - \cos \xi}$$

$0 \le \xi \le 2\pi$; $0 \le \psi \le 2\pi$; $0 \le \eta \le \infty$.

See also **Coordinate System**; and **Spheroidal Coordinate**.

TORQUE. A torque is a concept that may be simply expressed as the effectiveness of a force in setting a body into rotation. 1. For a single particle the torque is the moment of the resultant force on the particle with respect to a particular origin. This is expressed by the vector relation $\mathbf{L} = \mathbf{r} \times \mathbf{F}$, where $\mathbf{L}$ is the torque, $\mathbf{r}$ is the position vector with respect to the origin, and $\mathbf{F}$ is the resultant force. The torque is equal to the time rate of change of the moment of momentum. 2. For a rigid body, the torque with respect to a set of axes is expressed by the relation

$$\mathbf{L} = \int_v \mathbf{r} \times \mathbf{F}_v \, dv$$

where $\mathbf{F}_v$ is the resultant force per unit volume due to external forces on the element dv, and $\mathbf{r}$ is the position vector of the volume element.

For a rigid body undergoing free rotation about a single axis, the torque $\mathbf{L} = I\alpha$, where I is the moment of inertia and α is the angular acceleration. 3. In engineering mechanics usage, a torque often refers to the torsional or twisting moment or couple which tends to twist a rigidly fixed object

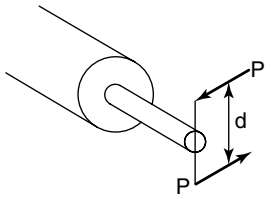

Fig. 1. Parameters of torque.

such as a shaft about an axis of rotation. In Fig. 1, a shaft of diameter d is connected to a rigid support. The forces **P** form a couple with a torque $\mathbf{L} = \mathbf{P}d$ and tend to rotate the shaft in a counterclockwise direction. See also **Moment**.

TORQUE AMPLIFIER. A device possessing input and output shafts and supplying work to rotate the output shaft, without imposing any significant torque on the input shaft. The speed of the output shaft is equal or proportional to that of the input shaft, regardless of the load on the former.

TORQUE CONVERTER. A device for changing the ratio of torque to speed in a system transmitting power by exerting torque. The most general case is that of two shafts connected by a gear system or a clutch. In the case of the former, or of the latter if it is of positive or of friction type, the torque in the driven shaft, T_d, is equal to $T_i(N_d/N_i)$, where T_i is the torque of the input shaft, N_i the rotational speed of the input shaft, and N_d is that of the driven shaft, assuming 100% efficiency. If the efficiency is less, T_d is decreased proportionately.

Among the other types of torque converters, the hydraulic type is most widely used. It consists essentially of an impeller mounted on the input shaft which pumps fluid so that it impinges on the blades of a turbine mounted on the output shaft. On leaving the turbine the fluid meets the blades of a reactor that is attached to the outer casing, and the fluid is thus returned into the impeller.

A number of modifications of this simple arrangement are found in practice. The torque converter may consist of more than one stage; the reactor may be mounted so that it is free to rotate with the fluid at high speeds, since no power at all is transmitted when the shaft speed equals the engine speed (efficiency zero); and the reactor may be divided into sections to obtain more uniform efficiency.

TORR. Provisional international standard term to replace the English term *millimeter of mercury* and its abbreviation *mm* of *Hg* (or the French *mm de Hg*). The torr is defined as 1/760 of a standard atmosphere or 1,013,250/760 dynes per square centimeter. This is equivalent to defining the torr as 1333.22 microbars and differs by only one part in seven million form the International Standard millimeter of mercury. The prefixes *milli* and *micro* are attached without hyphenation.

TORREY PINE. See **Pine Trees**.

TORSIONAL STRESS. The shearing stress which occurs at any point in a body as the result of an applied torque or torsional load is called a torsional stress. If the body is a circular shaft, the stress is found from the formula

$$s_s = \frac{Tc}{J}$$

in which

s_s = required unit stress
T = torque
c = radial distance from the center of the shaft to the point
J = polar moment of inertia of the cross-sectional area

This formula is based on the assumption that a plane section before twisting remains a plane after the torque is applied; also that the radii remain straight. The theory of elasticity shows that these assumptions are true for all sections except those adjacent to the applied torque and the supports.

The cross section of a noncircular body becomes decidedly warped after twisting, so the stress must be obtained by formulae developed from the theory of elasticity, by experimental means or by approximate formulae which are given in textbooks on advanced strength of materials.

TORSIONAL VIBRATION MEASUREMENT. Variations from uniform shaft speed reduce the efficiency of engines and machinery. Thus, it is important that reciprocating engine performance be evaluated and that machine tool vibration, as two examples, be analyzed and corrected. A seismic mass type transducer is commonly used for such analyses. Sectional and mounting views of such a device are shown in Figs. 1 and 2.

Internal construction of the device features an *Alnico V* magnet seismic mass suspended on ball bearings with no end play. Built to withstand transverse and longitudinal vibratory movements, the seismic mass is restricted to torsional vibration. Springs provide an elastic coupling to the case. The coil, rigidly affixed to the case, is oriented in the field produced by the magnet (seismic mass) case. Any relative motion between the two generates a voltage which is a function of the instantaneous velocity of this angular vibration. Solid silver slip rings and dual sets of silver-graphic brushes assure conduction of transducer coil output. Precision bearings and a silicone damping fluid acting as a lubricant and combine to give the device excellent amplitude linearity and no tendency to stick at low frequencies and amplitudes.

The instrument is designed to measure vibration precisely even when superimposed on modes other than angular. Output voltages resulting from shaft speed variations can be fed to a vibration meter for direct indications

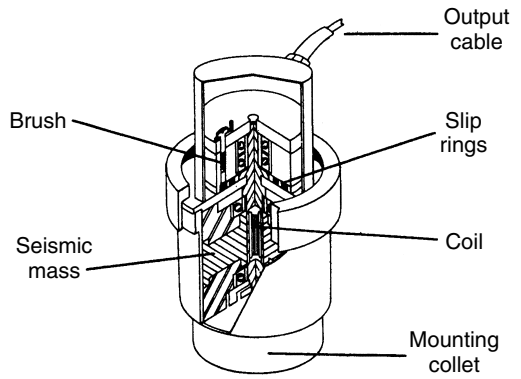

Fig. 1. Sectional view of seismic mass-type transducer for measurement of torsional vibration.

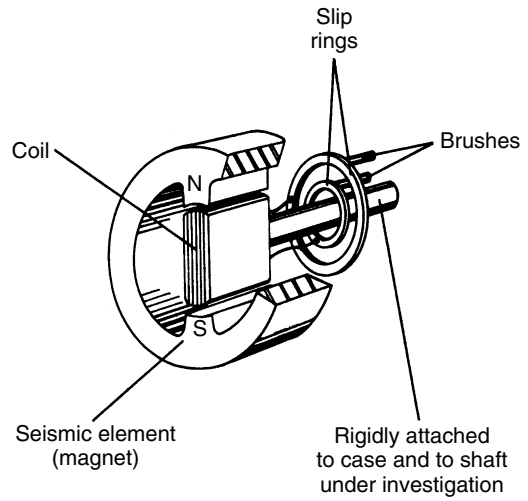

Fig. 2. Mounting of seismic mass-type transducers for torsional vibration measurement.

of vibrational angular velocity and amplitude. Or, the output can be fed to a recording oscillograph or to an oscilloscope. The device shown is suitable for applications up to a maximum of 6,000 revolutions per minute, and has a frequency response of 10 to 1,000 Hz, a natural frequency of about 3 Hz, a coil resistance of 700 ohms, and a temperature range of 0–150 °F (−17.8–66 °C).

TORSION BALANCE. The torsion balance is an instrument for measuring very feeble forces of attraction or repulsion. It has played an important role in the demonstration of Coulomb's laws and in measuring the gravitation constant and radiation pressure. It consists essentially of a light horizontal rod suspended by a slender elastic wire or fiber and carrying at each end a small ball, vane, or other object upon which the unknown force is to act tangentially. The resulting torsional deflection is measured by an optical lever, the small mirror of which is attached at the base of the suspension. To calculate the corresponding torque (and hence the force), the "torsion coefficient" of the suspension must have been previously determined. This is the torque required to twist the suspension through an angle of 1 radian, and is conveniently obtained by using the same suspension as the support for a torsion pendulum of known moment of inertia, and measuring the period. In the Cavendish method for determining the gravitation constant, small balls of gold or platinum are used and the torque applied by the attractions of much more massive balls or cylinders of lead in the same horizontal plane. The Eötvös balance is a highly specialized form of the torsion balance, used in gravity measurements.

TORTOISE. See **Turtles**.

TORTOISE SHELL. The mottled horny plates of the shell of a marine turtle, *Eretmochelys imbricata*. This species is found in warm seas, extending as far north as Massachusetts occasionally. It is known as the hawksbill or tortoise-shell turtle.

Tortoise shell was once highly valued for ornamental use, as in toilet articles and the handles of pocket knives, but it has been largely replaced by synthetic materials.

TOTAL OZONE MAPPING SPECTROMETER (TOMS)-EARTH PROBE (EP). See **Space Science Missions: Earth**.

TOTH PROCESS. A process for production of aluminum metal that utilizes kaoliln and other high-alumina clays. The clay is chlorinated after calcination, and the aluminum chloride resulting is reacted with metallic manganese to yield aluminum and manganese chloride. The reaction occurs at the comparatively low temperature of 260C. The manganese chloride is recovered as manganese metal and chlorine by oxidation and subsequent reduction, the manganese being recycled. This is a much cheaper and more efficient method than the Hall process, because it requires less energy input and does not utilize imported bauxite.

TOUCAN. See **Woodpeckers and Toucans**.

TOUCH (Sense). See **Tactile Organs**.

TOURIELLO. See **Winds and Air Movement**.

TOURMALINE. The mineral tourmaline is a complex silicate of aluminum and boron, but because of isomorphous replacements this mineral varies widely in chemical composition, iron, magnesium, and lithium entering into combination to a greater or less extent with the aluminum and boron. Its general formula is (Na, Ca) (Mg, Fe^{2+}, Fe^{3+}, Al, Li)$_3$Al$_6$ $(BO_3)_3(Si_6O_{18})(OH, F)_4$. Tourmaline belongs to the hexagonal system, its crystals are usually prismatic, tending to be long and slender, often acicular. The crystals are ordinarily terminated with three faces of a rhombohedron and usually hemimorphic. The smaller crystals are frequently found in radial arrangement, and columnar masses are common. The prisms are usually three-, six-, or nine-sided with heavy vertical striations producing a rounded effect.

Tourmaline is essentially without cleavage; fracture, conchoidal to uneven; brittle; hardness, 7–7.5; specific gravity, 3.03–3.25; luster, vitreous inclining to resinous; color, in common tourmaline black, bluish-black, brown, blue, green, red or pink, and in the transparent varieties colorless (rare), various shades of rose and pink, greens, blues and browns. The color arrangement in tourmaline is of considerable interest; bicolored crystals are common and may be green at one end and pink at the other, or green on the outside, and pink within, which, in the case of transparent or translucent crystals, is very attractive.

The opaque black tourmaline is called schorl, a term which was applied to all tourmaline until 1703 when the word *tourmaline* was introduced, it being a corruption of the Ceylonese word, *turamali*. The origin of the word *schorl* is not known, but is perhaps Scandinavian, and is used to identify the iron-bearing black tourmalines; elbaites and liddicoatites tend to light shades of blue, red, green, and their bicolored combinations; the brown colored tourmalines of varying shades of dark brown to yellow to nearly colorless are called dravites and uvites (with the exception of the black tourmalines found at Pierrepont, New York, which have been identified as uvites); the completely colorless variety, achroite, falls within the elbaite group. Small tourmalines are found in granites and some gneisses.

Due to the mineralizing action of magmatic vapors, tourmaline is found particularly well developed in pegmatites, and as a contact metamorphic mineral. A few of the important localities are: the Ural Mountains; Bohemia; Saxony; the Island of Elba; Norway; Devonshire and Cornwall, England; Greenland; Madagascar. Magnificent elbaite crystals are obtained from Madagascar, Brazil, and Afghanistan; liddicoatite crystals from Madagascar. In the United States in Oxford and Androscoggin Counties, Maine; Grafton and Sullivan Counties, New Hampshire; Hampshire County, Massachusetts; Haddam and Fairfield Counties, Connecticut; St. Lawrence County, New York; Sussex County, New Jersey; Delaware County, Pennsylvania; and San Diego County, California.

See also terms listed under **Mineralogy**.

ELMER B. ROWLEY, Union College, Schenectady, NY

TOWERING. A mirage in which the angular height of the image is greater than that of the object. As the width is unaffected (the angular width of image width remains that of the object because the refractive index gradient is vertical), the aspect ratio is altered and distant images appear vertically enlarged. Towering often accompanies *sinking* — distant features appear depressed and enlarged — but it can also accompany *looming*. See also **Looming**; **Mirage**; **Sinking**; and **Stooping**.

TOWER OF WINDS. See **Meteorology**.

TOWNSEND AVALANCHE. A term used in gas-filled counter technology to describe a process which is essentially a cascade multiplication of ions. In this process an ion produces another ion by collision, and the new and original ions produce still others by further collisions, resulting finally in an "avalanche" of ions (or electrons). The terms "cumulative ionization" and "cascade" are also used to describe this process. It occurs in a nonself-maintained gas discharge, where ions have sufficient energy.

TOWNSEND SUPPORT. A fixed support for mounting maximum and minimum thermometers of the liquid-in-glass type. The support holds the thermometers at the correct operating attitude and also permits their rotation for resetting when desired.

See also **Maximum Thermometer**; and **Minimum Thermometer**.

TOXEMIA. The spread of poisonous substances, either those produced by the body cells or those resulting from the growth of microorganisms. There is generalized infection in which the blood contains toxins, but not necessarily bacteria. A form of toxemia arises in certain pregnancies. A rise in blood pressure is often the earliest symptom of toxemia resulting from

a kidney disturbance. Analysis of the urine demonstrates the presence or absence of albumen which also may be indicative of toxemia. The cause of toxemia during pregnancy is not fully understood, but it is usually accompanied by accumulations of salt and water with a marked tendency to retain salt.

TOXICITY. The ability of a substance to cause damage to living tissue, impairment of the central nervous system, severe illness, or, in extreme cases, death when ingested, inhaled, or absorbed by the skin. The amounts required to produce these results vary widely with the nature of the substance and time of exposure to it. "Acute" toxicity refers to exposure of short duration, i.e., a single brief exposure; "chronic" toxicity refers to exposure of long duration, i.e., repeated or prolonged exposures.

The toxicity hazard of a material may depend on its physical state and on its solubility in water and acids. Some metals that are harmless in solid or bulk form are quite toxic as fume, powder, or dust. Many substances that are intensely poisonous are actually beneficial when administered in micro amounts, as in prescription drugs, e.g., strychnine.

Toxicity is objectively evaluated on the basis of test dosages made on experimental animals under controlled conditions. Most important of these are LD_{50} (lethal dose, 50%) and the LC_{50} (lethal concentration, 50%) tests, which include exposure of the animal to oral ingestion and inhalation of the material under test. A substance having an LD_{50} of less than 400 mg/kg of body weight is considered very toxic.

TOXICOLOGY. The technology of poisonous substances — their detection and counteractions. Basic to this branch of science is the realization that chemical compounds vary in their danger to humans and their environment. Poisons can be simple or complex, inorganic or organic chemical compounds, bacterial or viral byproducts (toxins), animal-produced substances, such as venom — all of which produce ill effects on humans ranging from a low level of debilitation to almost instant death. Drugs used in countering diseases or physiological deficiencies can, in some doses, act as poisons. Many metals or elements are essential for life, but their body concentration for optimum health varies from element to element and depends somewhat on bodily weight. Once these optimum concentrations are exceeded, the metals or elements become contaminating, polluting, and often harmful.

Natural and synthetic chemicals affect every phase of our daily lives in both good and noxious manners. The noxious effects of certain substances have been appreciated since the time of the ancient Greeks. However, it was not until the sixteenth century that certain principles of toxicology became formulated as a result of the thoughts of Philippus Aureolus Theophrastus Bombastus von Hohenheim-Paracelsus (1493–1541). Among a variety of other achievements, he embodied the basis for contemporary appreciation of dose–response relationships in his often paraphrased dictum: "Only the dose makes a poison."

Subsequently, further concepts of toxicology came from the work and writings of Bonaventura Orfila (1787–1853), a Spanish physician. Among his most important accomplishments were the delineation of the discipline of toxicology, attempts to correlate chemical nature and toxic effect, and the establishment of bases for the specialization of forensic toxicology. See also **Forensic Chemistry**. The twentieth century has seen significant development of the discipline of toxicology, and its establishment as a professional activity. This has been at least in part the result of a phenomenal increase in the number of synthetic industrial and agricultural chemicals and pharmaceutical preparations. Relying particularly on developments in the chemical, physical, and general biological sciences, toxicologists have made substantial advances in defining the nature and mechanisms of toxic injury, in determining factors which may influence the expression of a toxic effect, in developing methodologies, and in obtaining information on the toxicity of a multitude of discrete or combined substances.

There are about as many definitions of toxicology as there exist textbooks on the subject. Although they differ in detail, all good definitions embrace the concept the toxicology is concerned with the potential of chemicals, or mixtures of them, to produce harmful effects in living organisms. Toxicology is a study of the interactions between chemicals and biological systems in order to determine quantitatively the potential for such chemicals to produce injury that results in adverse health effects in intact living organisms, and to investigate the nature, incidence, mechanism of production, and reversibility of such adverse effects.

In the context of the above definition, adverse health effects are taken to mean those which are detrimental either to the survival or to the normal functioning of the individual. This definition is intended to highlight the following points with respect to phenomena investigated in toxicology.

Materials that produce harmful effects must come into close structural or functional relationship with the tissue or organ they may affect. As a result, they can physically or chemically interact with particular biological components in order to effect the toxic response.

Investigations are carried out using a variety of biological systems, including observations on exposed whole animals (*in vivo* studies) or on appropriately treated isolated tissues and cells, homogenates of tissues, or cultured lower organisms (*in vitro* studies).

If possible, there should be measurement of the toxic effect in order quantitatively to relate the observations made to the degree of exposure (exposure dose). Ideally, there is a need to determine quantitatively the toxic response to several differing exposure doses, in order to determine the relationship, if any, between exposure dose and the nature and magnitude of any effect. Such dose–response relationship studies are of considerable value in determining whether an effect is causally related to the exposure material, in assessing the possible practical (in-use) relevance of the exposure conditions, and to allow the most reasonable estimates of hazard.

A prime consideration in toxicology, and a principal reason behind the need for dose–response relationship information, is the potential for a material to produce harmful effects. Thus, different materials may produce similar toxic effects, but the exposure doses to produce a just-detectable (threshold) effect, or a given degree of injury, may vary significantly among the materials. Hence, the magnitude of the injury produced varies for similar exposure doses to different materials. Also, with a particular material that is known to cause a variety of toxic effects, the individual effects may be produced only by differing exposure conditions. In assessing the relation of any induced toxic effects to practical situations, and in comparing and contrasting different materials, potency is clearly a central issue. Toxicity describes the nature of harmful effects produced with respect to the conditions necessary for their induction; ie, the toxicity of a material is its potential to produce biological injury.

Although studies are carried out by *in vitro* and *in vivo* procedures, it is the primary aim of toxicology to determine the potential for harmful effects in the intact living organism, usually with an ultimate goal of assessing the significance of the findings with respect to humans.

There are four components to a complete risk assessment:

1. Hazard identification involves gathering and evaluating data on the types of health injury or disease that may be produced by a chemical and on the conditions of exposure under which injury or disease is produced. It may also involve characterization of the behavior of a chemical within the body and the interactions it undergoes with organs, cells, or even parts of cells. Hazard identification is not risk assessment. It is a scientific determination of whether observed toxic effects in one setting will occur in other settings.
2. Dose–response evaluation is used in describing the quantitative relationship between the amount of exposure to a substance and the extent of toxic injury or disease. Data may be derived from animal studies or from studies in exposed human populations. Dose–response toxicity relationship for a substance varies under different exposure conditions. The risk of a substance can not be ascertained with any degree of confidence unless dose–response relations are described.
3. Human exposure evaluation is used in describing the nature and size of the population exposed to a substance and the magnitude and duration of their exposure. The evaluation could concern past or current exposures, or exposure anticipated in the future.
4. Risk characterization is defined as the integration of the data and analysis of the above three components to determine the likelihood that humans will experience any of the various forms of toxicity associated with a substance. When the exposure data are not available, hypothetical risk is characterized by the integration of hazard identification and dose–response evaluation data.

Ideally, any series of toxicological investigations should attempt to define the following: the nature of the harmful effects, ie, the basic injury produced; the incidence and severity of the effects as functions of the exposure dose; the mechanisms by which the effects are produced, ie, the fundamental biological interactions and consequent biochemical and biophysical aberrations which are responsible for the initiation and maintenance of the toxic responses; the detection of the effects, ie, the development of methodologies for the specific recognition and quantitation of the toxic effects; and whether there is reversibility of the toxic injury. This may involve a determination of whether spontaneous resolution of injury, ie, healing, occurs after cessation of exposure, or if it is possible to induce reversibility of toxic injury by antidotal or other measures, ie, treatment.

Toxicity, the potential to produce harmful effects, is to be clearly differentiated from hazard, which is the likelihood that a particular material will exhibit its known toxicity under specific conditions of use. See also **Toxicity**.

Sources of information pertaining to toxic substances include local and national health organizations in many countries. Several treatises on the subject have been prepared, including the broad spectrum "Sax's Dangerous Properties of Industrial Materials," John Wiley & Sons, Inc., New York, NY, 2000. This book contains 20,000 entries, each of which gives physical, chemical, and toxicological data about potentially hazardous materials.

R. C. V.

TOXOID. A toxin treated to destroy its toxicity, but leaving it capable of inducing formation of antibodies.

TOXOPLASMOSIS. Toxoplasmosis, a coccidial disease, affects both humans and animals throughout the world. Approximately one-third of the population has antibodies to it but is asymptomatic. Although rare in the past, toxoplasmosis is an increasingly important opportunistic disease that afflicts immunocompromised hosts such as post-transplant patients taking immunosuppressive drugs and AIDS patients. The disease is responsible for a central nervous system infection with symptoms in humans that include fever, headache, swollen lymph glands, cough, sore throat, nasal congestion, anorexia, and skin rash. Complications include neurological abnormalities, seizures, and fatal toxoplasmic encephalitis. In pregnant women, toxoplasmosis can cause miscarriage, premature birth, or blindness in the fetus and is a leading cause of birth defects. In the newborn child, the disease may manifest itself primarily in the eye as chorioretinitis (fetal inflammation of the retina), but it may also cause hydrocephalus, microcephalus, carditis, and hepatitis.

Toxoplasmosis is caused by the protozoan *Toxoplasma gondii*. In humans, the disease is generally acquired by eating inadequately cooked meat or by association with infected felines. Meat becomes infected when cows or sheep graze in pastures contaminated by fecal matter from infected felines. Cats, the most important reservoir of the disease, become carriers by eating infected rodents or by the ingestion of infected feline feces. Pregnant women are advised to avoid eating insufficiently cooked meat, avoid having close contact with cats, and, especially, avoid cleaning feline litter boxes.

The cyst of *T. gondii* is persistant, making long-term therapy a requirement in patients whose immune systems are compromised. Treatment of cerebral or ocular toxoplasmosis is generally accomplished with antifolate compounds consisting of a combination of pyrimethamine (1, [CAS: 58-14-0] $C_{12}H_{13}ClN_4$) and a long-acting sulfonamide such as sulfadiazine (2, [CAS: 68-35-9] $C_{10}H_{10}N_4O_2S$). Sometimes the latter is replaced by triple sulfonamides or sulfalene (3, [CAS: 152-47-6] $C_{11}H_{12}N_4O_3S$). There is evidence that the related mixture of trimethoprim (4, [CAS: 738-70-5] $C_{14}H_{18}N_4O_3$) plus sulfamethoxazole (5, [CAS: 723-46-6] $C_{10}H_{11}N_3O_3S$) (mixture is called Bactrim) is nearly as effective but less toxic than the pyrimethamine combinations. Additional drugs for toxoplasmosis treatment are the antibiotics spiramycin (6, [CAS: 8025-81-8]), used alone or in combination with pyrimethamine or a sulfonamide, and clindamycin (7, [CAS: 18323-44-9] $C_{18}H_{33}ClN_2O_5S$). Clindamycin has been used by itself (reportedly not with great success) and in combination with pyrimethamine to treat chorioretinitis and toxoplasmic encephalitis in AIDS patients. It is especially useful for patients who cannot tolerate extended regimens of sulfonamides.

TRACE AND RESIDUE ANALYSIS. Trace analysis is the detection of minute quantities of organic and inorganic materials.

Trace analysis is generally recognized as those determinations that represent around 0.0001%, i.e., at the parts per million (ppm) level, where 1 ppm is equivalent to 1 μg/g. Ultratrace analysis, i.e., determination below trace analysis, corresponds to levels below ppm or <μg/g. Residue analysis is the analysis of material left from an operation, i.e., residual.

There are numerous applications for trace or ultratrace analyses in the chemical process industry. Environmental toxicology, in particular, is an area where determination of residues and traces of pesticides and other toxic substances is frequently employed.

Frontiers of Low Level Detection

Extremely low level detection work is being performed in analytical chemistry laboratories. Detection of rhodamine 6G at 50 yoctomole (50×10^{-24} mol) has been reported using a sheath flow cuvette for fluorescence detection following capillary electrophoresis. This represents 30 molecules of rhodamine, a highly fluorescent molecule. See also **Electrophoresis**.

Claims of single molecule detection in liquid samples have been made by combining the high sensitivity of laser-induced fluorescence (lif) and the spatial localization and imaging capabilities of optical microscopy. This technique combines confocal microscopy, diffraction-limited laser excitation, and a high efficiency detector. The probe volume is defined latitudinally by optical diffraction and longitudinally by spherical aberration. Using an unlimited excitation throughout and a low background level, this technique allows fluorescence detection of single rhodamine molecules at a signal-to-noise (S/N) ratio of approximately 10 in 1 ms. The use of confocal fluorescence microscopy can be extended to individual, fluorescently tagged biomolecules, including deoxynucleotides, whether single-stranded primers or double-stranded deoxyribonucleic acid (DNA).

Analysis of single mammalian cells by capillary electrophoresis has been reported using on-column derivatization and laser-induced fluorescence detection. Radioactive tracers are powerful tools for trace detection. A method of labeling proteins using ^{99m}Tc has been described. Radiotracer imaging agents have been used for mapping sympathetic nerves of the heart. The radioiodination of analogues of a calichemicin constituent have been employed as a possible brain-imaging agent.

Samples

Sampling. A sample used for trace or ultratrace analysis should always be representative of the bulk material. The principal considerations are determination of population or the whole from which the sample is to be drawn, procurement of a valid gross sample, and reduction of the gross sample to a suitable sample for analysis (see **Sampling**).

Sample Preparation. Sample contamination must be prevented throughout the sampling procedures. No significant changes should occur in the sample when it is being held for analysis. Sample stabilization generally includes storage at low temperatures; however, any stabilization generally includes storage at low temperatures; however, any stabilization step should be validated. A review of sample composition and properties is advised. This would include number of compounds present, chemical structures (functionality) of compounds, molecular weights of compounds, pK_a values of compounds, uv spectra of compounds, nature of sample matrix (solvent, fillers, etc.), concentration range of compounds in samples of interest, and sample solubility. Significant sample losses can occur during this step because of very small volume losses to glass walls of the recovery containers, pipets, and other glassware.

Solid-phase microextraction (SPME), used as a sample introduction technique for high speed gc, utilizes small-diameter fused-silica fibers coated with polymeric stationary phase for sample extraction and concentration. SPME has been utilized for determination of pollutants in aqueous solution by the adsorption of analyte onto stationary-phase coated fused-silica fibers, followed by thermal desorption in the injection system of a capillary gas chromatograph. Full automation can be achieved using an autosampler.

Polycyclic aromatic hydrocarbons (PAHs) have been extracted from contaminated land samples by *supercritical fluid extraction* (SFE) with both pure and modified carbon dioxide. Removing an analyte from a matrix using SFE requires knowledge about the solubility of the solute, the rate of transfer of the solute from the solid to the solvent phase, and interaction of the solvent phase with the matrix. These factors collectively control the effectiveness of the SFE process, if not of the extraction process in general. The range of samples for which SFE has been applied continues to broaden. Applications have been in the environment, food, and polymers.

Sample preparation techniques that prevent or minimize pollution in analytical laboratories, improve target analyte recoveries, and reduce sample preparation costs were evaluated with regard to the *microwave-assisted extraction* (MAE) procedure for 187 compounds and four Aroclors listed in EPA Methods 8250, 8081, and 8141A. The results indicate that most of these compounds can be recovered in good yields from the matrices investigated. Comparative studies were performed to evaluate microwave digestion with conventional sample destruction procedures. These included the analysis of shellfish, meats, rocks, and soils. Generally, comparable accuracy at much shorter digestion time was found for the MAE vs the classical digestion method.

Sample Cleanup. The recoveries from a quick cleanup method for waste solvents based on sample filtration through a Florisil and sodium sulfate column are available. This method offers an alternative for analysts who need to confirm the presence or absence of pesticides or PCBs.

Method Validation

Statistically designed studies should be performed to determine accuracy, precision, and selectivity of the methodology used for trace or ultratrace analyses. The reliability requirements for these studies are that the data generated withstand interlaboratory comparisons.

The following principles should be used to establish a valid analytical method: A specific detailed description and protocol should be written (standard operating procedure (SOP)). Each step in the method should be investigated to determine the extent to which environmental, matrix, material, or procedural variables, from time of collection of material until the time of analysis and including the time of analysis, may affect the estimation of analyte in the matrix. A method should be validated for its intended use with an acceptable protocol. Wherever possible, the same matrix should be used for validation purposes. The concentration range over which the analyte will be determined must be defined in the method, on the basis of actual standard samples over the range (standard curve). It is necessary to use a sufficient number of standards to adequately define the relationship between concentration and response. Determination of accuracy and precision should be made by analysis of replicate sets of analyte samples of known concentration from equivalent matrix.

Methodologies

The commonly used methods for ultratrace analyses together with the accepted detection limits are given in Table 1.

Atomic absorption or emission spectrometric methods are commonly used for inorganic elements in a variety of matrices. A radiochemical neutron activation analysis technique for determination of 26 elements,

TABLE 1. ULTRATRACE ANALYSES METHODS

Method	Minimum amount detected, g
Mass spectrometry

Gas chromatography/mass spectrometry	10^{-12}
Electron capture (negative)/ionization mass spectrometry	10^{-15}

including the emitting elements Th and U and Cu, Fe, K, Na, Ni, and Zn, has been developed. The radiochemical separation was performed by anion exchange on Dowex 1×8 column from HF and HF–NH_4F medium, leading to selective removal of the matrix-produced radionuclides ^{46}Sc, ^{47}Sc, ^{48}Sc, and nearly selective isolation of ^{239}Np and ^{233}Pa, the indicator radionuclides of U and Th, respectively. For K, Na, Th, and U, a limit of detection of 30, 0.05, 0.03, and 0.07 ng/g, respectively, was achieved.

The most commonly used approach in thin-layer chromatography (tlc) entails separations on a silica gel plate where the silica gel is coated as a thin layer on a glass plate. The plate is developed using the mobile phase of choice after a sample has been applied to the starting line of the plate. Quantification is achieved directly by scanning the plate or indirectly by scraping and eluting the sample.

A rapid TLC immunoaffinity chromatographic method has been reported for quantitation in serum of an acute phase reactant, C-reactive protein (CRP), which can differentiate between viral and bacterial infections.

A number of compounds have been quantified by TLC or high performance thin-layer chromatography (HPTLC) using absorption or fluorescence scanning densitometry.

Gas chromatography is a technique utilized for separating volatile substances (or those that can be made volatile) between two phases, one of which is a gas. Purge-and-trap methods are frequently used for trace analysis. Various detectors have been employed in trace analysis, the most commonly used being flame ionization and electron capture detectors.

High pressure liquid chromatography (HPLC), frequently referred to as simply LC or as high performance liquid chromatography, is used in virtually all fields of chemistry. Nonvolatile or thermally labile compounds are best separated by hplc. Although techniques such as adsorption and ion-exchange chromatography have been used, the technique of choice is reversed-phase liquid chromatography (RPLC). In RPLC the stationary phase is nonpolar and the mobile phase is polar and its polarity can be suitably changed.

In HPLC, detection and quantitation have been limited by availability of detectors. Using a uv detector set at 254 nm, the lower limit of detection is 3.5×10^{-11} g/mL for a compound such as phenanthrene. A fluorescence detector can increase the detectability to 8×10^{-12} g/mL. The same order of detectability can be achieved using amperometric, electron-capture, or photoionization detectors. Hplc is capable of routine determination at the nanogram range.

Increased use of liquid chromatography/mass spectrometry (LC/MS) for structural identification and trace analysis has become apparent. Thermospray lc/ms has been used to identify by-products in phenyl isocyanate precolumn derivatization reactions. Liquid chromatography/thermospray mass spectrometric characterization of chemical adducts of DNA formed during *in vitro* reaction has been proposed as an analytical technique to detect and identify those contaminants in aqueous environmental samples which have a propensity to be genotoxic, i.e., to covalently bond to DNA.

Using capillary hplc, femtomole amounts of recombinant DNA-derived human growth hormone (rhgh) have been successfully detected from solutions at nanomolar concentrations. A sample of rhgh that was recovered from rat serum was analyzed by capillary reversed-phase hplc, using both acidic- and neutral-pH mobile phases, as well as by capillary ion-exchange chromatography. Submicrogram amounts of rhgh were also analyzed by tryptic mapping, using capillary hplc, and the resulting peptides were identified by capillary lc/ms.

Capillary electrophoresis (ce) is an analytical technique that can achieve rapid high resolution separation of water-soluble components present in small sample volumes. The separations are generally based on the principle of electrically driven ions in solution. Selectivity can be varied by the alteration of pH, ionic strength, electrolyte composition, or by incorporation of additives. Typical examples of additives include organic solvents, surfactants, and complexation agents.

Supercritical fluid chromatography (SFC) combines the advantages of gc and hplc in that it allows the use of GC-type detectors when supercritical fluids are used instead of the solvents normally used in hplc. Carbon dioxide, *n*-petane, and ammonia are common supercritical fluids. For example, carbon dioxide employed at 7.38 MPa (72.9 atm) and 31.3 °C has a density of 448 g/mL. Derivatization of primary and secondary amines using 9-fluorenylmethyl chloroformate to form a nonpolar, UV-absorbing derivative has been reported.

Immunoassays may be simply defined as analytical techniques that use antibodies or antibody-related reagents for selective determination of sample components. These make up some of the most powerful and widespread techniques used in clinical chemistry. The main advantages of immunoassays are high selectivity, low limits of detection, and adaptability for use in detecting most compounds of clinical interest. Because of their high selectivity, immunoassays can often be used even for complex samples such as urine or blood, with little or no sample preparation.

A two-site immunometric assay of undecapeptide substance P (SP) has been developed. A number of solid-phase automated immunoassay analyzers have been used for performing immunoassays. A number of immunoassay methods have been found useful for environmental analysis (see **Automated Instrumentation**).

Applications

Trace or ultratrace and residue analyses are widely used throughout chemical technology. Areas of environmental investigations, explosives, food, pharmaceuticals, and biotechnology rely particularly on these methodologies.

Environment. Detection of environmental degradation products of nerve agents directly from the surface of plant leaves using static secondary ion mass spectrometry (SIMS) has been demonstrated.

Some of the methods used for determination of organic pollutants in the environment follow. The most notable are polyaromatic hydrocarbons (PAHs) and volatile organic compounds (VOCs).

A variety of organic and inorganic analytes have been analyzed in air and in water. See Table 2.

Explosives. Explosives can be detected using either radiation- or vapor-based detection. The aim of both methods is to respond specifically to the properties of the energetic material that distinguish it from harmless material of similar composition. These techniques are useful for detecting organic as well as inorganic explosives.

Food. Laws and regulations controlling contamination of food were once the province of religious organizations. As far back as the Dark Ages, government set standards. Significant changes have occurred only relatively recently, since the time analytical chemists could characterize most of the substances that comprise food and thus more effectively control contaminants in it. The reliability of data regarding medicated feeds, dairy products, seafood, meat products, fruits and vegetables, and beverages has been reviewed. See also **Millerite**.

The development of analytical strategies for the regulatory control of drug residues in food-producing animals has also been reviewed. Because

TABLE 2. METHODS FOR DETERMINATION OF ORGANIC POLLUTANTS

Analytes	Methods
n-Alkanes	GC/fid
VOCs	Prefraction and GC
PAHs	Sample clean up and GC
Bromoform and other bromine compounds	GC for flame-retardant compounds in air
Nitrodibenzopyranone	Isomeric separations based on gc
PCDDs and PCDFs	GC/MS
PAH	on-line LC/GC for PAH in air
Chlorinated PAH	LC/GC/MS
Nitrated PAH	HPLC with electrochemical detection
Azaarenes	column chromatography, cleanup, and TLC
Toluene diisocyanate	Micro LC
Dimethyl sulfoxide or sulfone	Atmospheric pressure chemical ionization (APCI) MS
VOCs	Ion trap monitoring
Volatile chlorine compounds	Fiber-optic emission sensor-based on AA of chlorine
Formaldehyde	Monitoring tape: hydroxylamine sulfate, methyl yellow
Methyl nitrite	Nitrogen oxide-indicating tubes with ir detection
VOCs	IR-based methods for on-site analysis
Isocyanate species	Chemiluminescent techniques
Benzene	Photoionization detector
Hydrazine	Coulometric methods
Nitrobenzene	Piezoelectric sensors
Fluorocarbon	Metal oxide sensors
Perchloroethylene	Quartz balance and calorimetric transducer

of the complexity of biological matrices such as eggs, milk, meat, and drug feeds, well-designed off-line or on-line sample treatment procedures are essential. For example, methylmercury in fish was extracted and cleaned using column chromatography and then determined using flameless atomic absorption. A rapid and sensitive electrothermal AA spectrophotometric method using a combination of microwave digestion and palladium as a stabilizer was used for detecting Cd and Pb at sub ppm levels in vegetables and protein in foodstuffs.

Inorganic elements in food can be determined by atomic absorption (AA) methods. These methods have been extensively reviewed.

Pharmaceuticals. Examples of trace and ultratrace analyses of various drugs and pharmaceuticals have been provided throughout. The purity of the active ingredient, its content and availability in dosage form, therapeutic blood levels, delivery to target areas, elimination (urine, feces, and metabolites), and toxicity are always of importance.

A safety profile of a generic drug can differ from that of the brandname product because different impurities may be present in each of the drugs. Impurities can arise out of the manufacturing processes and may be responsible for adverse interactions that can occur.

The subject of impurity analysis of pharmaceutical compounds has been insufficiently addressed in the scientific literature. Many monographs in the *U.S. Pharmacopeia* have nonspecific assay methods. An attempt has been made to address this problem by focusing on specific methodologies and delineating origination and concentration of impurities found in pharmaceutical compounds.

Chiral separations have become of significant importance because the optical isomer of an active component can be considered an impurity. Optical isomers can have potentially different therapeutic or toxicological activities. The pharmaceutical literature is trying to address the issues pertaining to these compounds. Frequently separations can be accomplished by glc, hplc, or ce.

Biotechnology. Particular attention must be paid to the detection of DNA in all finished biotechnology products because of the possibility that such DNA could be incorporated into the human genome and thus become a potential oncogene. The absence of DNA at the picogram-per-dose level should be demonstrated in order to assure the safety of biotechnology products.

The isolation and purification of DNA and ribonucleic acid (RNA) restriction fragments are of great importance in the area of molecular biology. These fragments are the product of site-specific digestion of large pieces of DNA and RNA with enzymes called restriction endonucleases. The fragments may range in size from a few base pairs to tens of thousands of base pairs. An ion-exchange column can provide DNA and RNA separations within one hour, giving resolution equivalent to that obtained with gel electrophoresis. Nucleic acid fragments are then visualized, using on-line uv detection and sample loading from 500 ng to 50 mg.

Molecular biologists are utilizing hplc for characterization and purification of proteins, peptides, and antibodies.

SATINDER AHUJA

TRACE ELEMENT (Micronutrient). An element essential to plant and animal nutrition in trace concentration, i.e., minute fractions of 1% (1000 ppm or less). Plants require iron, copper, boron, zinc, manganese, potassium, molybdenum, sodium, and chlorine. Animals require iron, copper, manganese, cobalt, selenium, and potassium. Such elements are also called *micronutrients*. Do not confuse with *tracer*.

TRACE (Mathematics). The sum of the diagonal elements of a matrix, indicated by $Tr\ \mathbf{A} = \Sigma A_{ii}$. Its properties include $Tr\ \mathbf{AB} = Tr\ \mathbf{BA}$; $Tr\ \mathbf{C} = Tr\ \mathbf{A} \cdot Tr\ \mathbf{B}$, where $\mathbf{C} = \mathbf{A} \times \mathbf{B}$, the direct product. It is also called *Spur* from the German word. When a matrix is a representation of a group, its trace is called the *character* of the representation. If **A** and **B** are two matrices related by a similarity transformation, so that $\mathbf{B} = \mathbf{Q}^{-1}\mathbf{AQ}$, then $Tr\ \mathbf{A} = Tr\ \mathbf{B}$.

TRACER. A chemical entity (almost invariably radioactive and usually an isotope) added to the reacting elements or compounds in a chemical process, which can be traced through the process by appropriate detection methods, e.g., Geiger counter. Compounds containing tracers are often said to be "tagged" or "labeled." Carbon-14 is a commonly used tracer, and radioactive forms of iodine and sodium are also used. Many complex biochemical reactions have been examined in this way (e.g., photosynthesis). Nonradioactive deuterium (hydrogen isotope) is sometimes used, the detection being by molecular weight determination. Radioactive enzymes are also available for tracer studies, e.g., ribonuclease, pepsin, trypsiln, and others.

See also **Carbon**; and **Radioactivity**.

TRACHEA. 1. An air tube of the arthropod respiratory system. These tubes open at the surface of the body through spiracles and lead inward, branching extensively and in some species expanding to form air sacs. At their inner extremities they connect with very fine tubules called tracheoles, of independent origin. Tracheae are ingrowths of the outer layer of the body and are lined with a continuation of the cuticula, which forms spiral rods in their walls. Near the spiracle they are often provided with a muscular closing device by which air can be excluded if it contains harmful materials. The tracheoles form within cells of the lining of tracheae, later breaking out and assuming their connection with the larger tubes. They have no spiral supporting rods (taenidia).

2. The principal air tube of the vertebrate respiratory system, also called the wind pipe. It leads from the pharynx to the major branches (bronchi) connecting it with the lungs, and its wall is supported by rings of cartilage. At the pharyngeal end in amphibians and mammals it forms an expanded larynx containing vocal cords, and at the point where it forks to form the bronchi in birds the remarkable vocal organ called the syrinx is developed.

TRACHEOSTOMY (Tracheotomy). For relieving certain types of airway obstruction, a surgical opening is made in the forward wall of the windpipe (trachea). A tube is inserted through this small aperture to provide access to an air supply for the patient. The procedure is used in life-saving situations, particularly in the case of children where complete closure of the larynx may occur. Other conditions which sometimes require the procedure include choking in connection with eating, injuries to the chest, poliomyelitis, extensive burns, and severe respiratory infections. Once the underlying cause of the injury or disease is ascertained and normal breathing can be restored, the tube is removed, and the aperture is closed. Usually the wound will close itself in a relatively short period without any aftereffects.

TRACHOMA. Trachoma is a chronic infection of the conjunctiva, the thin membrane that covers the outer surface of the eye and the inside lining of the eyelids. It is caused by a microorganism that grows only within eyelid cells, and it is one of the oldest infectious diseases, dating back several thousand years. Because the disease is not fatal and causes progressive rather than sudden damage to the eyes, it is often not taken seriously and may even be accepted as a fact of life in some countries. The trachoma infection is the leading cause of blindness in the world.

The disease is rare in the United States and is most often seen in third-world and developing nations where poverty, overcrowding, personal hygiene, and access to clean water and health care are problems. It is prevalent in many African countries, parts of Central and South America, and some countries in the Eastern Mediterranean and in Asia.

Trachoma is caused by infection with the microorganism *Chlamydia trachomatis* and is highly infectious, usually spread by contact with eye or nose discharge from an infected person. It is also transmitted by flies and gnats, which are attracted to eyes and runny noses. Because it is easily transmitted from person to person, the disease often strikes entire communities.

In the early stages, trachoma resembles conjunctivitis. It starts with an inflamed outer lining of the eye (conjunctiva) and is accompanied with eye discharge and sticky, red eyes. Tearing, light sensitivity, swollen eyelids, pain, and corneal inflammation are some of the first symptoms. As the disease progresses over time, the recurring infections scarring on the inside of the eyelid. Eventually the inside of the eyelids cause are scarred so badly that they turn inward with the eyelashes rubbing the eyeballs, scratching the lenses of the eyes with each blink and causing corneal ulcerations that become infected. This scarring leads to blindness. Although trachoma begins in childhood, blindness usually does not occur until the age of 40 or 50 after repeated infections cause inflammation and scarring.

In the early stages of the infection, antibiotics can effectively treat trachoma. However, if the disease progresses, as is often the case in underdeveloped countries, treatment becomes difficult. After scarring begins, a simple surgical procedure known as tarsal rotation is required to reverse the inturned eyelashes. Surgeries to repair lid deformities and corneal transplants are also options, but are not available to most people who are afflicted by the disease. Trachoma is preventable with proper diet, sanitation and education. By simply washing their faces and hands, children will not spread the infection.

Although blindness from trachoma has been eliminated in several countries around the world, the disease continues to be a serious public health problem in many underdeveloped areas. See also **Conjunctiva**; and **Vision and the Eye**.

Vision Rx, Inc., Elmsford, NY

TRACHYTE. The name of an extrusive, igneous, fine-grained or porphyritic rock, the surface equivalent of syenite. Trachyte is predominant in alkali feldspar and usually contains biotite and augite. Trachyte is an old name, proposed by Brongiart in 1813, and has never been altered or supplanted. It is derived from the Greek, meaning rough.

TRACKING. In radio circuits, this term is used to designate the maintenance of a relation between the resonant frequencies of two or more circuits tuned from the same shaft. Thus in the superheterodyne receiver the oscillator tuning must track with the tuned radio frequency circuits so the difference in frequency will always be the constant intermediate frequency.

In gunnery the term is used to designate the following of the target by the director or gun.

With radars used for following a target, tracking may be manual, where the operator turns azimuth and elevation angle controls in such a manner as to realize a maximum returned signal from the target; or it may be automatic, where a narrow conical or pencil-shaped beam is electronically "locked" on the target.

In correlation tracking and ranging, a nonambiguous trajectory-measuring system for aircraft and space vehicles, using short-baseline, single-station, continuous-wave phase-comparison measuring two direction cosines and a slant range, is used. In correlation tracking and triangulation, a trajectory measuring system for aircraft and space vehicles, and several antenna baselines, each separated by large distances, are used to measure direction cosines to an object. From these measurements, space position is computed by triangulation.

TRACKING AND DATA RELAY ($T + DRE$). See **Nimbus Satellite Program**.

TRACK (Navigation). A term used in navigation to describe the direction and distance a ship has moved in a given length of time. If a ship is known to be in a definite position at a given time and to be in another position after the elapse of a definite period of time, then the direction of the rhumb line between the two points is the track, and the length of the lines gives the track distance. Other lines, such as Lambert, great circle, etc., might be computed between the two points, yielding the Lambert track, but the term track is usually restricted to the rhumb line. It should be carefully noted that the positions at the extremes of the track must be accurately known. These may be determined by any reliable fix or, in the case of airplanes, by landmarks beneath the ship. See also **Course**; **Heading**; and **Navigation**.

TRACTION. In a narrow sense, traction refers to the friction developed between a powered surface and one in contact with it. The most common example of traction is the resistance to slipping developed at the point of contact of a driven wheel with the surface on which it rolls. The locomotive driver on its rail, the pneumatic tire on the highway, or the traction engine wheel on earth, illustrate this case. But traction is not confined to wheels, as may be proved by citing another example. The traction sheave of an elevator is a grooved pulley, power-driven, over which passes a rope which is driven by the sheave. The friction between the rope and pulley constitutes the traction.

In a larger sense, traction includes the act of pulling a load over a surface by overcoming the resistance to motion, and the word may also be used descriptively of any vehicle which by its excess of power over its own tractive needs is able to pull other vehicles. In the case of an automobile rolling on a highway, traction is applied through the rear wheels by means of a live axle which delivers a torque to the wheel. The load on the wheel presses it against the road surface enough to develop sufficient friction so that the resistance to motion will be overcome before the wheel slips on the road. If the roadbed be covered with a surface of low frictional power, for example, wet clay, there will be little traction developed because of the low coefficient of friction. The traction of an automobile must overcome wind resistance, wheel bearing friction, rolling resistance, and grade.

TRACTRIX OF HUYGENS. A higher plane curve of transcendental type. Its equation is the solution of a differential equation resulting from the following problem in mechanics. A rope of length a, attached to a massless particle, moves along the X-axis. The path of the particle in the XY-plane is determined by the differential equation $(y^2 - a^2)p^2 + y^2 = 0$, where $p = dy/dx$. The solution, which is the equation of the tractrix, is

$$\pm x = \sqrt{a^2 - y^2} - a \ln \left\{ \pm \frac{a + \sqrt{a^2 - y^2}}{y} \right\}$$

The evolute of the tractrix is a pair of catenaries, one lying above the X-axis and the other below. There are four branches to the curve, with cusps at $(0, \pm a)$. The X-axis is an asymptote.

See also **Catenary**; and **Curve (Higher Plane)**.

TRADE INVERSION. A characteristic temperature inversion usually present in the trade-wind streams over the eastern portions of the tropical oceans. It is found in large-scale subsiding flows constituting the descent branches of the *Hadley cell* and *Walker circulation.* The subsidence warming in the inversion layer is balanced by radiative cooling and evaporation from the tops of trade cumuli. The height of the base of this inversion varies from about 500 meters (1,640 feet) at the eastern extremities of the subtropical highs to about 2,000 meters (6,562 feet) at the western and equatorial extremities. In the equatorial trough zone and over the western portions of the trade-wind belt, the inversion does not exist as a mean condition, although it appears in certain weather patterns. The strength of the inversion varies enormously, occasionally being more than 10 °C (50 °F) over 1 km (0.62 mi), but sometimes being absent altogether, especially in the Northern Hemisphere. The inversion is generally strongest when the height of its base is lowest, and vice versa. The thickness of the inversion layer varies from only a few meters to more than 1,000 meters (3,281 feet). On the average its thickness is about 400 meters (1,312 feet). The airflow below the inversion is very moist and filled with cumulus clouds (trade cumuli). Above it, the air is warm and exceedingly dry; this structure is so characteristic of the trade current that tropical analysts think of the tropical troposphere as consisting of a lower moist and an upper dry layer. See also **Hadley Cell**; **Meteorology**; and **Walker Circulation**.

TRADEMARKS. Conventionally, a trademark comprises a name, word, phrase, logo, symbol, design, image, or a combination of two or more of these elements. There is also a range of non-conventional trademarks comprising marks which do not fall into these standard categories.

A trademark's function may be characterized as an identification of origin, a guarantee of quality, and an advertising device. In identifying origin, a trademark affords a convenience to both owner and customers by minimizing confusion of the goods of the trademark owner with those of others. In guaranteeing quality, it assures the purchaser that the goods bearing the mark will have the same quality as those previously purchased under the same mark. In both instances, the public interest is cited by the courts as a basis for protection to avoid deception or confusion. In advertising, the trademark offers a convenient shorthand device to help focus the attention and the good will of the public on the product. Protection of the trademark represents protection by the courts of a property right of the trademark owner.

Related to trademarks are service marks, certification marks, and collective marks. Service marks are words, names, symbols, devices, or combinations thereof, used to identify the services of one party and distinguish them from the services of others. Certification marks are used in connection with the products or services of one or more parties other than the owner of the mark to certify the product's origin, material, mode of manufacture, quality, accuracy, or other characteristics, or that the work or labor on the product was performed by members of a union or other organization. Collective marks are trade or service marks used by members of a cooperative, association, or other collective group. They include marks indicating membership in a union, association, or other organization. Principles applicable to service, certification, and collective marks are generally similar to those applicable to trademarks.

Ownership of a trademark confers the exclusive right to use it or authorize its use in connection with the goods of its owner or goods made by others to the owner's quality standards. Conversely, it also confers the right to prevent others from using the mark, or another mark so similar as to be confused for the original, on similar or related goods. Trademark protection is a type of restraint afforded by the courts against unfair competition.

In the United States and other common law countries, the right to protection of a trademark arises independently of statutory provisions. Both the public and the owner have an interest in such protection. The owner's interest lies in protecting the value of the mark as a device for attracting and retaining customers for the goods sold under the mark, based on recognition gained through use of the mark in advertising and the reputation for quality of the goods on which it is used. The public interest lies in avoiding the confusion, deception, and fraud that would likely result from unauthorized use of the mark or similar marks by others.

Although distinct from trademarks, trade names also are entitled to protection against unfair competition. Trade names and trademarks should not be confused. A trademark identifies particular goods as originating from a specific business; a trade name identifies the business itself. Trade names include individual names and surnames, firm names, and other names used by manufacturers, industrialists, merchants, and others to identify their businesses, vocations, or occupations. Depending on the manner of its use, a trade name may also function as a trademark. For example, the name General Electric, when used to refer to the corporation, is a trade name; when applied to merchandise, eg, General Electric refrigerators, it is a trademark.

Trademarks, as Distinct from Patents and Copyrights

Trademark rights are generally acquired by use of the mark on or in connection with the goods of its owner. It is accorded legal protection at common law independent of statutory provisions or registration. Registration, available under the laws of the states as well as under federal statute, enhances or facilitates protection of the trademark right. Acquisition of the trademark right by use in connection with the goods is a prerequisite to obtaining registration. Under the 1988 Trademark Revision Act, applications for trademark registration may be filed on the basis of a bona fide intent to use the mark, but proof of actual use is still required before a registration is issued.

Patents afford the owner the right to exclude others from making, using, or selling an invention or process, and are entirely dependent on statutory registration. They are acquired by disclosing an invention in an application duly filed and prosecuted in accord with the patent laws.

Copyrights afford in most cases an exclusive right to control distribution, reproduction, adaptation, public performance, and public display of literary or artistic works. They arise automatically upon creation of an eligible work, but the exercise of such rights is governed exclusively by federal statute.

Authority for protection of patents and copyrights is set out in the Constitution and is the exclusive province of the federal government. Trademark protection is provided by federal and state legislation, as well as common law. Federal legislation to protect trademarks is based on the authority of Congress, under the commerce clause of the Constitution, to regulate interstate and foreign commerce of the United States; protection afforded by individual states is based on their power to regulate intrastate commerce.

History

Trademarks were known in ancient civilizations. Wine jars found in Pompeii bore the mark Vesuvinum, identifying their contents as a wine produced in the region of Vesuvius. The artisan's guilds of Europe adopted marks to identify merchandise originating with their members; such marks were protected against falsification by penal laws.

British and U.S. courts began developing case law to protect trademarks against infringement in the early 1800s. In 1883, the United Kingdom adopted a statute that provided for registration of fancy words as trademarks. The United States enacted its first federal trademark statute in 1870, but the statute was declared unconstitutional in 1879. Subsequent federal trademark statutes were adopted in the United States in 1881, 1905, and 1920; the present comprehensive statute, known as the Lanham Act, was enacted in 1946. The Lanham Act was substantially revised for the first time in 1988 by the Trademark Law Revision Act of 1988. The 1988 act, which became effective on November 16, 1989, both modified and supplemented the earlier statute.

TRADE-WIND CUMULUS. See **Clouds and Cloud Formation**.

TRADE WINDS. See **Winds and Air Movement**.

TRAGACANTH. See **Gums and Mucilages**.

TRAGOPANS *(Aves, Galliformes)*. The tragopans (subfamily *Tragopaninae*) are fairly large, compact, and very colorful *Galliformes*. The tail is short and rounded. There are 18 tail feathers. The tarsi have a short spur in the male. In the male, the throat and side of the face are bare. The male also has a distensible skin flap at the throat which can be inflated in excitement along with hornlike, stalk-shaped erectile bodies on the back of its head. There is 1 genus (*Tragopan*) with 5 closely related species. See Fig. 1.

Fig. 1. Satyr tragopan (*Tragopan satyra*). (*Sketch by Glenn D. Considine.*)

Like the curassows and guans of tropical America, the tragopans spend a great deal of time on the branches in the crowns of trees where they find much of their food. They mainly eat tender leaves, buds, berries, fruit, and lesser amount of animal food. They are unbelievably shy and have a very acute sense of hearing. At the slightest suspicious sound they slink off like cats, using every bit of cover. Only rarely do they leave the protective darkness of shady forests and, at the most, take a sunbath in lightly wooded areas at noon. Their flight is swift and accompanied by a whirring noise. But in general, tragopans are rather disinclined to fly. See also **Galliformes**.

TRAGULINES *(Mammalia, Artiodactyla)*. A very small group of animals in the order of *Artiodactyla* (even-toed hoofed animals). The Chevrotains, sometimes called Mouse-Deer, appear to be leftovers from an ancient and quite diverse number of ruminating animals. It appears that the ancestors of these small mammals were also the ancestors of other groups in *Artiodactyla*, including the bovines, caprines, cervines, antelopines, and giraffines. Mouse-deer is a misleading term because there is no direct connection between the chevrotains and the deer in particular. Two types of chevrotains are recognized: (1) The Oriental Chevrotains (*Tragulus*); and (2) the Water-Chevrotains (*Hyemoschus*).

There are several species of the Oriental Chevrotains, appearing in southeast Asia, ranging from India to the Philippines. The Indian chevrotain (*T. meminna*) is a slender delicate animal, about the size of a rabbit. Its fur is red-brown with small white spots, with lighter fur underneath. The animal is nocturnal and prefers the tangled undergrowth. The Water-Chevrotains occur in central Africa. They are semi-aquatic. Some of the Oriental Chevrotains have been domesticated.

TRAJECTORY (of a Path). A curve in space tracing the points successively occupied by a particle or body in motion. At any given instant the velocity vector of the object is tangent to the trajectory. In the steady-state flow of aggregates of particles, such as parcels of fluid, the trajectories and streamlines of the fluid parcels are identical. Otherwise, the curvature of the trajectory K_T is related to the curvature of the streamline K_S by Blaton's formula

$$K_T = K_S - \frac{1}{V}\frac{\partial \psi}{\partial t}$$

where V is the parcel speed and $\partial\Psi/\partial t$ is the local change of its direction. Note that the use of the term *trajectory* for the path of a body implies that its motion is the result of an externally applied force (i.e., not an engine or propellant in the body itself), and that it usually implies also an open path.

TRALLES SCALE. See **Specific Gravity**.

TRAMONTANA. See **Winds and Air Movement**.

TRANSACTINIDE ELEMENTS. See **Chemical Elements**.

TRANSACTINIUM EARTHS. A group of chemical elements more frequently termed the Actinides. In order of increasing atomic number, they include actinium, thorium, protactinium, uranium, neptunium, plutonium, americium, curium, berkelium, californium, einsteinium, fermium, mendelevium, nobelium, and lawrencium. See also **Actinide Series**.

TRANSCENDENTAL. A term applied to numbers, equations, or functions that are not algebraic. The word comes from the Latin, *scandere*, to climb, and it is intended to suggest only that transcendental operations cannot be defined by elementary methods ("*Quod algebrae vires transcendit*"). No special difficulty in understanding their properties is signified nor is there any religious or philosophical connotation to the word.

A transcendental number is not a root of a polynomial in one unknown, with integral coefficients. Typical examples are: e, the base of natural logarithms and π, the area of a circle with unit radius.

Some transcendental functions are: trigonometric and hyperbolic, with their respective inverses; exponential and logarithmic; beta and gamma; elliptic; Bessel; etc. They may be subdivided into a class defined as the solution to a differential equation, which is true for those listed in the previous sentence and one not so defined, like the Riemann zeta function.

Transcendental equations contain one or more transcendental functions. They cannot, in general, be solved by direct analytical means and some approximate method must be used.

See also **Number Theory**.

TRANSDUCER. 1. A device by means of which energy can flow from one or more transmission systems to one or more other transmission systems. The energy transmitted by these systems may be of any form (for example, it may be electric, mechanical, or acoustical), and it may be of the same form or different forms in the various input and output systems. 2. For some purposes, the transducer is defined (more narrowly) as a device capable of being actuated by waves from one or more transmission systems or media, and of supplying related waves to one or more other transmission systems or media. It is sometimes implied that the input and output energies shall be of different forms. For example, an electroacoustic transducer accepts electrical waves and delivers acoustic waves.

Among the types of transducers in addition to those designated by nature of energy change, such as electroacoustic or electromechanical transducers, are:

The *active transducer*, whose output waves are dependent upon sources of power, apart from that supplied by any of the actuating waves, which power is controlled by one or more of these waves.

The *conversion transducer*, an electric transducer in which the input and the output frequencies are different. If the frequency-changing property of a conversion transducer depends upon a generator of frequency different from that of the input or output frequencies, the frequency and voltage or power of this generator are parameters of the conversion transducer.

The *harmonic conversion transducer*, a conversion transducer in which the useful output frequency is a multiple or a submultiple of the input frequency. Either a frequency multiplier or a frequency divider is a special case of harmonic conversion transducer.

The *heterodyne conversion transducer*, a conversion transducer in which the useful output frequency is the sum or difference of the input frequency and an integral multiple of the frequency of another wave.

The *passive transducer*, whose output waves are independent of any sources of power which is controlled by the actuating waves.

The *ideal transducer*, a hypothetical passive transducer that transfers the maximum possible power from a specified source to a load. In linear electric circuits and analogous cases, this is equivalent to a transducer which (a) dissipates no energy and (b) when connected to the specified source and load, presents to each its conjugate.

TRANSFERASES. See **Enzyme**.

TRANSFER CHARACTERISTIC. In electron devices a relation, usually shown by a graph, between the voltage or current of one electrode and the current to another electrode, all other electrode voltages being maintained constant.

TRANSFERENCE NUMBER (or Transport Number). The transport number of a given ion in an electrolyte is the fraction of total current carried by that ion.

TRANSFER FUNCTION. The ratio of output response to input signal or a particular component or system is known as the transfer function. Although this ratio is usually expressed in a mathematical statement, it can be also be expressed in a frequency response plot. In the case of a simple resistive-capacitive type component, the transfer function may be expressed as follows:

$$\frac{E_0(s)}{E_i(s)} = \frac{1}{1+Ts}$$

This is the Laplace transform of the general equation (see also **Time Constant**) for a first-order system with zero initial conditions. Similar transformations can be developed for more complex systems. In most cases transfer functions are expressed in Laplace notation.

TRANSFER ORBIT. See **Astronautics**.

TRANSFINITE NUMBER. An important concept in the modern mathematical idea of infinity, developed by George Cantor (1845–1918), a German mathematician. Consider the natural numbers 1, 2, 3, …, which are said to be denumberably infinite and compare them with another set, also containing an infinite number of elements. The latter, too, is denumerably infinite if its members can be matched up one-by-one with the natural numbers. Thus, the even numbers form such a set, for the two sets could be matched up as follows: (1, 2), (2, 4), (3, 6), and so on. All sets of this kind are said to have the cardinal number *aleph-null*, written with the Hebrew character, $\aleph_0$ and this is the first transfinite cardinal number.

However, surprising as it seems at first, given a denumerably infinite set of real numbers between 0 and 1, there are real numbers in this range which are not members of the set. These are the transcendental numbers; the set of all real numbers is not denumerably infinite and Cantor called the cardinal numbers of this set, C, "*the power of the continuum*," which he believed was equal to $\aleph_1$. Mathematicians today, however, are uncertain about this and there may be other transfinite numbers between $\aleph_0$ and C. It is generally agreed that the following are some properties of these strange numbers (n is a finite number): (1) $\aleph_0 + n = \aleph_0$; (2) $\aleph_0 + \aleph_0 = \aleph_0$; (3) $n\aleph_0 = \aleph_0$; (4) $\aleph_0^n = \aleph_0$; (5) $\aleph_0\aleph^0 = C$; (6) $\aleph_0 + C = C$; (7) $\aleph_0 C = C$. It is also possible to conceive of cardinal numbers $\aleph_0, \aleph_1, \aleph_2, \ldots, \aleph_n$ where n is a natural number and then $\aleph_w, \aleph_{w+1}, \ldots$ larger in turn than any of the previous ones. See also **Infinity**.

TRANSFORM. 1. If A, B, X are three matrices or three elements of a group then $B = X^{-1}AX$ is the transform of A by X and A, B are conjugate to each other. The complete set of group elements which are conjugate to each other form a class of the group.

2. An integral equation of the first kind,

$$f(y) = \int K(x, y)F(x)\,dx$$

is called the transform of $F(x)$. For certain special cases, see also **Integral Transform**.

TRANSFORMATION (Mathematics). A change of variables in an algebraic expression. Consider a point (x, y) in a plane, referred to a rectangular coordinate system, XOY and let another coordinate system $X'O'Y'$ have its origin at the point (h, k). Then the coordinates of the point in the second system will be (x', y'), where $x = x' + h$, $y = y' + k$. Similarly, if another system $X''OY''$ has the same origin as XOY but the coordinate axes are rotated by the angle θ, the relations are $x = x'\cos\theta - y''\sin\theta$, $y = x''\sin\theta + y''\cos\theta$. A more general case is an affine transformation, $x' = a_1x + b_1y + c_1$, $y' = a_2x + b_2y + c_2$. If the determinant of the coefficients, $\Delta = a_1b_2 - a_2b_1 \neq 0$, special cases of it are translations, rotations, reflections in the axes, strains, elongations, and compressions. Parallel lines or finite points are transformed into similar configurations; the line at infinity remains fixed. If $\Delta = 0$, the transformation is singular.

Matrix notation is frequently useful for discussing transformations. Consider now rectangular coordinate systems in space, $OXYZ$ and $OX'Y'Z'$. The same vector could be described in either system by the relation $\mathbf{x'} = \mathbf{Bx}$, where the elements of the matrix $\mathbf{B}$ are direction cosines for the various pairs of coordinate axes. Alternatively, one may have one coordinate system and rotate the vector $\mathbf{x}$ through the angle θ to obtain a new vector $\mathbf{y}$. A similar matrix equation results, $\mathbf{x} = \mathbf{Ry}$, but the elements of $\mathbf{B}$ and $\mathbf{R}$ are not identical.

Given a transforming matrix like $\mathbf{B}$ or $\mathbf{R}$, it is often the case, that still another coordinate system is desirable so that simpler relations exist between the two vectors. We then seek a transformation of the form $\mathbf{B} = \mathbf{PAQ}$, in which $\mathbf{A}$ and $\mathbf{B}$ are said to be equivalent. Important special transformations are: (a) $\mathbf{P} = \mathbf{Q}^{+1}$, collineatory or similarity transformation (German, *Ähnlichkeits-transformation*); (b) $\mathbf{P} = \tilde{\mathbf{Q}}$, congruent; (c) $\mathbf{P} = \mathbf{Q}\dagger$, conjunctive; (d) $\mathbf{P} = \mathbf{Q} = \mathbf{Q}^{+1}$, real orthogonal; (e) $\mathbf{P} = \mathbf{Q}\dagger = \mathbf{Q}^{+1}$, unitary. Case (c) is identical with (b) if the matrices are real; (d) is also case (b) and case (e) is also (c). For the meaning of the symbols designating the properties of $\mathbf{P}$, see also **Matrix (Mathematics)**.

If w is a function of the complex variable z, the linear fractional transformation is

$$w = (az + b)/(cz - d); (ad - bc) \neq 0$$

where a, b, c, d are constants, real or complex. It is a mapping or transformation in the complex plane. A circle in the z-plane is transformed into a circle in the w-plane. A straight line transforms in the same way, for it may be regarded as a special case of a circle. Since there are only three independent constants in the transformation, any three points z_1, z_2, z_3 are images of w_1, w_2, and w_3. Thus the points in the z-plane become 0, 1, ∞ by the transformation,

$$w = (z_2 - z_3)(z - z_1)/(z_2 - z_1)(z - z_3)$$

Other terms used for this type of transformation are MÄbius, general bilinear, and homographic transformation. See also **Conformal Representation**.

The equation of a polynomial is sometimes transformed in order to change the values of its roots.

TRANSFORMER. A device that raises or lowers the voltage of an alternating current; a static electric device consisting of a winding, or two or more coupled windings, with or without a magnetic core, for introducing mutual coupling between electric circuits (IEEE). Transformers are extensively used in electric power systems to transfer power by electromagnetic induction between circuits at the same frequency, usually with changed values of voltage and current. For example, electricity generated at a central utility station with a voltage of about 22,000 V is transformed to 500,000 V for transmission over high-tension lines. Further downline, the electricity is transformed to about 66,000 V, at which value it may be fed to heavy industries; and still further downline, transformers step the voltage down to about 4000 V for local area distribution to commercial and industrial consumers. Ultimately, transformers (usually pole-mounted) step the voltage down to 230–115 V for use by residential and small business and retail consumers.

The use of transformers by the electric lighting and power industry was commenced more than a century ago (Great Barrington, Massachusetts, 1885; Chicago, Illinois, 1893; Niagara Falls, New York, 1895), during a period when alternating current was winning over direct current as the medium of choice for electric utility systems. As important as transformers are and have been to the electric power distribution system, these devices also find innumerable other applications involving electric circuitry. The wide range of uses include battery chargers, communication systems, electric furnaces, electric tools and toys, and desk lamps, among many others. Instrument transformers for metering electricity consumption (a very difficult problem in the early days of electric utilities) are described in the following article in this encyclopedia.

Stepwise Evolution of the Transformer

The concept of the transformer as ultimately used, unlike many other electrical/electronic inventions (transistor, for example), did not occur as a sudden breakthrough, but rather the transformer developed out of a series of fundamental scientific discoveries. A capsule of the scenario is about as follows: (1) Oersted (1820) demonstrated that an electric current flowing through a conductor creates a magnetic field around that conductor. At that time, Oersted's finding was exciting because electricity and magnetism were considered to be separate, unrelated forces. (The question may have been raised: If, on the one hand, an electric current can create a magnetic field, would a reverse phenomenon occur? i.e., a magnetic field creating an electric current.) (2) Faraday (1831) showed that for a magnetic field to induce a current in a conductor, the field must be a changing one, thus suggesting that the phenomenon would be operative with an interrupted or pulsing direct current, not a steady dc flow, or what later was to be developed, the alternating current, ac. (Tesla did not design the first practical system for generating and transmitting alternating current for electric power until the mid-1880s.) Faraday's experiments are described in some detail in article on **Motor (Electric)**. (3) Although some essential research occurred during the middle 1800s (as by Joseph Henry, whose research on electromagnetic induction independently and unknowingly paralleled that of Faraday), no impelling needs for a transformer-like device existed. It required the economic thrust of ac power generation and distribution, with its almost unlimited commercial potential, for technologists to reduce the principles underlying the transformer to practical, reliable hardware.

Fundamentals of the Transformer

In the transformer, there are no moving parts and no electrical connection between circuits because energy is transferred through a magnetic linkage. Regardless of the voltage, the energy-supply circuit is termed the *primary*; the energy-receiving circuit is the *secondary*. Since so many types of transformers require power to be supplied at changed voltages, and all electric power transmission systems involve changes in voltage, the range of transformer sizes, types, and specifications is very great indeed. In serving a multiplicity of applications, the transformer can range from tiny assemblies the size of a pea or less to massive units weighing 500 tons or more.

In an elementary form, the transformer consists of two coils wound of wire and inductively coupled to each other. When alternating current at a given frequency flows in either coil, an alternating electromotive force (emf) of the same frequency is induced into the other coil. The value of this emf depends upon the degree of coupling and the magnetic flux linking the two coils. The coil connected to a source of alternating emf is usually called the *primary coil*; the emf across this coil is the *primary emf*. The emf induced in the *secondary coil* may be greater than or less than the primary emf, depending upon the ratio of the primary to secondary turns. A transformer is termed a *step-up* or a *step-down* transformer accordingly. Most transformers have stationary iron alloy cores, around which the primary and secondary coils are placed. Because of the high permeability of iron alloys, most of the flux is confined to the core and tight coupling between the coils is thereby obtained. So tight is the coupling between the coils in some transformers that the primary and secondary emfs bear almost exactly the same ratio to each other as the turns in the respective coils or windings. Thus, the turns ratio of a transformer is a common index of its function in raising or lowering potential.

A simple transformer coil and core arrangement is shown in Fig. 1. The primary and secondary coils are wound one over the other on an insulating coil tube or form. The core is laminated to reduce eddy currents. Flux flows in the core along the path indicated, so that all the core flux links both windings. In a circuit diagram, the transformer is represented by the symbol given in Fig. 2.

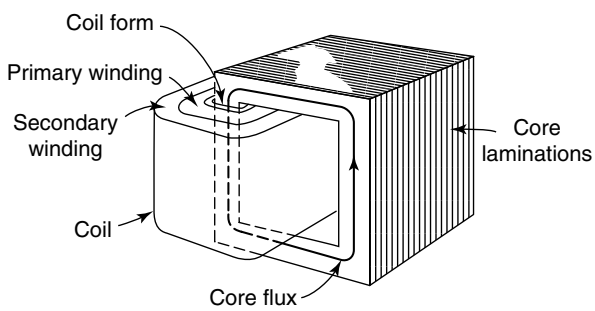

Fig. 1. Transformer coil and core.

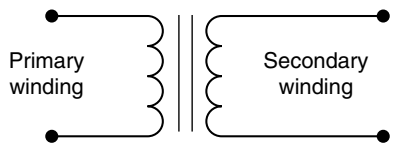

Fig. 2. Simple transformer.

Common contemporary transformer configurations are given in Fig. 3.

In order for a transformer to deliver secondary emf, the primary emf must vary with respect to time. A dc potential produces no voltage in the secondary winding or power in the load. If both varying and dc potentials are impressed across the primary, only the varying part is delivered to the load. This comes about because the emf e in the secondary is induced in that winding by the core flux ϕ according to:

$$e = N\, d\phi\, dt.$$

Reduced to words, the voltage induced in a coil is proportional to the number of turns and to the time rate of change of magnetic flux linking the coil. This change of magnetic flux may be large or small. For a given potential, if the rate of change of flux is small, many turns must be used. Conversely, if a small number of turns is used, a large rate of change of flux is necessary to produce a given potential.

An ideal transformer may be defined as one which neither stores nor dissipates energy. Departures from the ideal transformer are caused by: (1) winding resistance and capacitance; (2) leakage inductance (due to flux which does not link both windings); (3) core hysteresis and eddy current losses; and (4) magnetizing current.

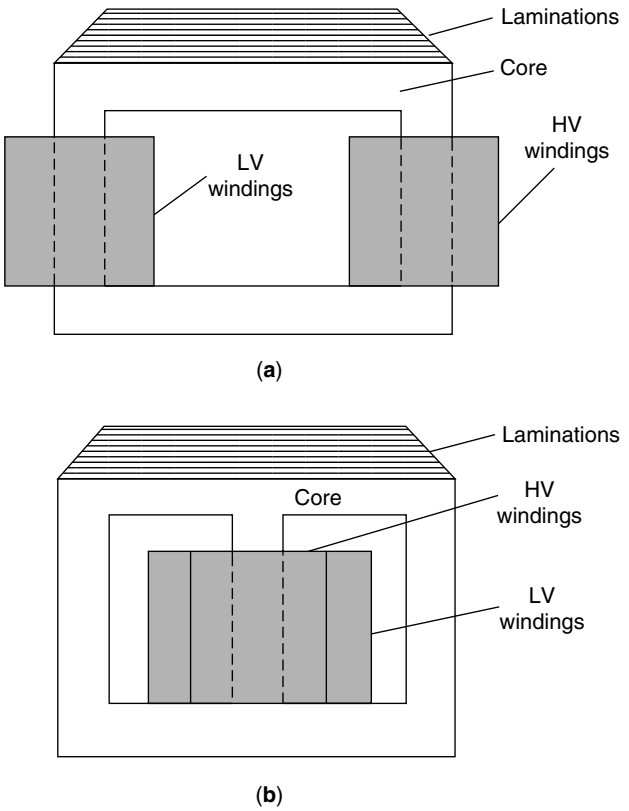

Fig. 3. Highly schematic diagram of common contemporary transformer configurations; (**a**) *core form*, where the primary encloses one arm of the core and the secondary the other; (**b**) *shell form*, which is made up of E-shaped stampings with the primary and secondary coils nested together on the middle bar. Both cores are constructed from stacked laminations stamped out of iron sheets. In three-phase transformers, the coils are nested on all three bars of (**b**). HV = high voltage; LV = low voltage.

Transformers are required in electronic apparatus to provide the different values of potential for device operation to insulate circuits from each other; to furnish high impedance to alternating current but low impedance to direct current; to change from one impedance level to another; to connect balanced lines to unbalanced loads; and to maintain or modify wave shape and frequency response at different potentials. Electronic transformers differ from power frequency transformers in range of impedance levels, frequencies, size, and weight.

Electronic power transformers are used to supply rectifiers at potentials ranging from 150 V to 750 V. Frequency range transformers are used where the frequency varies, including audio, video, carrier, and control frequencies. Such frequencies vary from a fraction of 1 Hz to uhf (300 to 3000 MHz). Transformers may be wide-band or narrow-band in frequency response, and the core material changes accordingly. In wide-band transformers, the ratio of lowest to highest frequency may be as great as 10^5. For such a wide band, the core material may consist of nickel alloy laminations of high permeability, which maintain uniform secondary voltage at the lowest frequency. This material also makes possible low leakage inductance and winding capacitance, both of which are essential to good response at the highest frequency.

Narrow-band applications use mostly high frequencies and operate over a small percentage of the carrier frequency (e.g., 50 to 55 MHz). At rf frequencies, air-core transformers are used. Pulse transformers are used in radar modulators and computers.

TRANSFORMER (Instrument). Current and potential transformers extend the ranges of alternating current instruments in the same way as shunts and series resistors work for direct current instruments. See Fig. 1. Taps on the windings permit a single transformer to operate over a wide range. Basic instrument ranges for transformer use are usually 5 amperes or 115 volts. These are nominal secondary ranges for the transformers and are used for computing ratios for the overall range of the meter and transformer combined. In actual practice, the range of the voltmeter may be 150 volts. For relatively high current ranges, the primary often consists of one or more turns passing through the center hole, as shown in Fig. 2. In the case of one turn, the ratio would be 800:5, for two turns, 400:5, and so on. Standard operating procedure and safety for the current transformer requires that the secondary winding always be shorted or connected to the ammeter. Otherwise, dangerous potentials may occur on the secondary of the transformer. Instrument transformers, in addition to permitting measurement of large currents and voltages, perform the important function of insulating the instrument from the line. This affords safety in use. Insulation protection between primary and secondary windings is usually several times the maximum rated voltage of the transformer.

A type of potential transformer arranged with means for connecting the two primary coils in multiple or in series is shown in Fig. 3. This provides for two ranges in a ratio of 2:1. A single secondary winding is used.

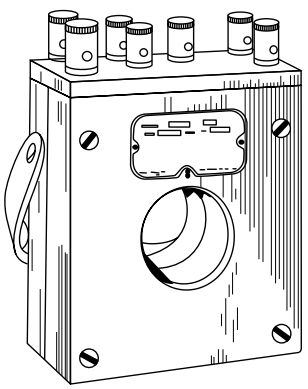

Fig. 1. External view of instrument transformer.

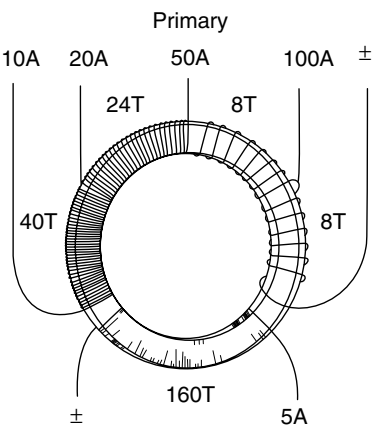

Fig. 2. Instrument transformer for relatively high current ranges. The primary often consists of one or more turns passing through the center hole.

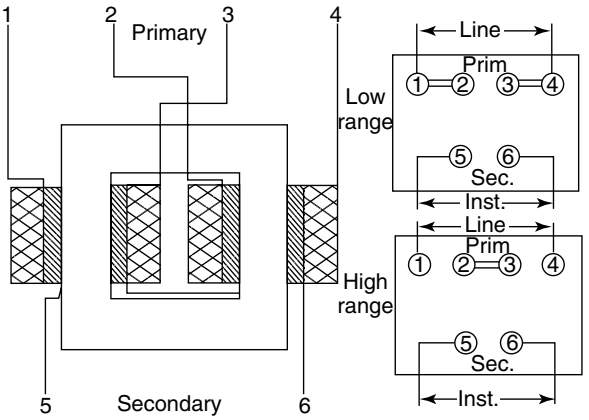

Fig. 3. Potential transformer arranged with means for connecting the two primary coils in multiple or series.

The chief errors in instrument transformers are due to ratio and phase angle, both of which are controllable in design by using proper flux densities for the magnetic material involved and appropriate construction.

TRANSFUSION (Blood). See **Blood**.

TRANSIENT (Electrical). A transient arises when the current in any part of a network changes because of a change of resistance of that part of the circuit, or because the electromotive force operative in its changes. There is an immediate readjustment of the potential differences and currents in the other parts of the circuit. Such readjustments take place very quickly, and the corresponding momentary fluctuations of current are called transients.

Analytically, the general expression for the current in any circuit as a function of time contains both the steady-state terms and the transient terms. The transient terms rapidly become negligible. An example is found in the case of the current in a simple series R-L circuit to which a sinusoidally impressed voltage, $E_{\max}\sin(\omega t+\alpha)$ is applied. The current

$$i=\frac{E_{\max}\sin(\omega t+\alpha+\theta)}{\sqrt{R^2+\omega^2L^2}}-\frac{E_{\max}\sin(\alpha+\theta)}{\sqrt{R^2+\omega^2L^2}}e^{-Rt/L}$$

The first term on the right of the above relation is the steady-state term. The second term is the transient, which decays with time and eventually becomes very small. The angle θ = phase angle $=-\tan^{-1}\omega L/R$.

The term *transient* is also applied generally to that part of a forced oscillation of a linear system (not necessarily an electric circuit, as defined above) that decays more or less rapidly after the imposition of the force; to be distinguished from the steady state.

TRANSISTOR (Invention and Development). A semiconducting device capable of performing numerous functions in electronic circuits — amplifying electric signals; mixing signals; performing modulation and demodulation, gating, buffering, storing, shifting, and shaping functions, among others. A transistor can operate at high frequencies and has a low power dissipation loss. The transistor is well suited as a switching device for computer and communication systems, as in the areas of transmission, multiplexing, and signal processing. In a very large majority of uses, the transistor has replaced the formerly widely used vacuum tube of the 1940s and 1950s. Transistors are available as discrete units for plug-in boards, but their principal usage in recent years has been in integrated circuits, ranging from small-scale to very-large scale ICs, with a target of incorporating a billion transistors in a single IC by the year 2000 or sooner. The size, speed, and other characteristic advantages of the transistor are described in articles on **Integrated Circuit (IC)**; **Microelectronics**; and **Semiconductors**.

The point-contact transistor was invented in 1948 at the Bell Laboratories. The early device consisted of a piece of n-type germanium about $0.05\times0.05\times0.005$ inches ($1.3\times1.3\times0.1$ mm) on which were placed two sharpened points (a beryllium-copper emitter and a phosphor-bronze collector) approximately 0.002 inch (0.05 mm) apart. Each of these points exhibited rectifying diode type current-voltage characteristics. It was then theorized that the operation of the transistor depended on the injection of "holes" into the n-type material through the forward-biased emitter point and the collection at the reverse-biased collector point. The third electrode in the transistor was a low resistance, nonrectifying contact made to the n-type germanium and was designated the base electrode. Power gain was achieved in the structure because the collector current increased at a rate equal to two or three times the emitter current and because the reverse-biased collector terminals could be matched in a circuit to a higher impedance load than the input emitter impedance. The early device is diagrammed in Fig. 1.

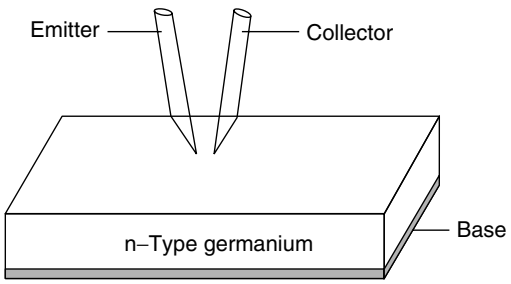

Fig. 1. Point-contact transistor of the type invented in 1948.

During the intervening years since its invention, the transistor has undergone numerous alterations and refinements, particularly as regards materials of construction (general switchover from germanium to silicon) and the methods used to fabricate the transistor. These refinements represent a continuing process right up to the present day and a process that will continue until sometime in the next century when molecular-scale switching devices emerge. However, it should be stressed that the underlying principles of the solid-state transistor still apply.

Junction Transistor. The junction transistor has numerous advantages over the point-contact transistor of Fig. 1. In a junction transistor, the rectifying characteristics are obtained within the bulk of the semiconductor crystal by placing different types of impurities at different points in the crystal. The structure of an n-p-n junction transistor is shown in Fig. 2. The emitter and collector regions have an excess of n-type impurities, while the base region has an excess of p-type impurities. The transition from p-type material to n-type material is designated as a p-n junction. In order to achieve transistor action, it is necessary to have the emitter and collector p-n junctions in close physical proximity (fractions of a millimeter and much less). The yardstick of size in the semiconductor industry is the micrometer (micron).

Although in the early days of the transistor germanium was used extensively, the majority of current transistors are made from silicon crystals. The advantages of silicon over germanium include operation at higher temperatures, lower power consumption, and greater surface stability. However, germanium offers advantages in the high-frequency area because electrons and holes travel faster in germanium than in silicon.

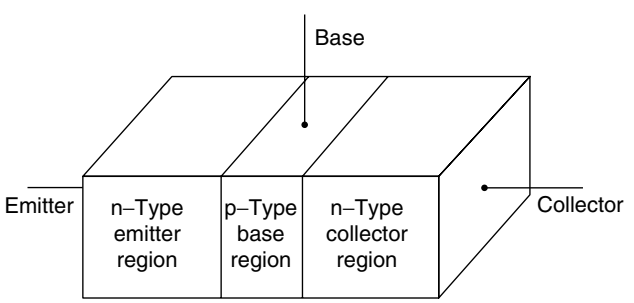

Fig. 2. Structure of n-p-n junction transistor.

Gallium arsenide transistors, long under study, are just beginning to take their place commercially. In addition, there are also *p-n-p* transistors where the type of material used for emitter, base, and collector regions is reversed from the configuration shown for the *n-p-n* transistor in Fig. 2. The basic difference is that the polarity of all the operating voltages and currents are opposite for these two types of transistors.

The operation of the *n-p-n* transistor hinges upon the injection of electrons across the forward biased emitter *p-n* junction into the base region of the transistor. Once these electrons are injected across the junction they diffuse across the base and arrive at the reverse-biased collector junction. While the emitter junction acts as a source for these electrons, the reverse-biased collector junction acts as a sink for them. We measure the efficiency of such transistors by the current multiplication factor α_F defined as

$$\alpha_F = \frac{\partial I_C}{\partial I_E} \tag{1}$$

where I_C is the collector current and I_E is the emitter current. In most junction transistors α_F is between 0.95 and 1.00.

The junction transistor can be connected in a circuit so that any one of its three terminals is the common terminal. Figure 3 shows an *n-p-n* transistor connected in the common emitter configuration with typical operating voltages and currents. Note that in this connection a small incremental increase in base current produces a sizeable increase in collector current. This ratio is defined as

$$h_{FE} = -\frac{\partial I_C}{\partial I_B} = \frac{\alpha_F}{1 - \alpha_F} \tag{2}$$

Typical values of h_{FE} are between 20 and 200.

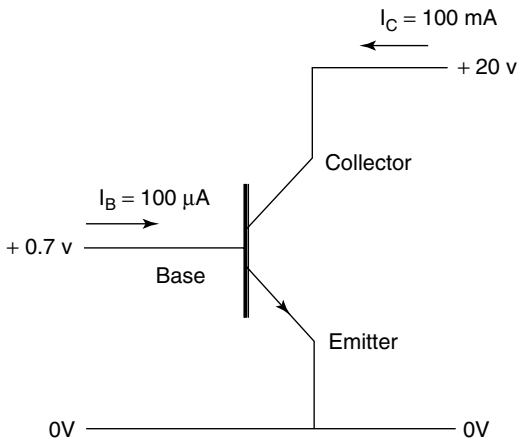

Fig. 3. Circuit symbol and typical potentials for *n-p-n* silicon-junction transistor.

There are many types of junction transistors, dependent on the specific method of fabrication chosen. In all cases *n*-type impurities such as phosphorus, arsenic, or antimony, and *p*-type impurities such as boron, indium, gallium, or aluminum are introduced into the appropriate regions of the transistor. In a grown-junction transistor, the impurities are introduced at the time that the silicon or germanium crystal is being fabricated. In an alloy-junction structure, the impurities are introduced by melting a pellet of the appropriate doping material on the surface of the semiconductor and regrowing the crystal. Diffused junction transistors are produced by placing the semiconductor material in a furnace at an elevated temperature in an atmosphere containing the desired doping element. The doping material then diffuses into the semiconductor crystal and substitutionally replaces some of the silicon or germanium atoms in the crystal lattice. A region of the opposite type can be created by overcompensating, diffusing into the same region the other type of impurity to a concentration in excess of that previously diffused.

Fig. 4 shows the structure for a silicon planar transistor. This transistor is produced by diffusing boron impurities into *n*-type silicon in order to create the *p*-type base region and later diffusing phosphorus to create the

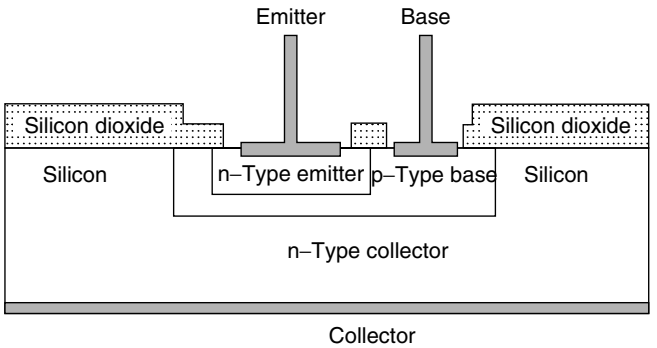

Fig. 4. Cross section of silicon *n-p-n* planar transistor.

n-type emitter region. Note that the surface of the transistor is covered by a layer of silicon dioxide (quartz) which acts as a protection for the exposed *p-n* junctions; such layer assures a very high-reliability transistor.

This transistor is also economical to fabricate because mass processing techniques can be utilized. The precise geometrical control achieved by using diffusion techniques results in very reproducible electrical characteristics. See previously mentioned article on microstructure fabrication.

Field effect transistors have been widely used for several years. Of these, the MOS (metal-oxide semiconductor) has been a leading choice of designers. In these transistors, a conducting channel of either electrons or holes is established between two regions, called source and drain, to which ohmic low-resistance contacts are made. Control of the source-to-drain current is achieved by applying a potential to the gate electrode, which affects the width of the conducting channel and/or the number of mobile carriers in the channel. Power gain is achieved between the gate-source input terminals and the drain-source output because of the high input impedance.

In a diffused junction field-effect transistor, the gate is a reverse-biased *p-n* junction. In an *n*-channel enhancement mode MOS transistor, the gate electrode is a metallized region separated from the semiconductor by an insulating oxide layer. Application of a positive gate potential to the MOS transistor creates an electron-rich region in the semiconductor (effectively converts the surface of the semiconductor from *p*-type to *n*-type) which serves as a conducting path (*n*-type channel) between the source and the drain. Increasing the gate bias widens the channel and also increases the source-to-drain electron flow.

MOS transistors have been used for integrated circuits because they require a minimum number of fabrication steps and can be produced at high yields. The transistor of Fig. 5, for example, requires only a single *n*-type diffused region of noncritical dimensions. There are also depletion mode transistors, where the *n*-type channel is permanently established and the gate bias (negative) is used to decrease and eventually cut off the drain-to-source current flow.

As amplifiers, transistors are useful up to frequencies of several gigahertz and at power levels of several hundred watts. Transistors have been widely used as switches in computers. The electrical characteristics of a transistor are well suited to this application, in that they closely simulate a relay in its open and closed positions. Computer memory circuits hold tens of

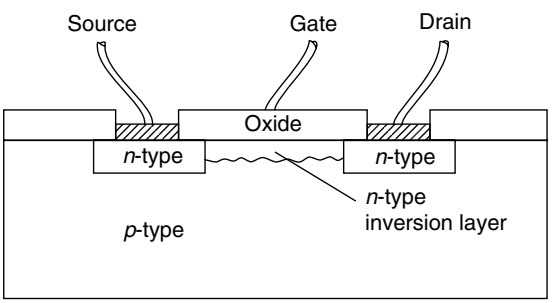

Fig. 5. An *n*-channel enhancement mode MOS transistor.

thousands of transistors, contained on a small chip of silicon. See also **Memory (Electronic)**.

So-called soft errors become much more important as the transistor becomes smaller. Such errors may be due to the passage of high-energy nuclear particles through a microcircuit, which can cause an error for a short instant, while after the event the circuit works perfectly normally again. Such events arise from the radioactive decay of uranium or thorium, which may be contained in trace quantities in various packaging materials that house the integrated chip. Decay events yield alpha particles, which leave a path of electrical charge as they ionize the silicon atoms during their journey through the microcircuit. Cosmic rays comprise another source of soft error. Among the numerous elementary particles in the cosmic spectrum are neutrons, which interact with silicon atoms causing alpha particles.

TRANSIT (Astronomy). Both Venus and Mercury revolve about the sun in orbits that lie inside the orbit of the earth about the sun. Accordingly, when the planes of the planetary orbits coincide with the plane of the ecliptic, once during the synodic period of each planet the object will pass between the earth and the sun. Because of the small angular diameter of the planets relative to that of the sun, at the time they pass between the earth and sun they appear as small black spots moving across the brilliant disk of the sun. Such a phenomenon is known as a transit of Venus or a transit of Mercury.

The orbits of both Mercury and Venus are inclined to the plane of the ecliptic with the result that transits do not occur during each synodic period, but only when the planet happens to come to inferior conjunction close to the passage through a node. Transits of Mercury can occur only in May and November, when the earth crosses Mercury's lines of nodes; those of Venus occur only in June and December. Since Mercury is closer to the sun than Venus, transits of Mercury are more common than those of Venus. The last transit of Venus came in 1882 and the next will take place in 2004.

The first recorded observation of a transit of Venus was made in England in 1639 by Horrocks. Four transits have been observed since that time. Since observations of the duration of transit of the planet across the disk of the sun, made from widely separated positions on the earth, provide a method for determination of the important astronomical constant known as solar parallax, expeditions have always been dispatched to observe the phenomena. Within recent years, more accurate methods for determination of solar parallax have been devised, and henceforth, transits of planets across the sun will be of value only for the purpose of obtaining accurate positions of the objects and thus improving the orbital elements.

TRANSITION (Allowed). A transition between two states of a quantum-mechanical system marked by a comparative ease with which the change in quantum numbers involved can be accomplished. For example, transitions in which the total angular momentum quantum number changes by one in units of h are frequently allowed; and, other things being equal, a transition involving a change of one will take place with greater probability than a competing transition involving a change in this quantum number of two or more.

TRANSITION EFFECT. A change in the intensity of the secondary radiation associated with a beam of primary radiation as the latter passes from a vacuum into a material medium, or from one medium into another.

TRANSITION ELEMENT (Transition Metal). Any of a number of elements in which the filling of the outermost shell to eight electrons within a period is interrupted to bring the penultimate shell from 8 to 18 or 32 electrons. Only these elements can use penultimate shell orbitals as well as outermost shell orbitals in bonding. All other elements, called "major group" elements, can use only outermost shell orbitals in bonding. Transition elements include elements 21 through 29 (scandium through copper), 39 through 47 (yttbrium through silver), 57 through 79 (lanthanum through gold) and all known elements from 89 (actinium) on. All are metals. Many are noted for exhibiting a variety of oxidation states and forming numerous complex ions, as well as processing extremely valuable properties in the metallic state.

TRANSITION LOSS. In audio systems and components, the transition loss is defined as follows: At any point in a transmission system, the ratio of the available power from that part of the system ahead of the point under consideration to the power delivered to that part of the system beyond the point under consideration. If the input and/or output power consist of more than one component, such as multifrequency signal or noise, then the particular components used and their weighting should be specified. This loss is usually expressed in decibels.

In wave-propagation usage, transition loss is defined in one of two ways, as follows: (1) At a transition or discontinuity between two transmission media, the difference between the power incident upon the discontinuity and the power transmitted beyond the discontinuity which would be observed if the medium beyond the discontinuity were match-terminated. (2) The ratio in decibels of the power incident upon the discontinuity to the power transmitted beyond the discontinuity which would be observed if the medium beyond the discontinuity were match-terminated.

TRANSITION PROBABILITY. The probability per unit time, symbol w_{if}, that a system in state i will undergo a transition to state f. The quantity

$$w_i = \left[\sum_{\substack{\text{over} \\ \text{all } f}} w_{if} \right]$$

is the total transition probability for state i. The probability that the system is still in state i at the end of time t is then e^{-wit}. For radioactive transitions, the symbol λ is used instead of w_i, and the total transition probability is then called the disintegration constant.

TRANSITION TEMPERATURE. 1. An arbitrarily defined temperature within the temperature range in which metal fracture characteristics determined usually by notched tests are changing rapidly such as from primarily fibrous (shear) to primarily crystalline (cleavage) fracture.

2. The arbitrarily defined temperature in a range in which, the ductility of a material changes rapidly with temperature.

TRANSIT (Surveying). An instrument used by engineers and surveyors for measuring horizontal angles. Modern transits are usually equipped with a level attached parallel to the telescope, and a graduated vertical circle as well, so that the transit may be employed as a level, and may also be used to read vertical angles. It may also be equipped with stadia wires. An exceptionally accurate transit of the type used for precise surveying is known as a theodolite. See also **Theodolite**.

TRANSLATION. A motion in which all points of a system have identical displacements. If each point moves on a straight line the translation is rectilinear, if on a curve it is curvilinear. The general motion of a rigid body is a combination of translation and rotation.

TRANSLATION OPERATION (Geometry). The geometrical process of displacing a body along a straight line, keeping lines fixed in the body always parallel to themselves.

TRANSLATOR. A network or system having a number of inputs and outputs and so connected that signals representing information expressed in a certain code, when applied to the inputs, cause output signals to appear which are a representation of the input information in a different code. Sometimes called *matrix*.

TRANSLATORS. A *translator* is a computer program that takes as its input a program written in a particular programming language and transforms it into a functional equivalent program written in another programming language. Two programs are said to be functional equivalent or operation equivalent when, under all circumstances, they exhibit the same behavior and produce the same output for a given set of inputs, if any. The programs themselves are not required to be of the same size or have their operations executed in the same order.

The input to the translator, the *source program* (SP), is written in a *source language* (SL). Likewise, the output of the translator, the *target program* (TP), is written in a *target language* (TL). Since the translator itself is a program, it must be written in some programming language and executed on some computer. The language in which the translator is written is called the *host language* (HL) and the computer on which it is executed is called the *host computer* (HC). The languages involved in the translation process can be illustrated using the T-notation. See Fig. 1.

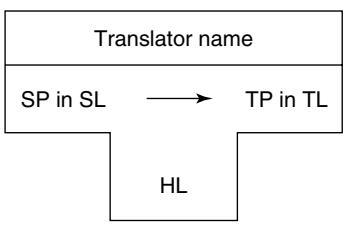

Fig. 1. Use of the T-notation to illustrate the translation process.

During its operation, the translators may provide the programmer with diagnostics concerning the syntactical or semantic errors that may be present in the source program. What a translator does when it encounters an error is implementation dependent. Some translators notify the programmer about the error and continue processing, checking for possible additional errors; other translators stop translating as soon as they encounter an error.

Translators are generally classified according to the following criteria:

- the source language that they process and the target language to which they translate
- the machine for which they produce the target program.
- the language in which the translator itself is written.
- the completeness of the translation process itself and how they execute the translated programs.
- the number of different activities or phases to carry out the translation process

When classified according to the source language that they process and the target language into which they translate it, translators are called *compilers* if the source language is a high-level language such as C, C++, FORTRAN and the target language is a low-level language such as assembly or machine code. If the source language that they process is assembly language and the target language is machine language the translators are called *assemblers*.

If the target program can be executed on the host computer the translator is called *self-resident*. If the target program cannot be executed on the translator's host computer but in a computer with a different architecture the translator is called a *cross-translator*. Depending on its characteristics a translator may fall into more than one category. For instance, if a translator that runs on an IBM compatible PC translates a source program written in a high-level language into an equivalent target program written in assembly language for an Apple computer, we say that the translator is a cross compiler.

If the translator itself is written in the source language that it processes, the translator is called a *self-translating translator*, for example, a compiler for C++ source programs that is itself written in C++ is a *self-compiling compiler*.

Translators are also classified into two categories based on the completeness of the translation process itself and how they execute the instructions of the target programs. These categories are: compilers and interpreters. Provided that there are no errors, compilers always translate the entire source programs before executing them. *Interpreters* translate and execute the instructions of the source program one instruction at a time. Interpreters, like any other translator, can also be classified according the criteria previously explained. In general, interpreters produce programs that are slower to execute and larger in size than their compiled counterparts. However, interpreters can help programmers to develop programs quicker because, in interactive environments, they provide programmers with instant feedback about the syntax of the program as it is being typed. It is not necessary to translate the entire program to realize that the program has a syntax error.

As translators carry out their tasks, the source program undergoes a series of intermediate transformations. The main sequential operations or phases carried out by a translator to transform a source program into a target program are generally called the lexical analysis, syntax analysis, and code generation. During the lexical analysis phase the translator reads the instructions of the source programs and groups the different elements of these instructions into logical units called tokens or lexems, short for lexical elements. A token may be a single character or a sequence of characters that have a particular meaning to the compiler. When processing an instruction the translator ignores comments or white spaces (blanks, carriage return, and tabs). For instance, when a compiler for the programming language Pascal "sees" the statement

$$\text{if value1} >= \text{value2 then value2} := \text{value2} + 1;$$

it recognizes the sequence *if* not as two consecutive individual letter but as a single token with special meaning within the language (*keyword*). Likewise, the compiler considers sequence *value1* and *value2* as single tokens and not a sequence of six individual characters. Some symbols that may consist of two or more characters (composite symbols) such as $>=$ and $:=$ are also considered single tokens. However, some aspects of the instruction such as the sequence $+1;$ is considered as three individual tokens even if they are written with no space between them. As the individual tokens are recognized by the translator they are classified, in turn, into a larger entity such as a declaration, an assignment statement, etc. To recognize the individual tokens that are present in an instruction, the translator must have the necessary built-in logic. However, what constitutes a token is language dependent and is determined by the grammatical description of the language being translated. The latter is determined by the creator or implementor of the language. The builder of the translator also determines the format of these tokens. Since this phase must read all possible input characters in the source program it sometimes is called a *scanner*. The output of the lexical analysis phase is a sequence of tokens.

The output of the lexical analysis phase is the input for the syntax analysis phase. In this latter phase, the translator checks that the tokens are in the correct order as determined by the grammatical description of the language; that is, that the sequence is grammatically correct. Some authors refer to this activity of the syntactical analyzer as the parsing phase. In addition to checking for the correct order of the token sequence the syntax analyzer may also check that the instructions are semantically correct; that is, that they make sense from an operational point of view. For this reason this phase is sometimes called a semantic analyzer. In some implementations the semantic analyzer is considered a separate phase of the translation process. In general, the output of this syntax analyzer is an abstract data structure called an abstract-syntax tree. The tree is a useful representation of the structure of the operations of the program that, if necessary, can be further operated on to reduce the number of instructions of the target program.

The code generator phase produces as its output the final transformation of the source program into the target program. The input of this phase is the abstract-syntax tree produced by the syntax analysis phase. If necessary, the implementers of the translator may attempt to optimize the code so that it runs faster or so that it occupies a minimum amount of memory when

it runs. Most of the time the code generator phase tries to strike a balance between these two frequently incompatible optimal states. The output of this phase can be machine language or assembly language.

In some translators the lexical, syntax, and code generator phases are carried out as separate and individual activities; in some other translators these phases are carried out as a single activity. Depending on the number of these individual phases the translators are called multi-phase or multi-pass or single-phase or single-pass translators.

TRANSMISSION CONTROL PROTOCOL (TCP) / INTERNET PROTOCOL (IP) SUITE. The Internet and the World Wide Web are based on TCP/IP. The term "TCP/IP" refers to not only the TCP (transmission control protocol) and IP (Internet protocol), but also includes other protocols, applications, and even the network medium. These protocols include UDP, ARP, and ICMP. These applications include telnet, FTP, Secure Shell, NFS, Web browsers and servers, and the many items collectively called the Web services. This article is an encyclopedic survey of these topics starting from the seven-layer OSI model to recent improvements in the implementations of the protocol stack and firewalls.

A computer system *communicates* with another system by sending a stream of bytes. A *byte* is a sequence of 8 bits. A *checksum* is the arithmetic sum of a sequence of numbers used to detect errors that may have altered some of the numbers in the sequence. The communication is actually between a process running on one system with one running on the other system. The two processes communicate information in a pre-agreed form known as protocol. That is, the two processes agree on the meaning of specific byte values occurring in specific positions in the stream.

This article describes the core protocols known as IP and TCP, and a few application protocols based on these. The details of IP and TCP are not directly experienced by the ordinary user unless a network sniffer is used. Nevertheless, it is crucial to understand these before attempting to understand the application protocols.

In each protocol, there is a stream of bytes known as a frame, a datagram, a packet or a segment depending on the "level." The content of such a protocol data unit is described as a rectangular diagram such as the one shown in Fig. 1. The width of such a diagram is always 32-bits, numbered from 00 to 31. The units digits of these bit indices are shown in one row, and the tens digits are shown in the row above it. Each boxed row stands for a sequence of 32 bits (4 bytes).

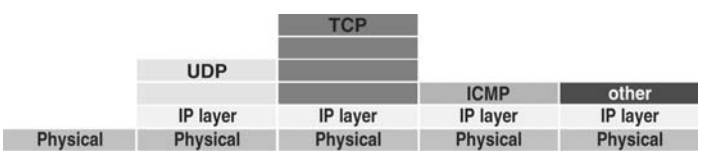

Fig. 1. Protocol stack.

Layers

Computer networking is easier to understand as a stack of layers, each layer providing the functionality needed by the layer above it. There are two such models.

The *OSI* (*Open Systems Interconnection*) *model* of computer networks has seven layers. Each layer provides functionality that the next higher layer depends on.

The *physical* layer provides the physical means of carrying the stream of bits. Ethernet, Fast Ethernet, Wireless 802.11, T-carrier, DSL (digital subscriber line), and ATM are examples of this layer. All media are considered functionally equivalent. The differences are in speed, convenience, and cost. Converters from one media to another exist and make it possible to have different physical layers in a computer network.

The *data link* layer takes the raw stream of bits of the physical layer and provides the functionality of sending and receiving a meaningful message unit called a *frame* and also provides error detection functions. A frame includes checksum, source and destination addresses, and data. The frame boundaries are special patterns of bits. Software of this layer will retransmit a frame if it is damaged, say due to a burst of noise on the physical layer. The data link layer is divided into the media access control (MAC) sub-layer, which controls how a computer on the network gains access to the data and permission to transmit it, and the logical link control (LLC) sublayer, which controls frame synchronization, flow control, and error checking. This layer describes the specification of interface cards to specific types of networks, e.g., Ethernet, Token Ring, etc. Protocols from the TCP/IP suite that occupy this layer are SLIP and PPP.

The *network* layer accepts messages from the source host, converts them into packets of bytes, and sends them through the data link. This layer deals with how a route from the source to the destination is determined. This layer also deals with congestion control. The IP, address resolution protocol (ARP), reverse ARP (RARP), Internet control message protocol (ICMP), and IGMP belong to this layer.

The *transport* layer transfers data, and is responsible for end-to-end error recovery and flow control. The TCP and user datagram protocol (UDP) belong to this layer.

The *session* layer establishes, manages, and terminates connections between the programs on the two hosts that are communicating. The concepts of ports and connections belong to this layer.

The *presentation* layer provides independence from possibly different data representations of the host machines. The HTTP (hypertext transfer protocol), FTP (file transfer protocol), telnet, DNS, SNMP (simple network management protocol), NFS (network file system), etc. belong to this layer.

The *application* layer supports the end-user invoked programs. FTP, HTTP, IMAP (Internet message access protocol), NTP (network time protocol), POP3 (post office protocol version 3), rlogin (remote login), SMTP (simple mail transfer protocol), SNMP, SOCKS, telnet, X-Window, Web services, etc. are part of this layer.

The OSI model is officially recognized by the ISO (International Standards Organization). The practical world of TCP/IP networking was in full use by the time the OSI model was formulated. Its unofficial model, referred to as the *TCP/IP model,* the U.S. Department of Defense *DoD model,* or even more simply the *Internet model,* organizes the networks into the following five layers:

- The *physical* layer, matching the OSI physical layer.
- The *link* layer, similar to the OSI link layer. This is also called the network access layer. It defines the network hardware and device drivers.
- The *IP* layer, also called the Internet protocol layer. This layer deals with identifying individual hosts and routing. It is similar in functionality to the OSI network layer.
- The *transport* layer, containing the UDP and TCP. The UDP provides "connectionless service" and TCP provides "connection-oriented service." UDP does not guarantee, unlike the OSI transport layer, reliable delivery.
- The *application* layer, handling the responsibilities of the session, presentation, and application layers of the OSI model.

The data unit of each layer is *encapsulated* by the layer below it. An application data unit [AP] is encapsulated by the TCP layer, which prefixes a TCP header TCPH as [TCPH [AP]]. The IP layer encapsulates it as [IPH [TCPH [AP]]], where IPH is the IP header. Assuming the Ethernet, it encapsulates it as [EH [IPH [TCPH [AP]]] FSC], where EH is the Ethernet header and FSC is a frame check sequence, generated by the Ethernet hardware.

Protocol Stack. The computer network literature talks of protocol stacks. Each item in the stack is a layer of software that implements a collection of protocols. In Fig. 1, the relative heights indicate the level of functionality and the dependency of the layers. Except for the layer marked "Physical" all others are software layers. The protocol stack is an integral component in a modern operating system.

Lower Layers. In this section, the layers that support the IP are described. The TCP/IP protocol family runs over a variety of network media including; IEEE 802.3 (Ethernet) and 802.5 (Token Ring), LANs, X.25 lines, satellite links, and serial lines.

Ethernet. Ethernet can support IP and other protocols simultaneously. Ethernet was invented in 1972 at Xerox PARC by Metcalfe and his colleagues. They named it so as to emphasize the capability of the physical medium to carry bits to all hosts, analogous to the "luminiferous ether" of old physics. The word Ethernet now refers to 10 mega-bits-per-second (Mbps) transmission speed, Fast Ethernet refers to 100 Mbps, and Gigabit Ethernet refers to 1000 Mbps. The media varieties include the current twisted-pair (10baseT, with RJ45 connectors), the original thick coaxial system (10base5), thin coaxial (10base2), and fiber optic systems (10basesF). Ethernet has been standardized by the Institute of Electrical and Electronics Engineers as IEEE 802.3.

All hosts attached to an Ethernet are connected to a shared signaling medium. Ethernet signals are transmitted serially, one bit at a time, over the shared medium that every attached host can observe. Ethernet is a broadcast medium. That is, when a frame is sent out on the Ethernet, every controller on the local unswitched network can see the frame. To send data, a host waits for the channel to become idle, and transmits its frame. All hosts on the network contend equally for the transmission opportunity. Access to the shared medium is governed by the MAC mechanism based on the Carrier Sense Multiple Access with Collision Detection (CSMA/CD) system. This ensures that access to the network channel is fair, and that no single host can lock out other hosts. If two or more devices try to transmit at the same instant, a transmit collision is detected, and the devices wait a random (but short) period before trying to transmit again.

An Ethernet controller comes with a 48-bit MAC address built-in from the factory. Every Ethernet frame has a 14-byte header that includes the Ethernet MAC addresses of the source and destination, and a 2-byte type code (see Fig. 2). The type code identifies the protocol family (such as IP, ARP, NetBEUI). The Data field is from 48 to 1500 bytes in length. Following the data, there is a checksum computed by the Ethernet controller for the entire frame.

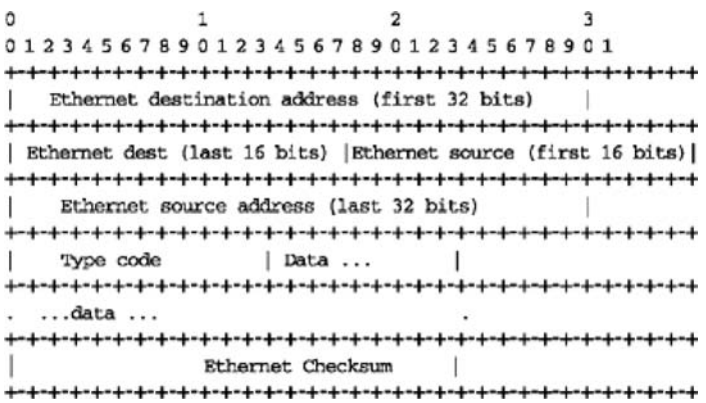

Fig. 2. Ethernet frame.

The Ethernet address is written with each byte in hexadecimal, separating bytes with either a hyphen or a colon. Every device is expected to listen for Ethernet frames with their destination address. All devices also listen for Ethernet frames with a wild-card destination address of "FF-FF-FF-FF-FF-FF" (in hexadecimal), called a *broadcast* address. When these packets are received by the Ethernet Network Interface Card (NIC), it computes the checksum, and throws the packet away if an error is detected by the checksum. If the type code is IP, the Ethernet device driver passes the data portion of the frame up to the IP layer of the OS. Under OS control, the NIC can be put into a so-called *promiscuous* state wherein the NIC listens to all frames regardless of their destinations.

Asynchronous Transfer Mode (ATM). Asynchronous transfer mode (ATM) is widely deployed as a backbone technology. ATM uses 53-byte fixed-length packets called *cells* for transport. Information is divided among these cells, transmitted, and then re-assembled at their final destination. ATM is connection-oriented. ATM itself consists of a series of layers. Its physical layer is based on various transmission media that range in speed from kilobits per second to gigabits per second. The layer, known as the adaptation layer, holds the bulk of the transmission. This 48-byte payload divides the data into different types. The ATM layer contains 5 bytes of additional information, referred to as overhead.

Serial Line Internet Protocol (SLIP). A serial network is a link between two computers over a serial line, which can be a dial-up connection over telephone lines or a direct connection between the serial ports of two computers. Serial line IP (SLIP) [Request for Comment (RFC) 1055, available at http://www.rfc-editor.org/] defines the encapsulation protocol, just as an Ethernet frame envelopes an IP packet. Unlike Ethernet, SLIP supports only the IP and not multiple protocols across a single link. The serial link is manually connected and configured, including the specification of the IP address. SLIP does not provide mechanisms for address negotiation, error correction, or compression. However, many SLIP implementations record the states of TCP connections at each end of the link, and use header compression that reduces the size of the combined IP and TCP headers from 40 to 8 bytes.

Point-to-Point Protocol (PPP). Point-to-point protocol (PPP) [RFC 1661, RFC 2153] replaces the older SLIP, and is an encapsulating protocol for IP and other protocol datagrams over serial links. The encapsulation and framing adds 2, 4, or 8 bytes depending on the options chosen. PPP includes a link control protocol (LCP) that negotiates the encapsulation format, sizes of packets, authentication methods, and other configuration options. The CCP (compression control protocol) used by PPP negotiates encryption. The *IP control protocol* (*IPCP*) included in the PPP configures the IP address, and enables the IP protocol on both ends of the point-to-point link.

Point-to-Point Tunneling Protocol (PPTP). Point-to-point tunneling protocol (PPTP) encapsulates PPP packets into IP datagrams. Its use is in providing virtual private networks (VPN). After the initial PPP connection to a PPTP server, a PPTP tunnel and a PPTP control connection are created. *Tunneling* is the process of sending packets of a certain protocol embedded in the packets of another protocol. PPTP uses an enhanced Generic Routing Encapsulation (GRE) mechanism to provide a flow- and congestion-controlled encapsulated datagram service for carrying PPP packets.

The Internet Protocol

IP [RFC 791] delivers a sequence of bytes from a source host S to a destination host D, even when the hosts are on different networks, geographically vastly separated. The byte sequence and the destination are given to the IP layer by the upper layer. The IP layer forms an IP datagram from the sequence. An IP datagram consists of an IP header followed by transport layer data. The IP layer software discovers routes that the packet must take from S to various intermediate nodes, known as routers, ultimately arriving at D. Thus, IP is routable. Each packet travels independently even when the host S wishes to send several packets to D; each packet delivery is made independently of the previous ones. The routes that each packet takes may change. Thus, IP is connectionless. The IP layer is designed deliberately not to concern itself with guaranteed delivery (i.e., packets may be lost or duplicated), but instead it is a "best effort" system. The ICMP described later aids in this effort.

IP Address. An operating system during boot-up assigns a unique 32-bit numeric ID known as its IP address to each NIC located in the host system. There is no rigid relationship between the Ethernet address and the IP address. The IP address is obtained either by looking it up in a configuration file or via dynamic host configuration protocol (DHCP). The IP addresses are carefully controlled world-wide. The IANA, Internet

Assigned Numbers Authority (www.iana.org), assigns the so-called *public IP addresses* to organizations and individuals upon application.

Three address ranges known as Class A, Class B, and Class C are of importance. In a Class A address, the 0-th bit is always a 0, bits 1 through 7 identify the network, and bits 8 through 31 identify the host, permitting 2^{24} hosts on the network. In a Class B address, the bit 0 is always a 1, bit 1 is always a 0, bits 2 through 15 identify the network, and bits 16 through 31 identify the host, permitting 2^{16} hosts on the network. In a Class C address, bits 0 and 1 are both 1 always, bit 2 is a 0 always, bits 3 through 23 identify the network, and bits 24 through 31 identify the host, permitting 2^{8} hosts on the network.

IP addresses are typically written in a dotted-decimal notation as a.b.c.d where a is the first byte, b the second, c the third, and d the fourth byte. Each of a–d is a number in the range 0–255, written in the decimal notation. A subnet is a collection of hosts whose IP addresses match in several bits indicated by the ones in a sequence of 32-bits known as a subnet mask, also written in the dotted-decimal notation. Thus, 255.255.255.0 is a mask of 24 ones followed by 8 zeroes. Because of this structure, the mask is also written as /24. Nodes and routers use the mask to identify the address of the network on which the specific host resides. The address of the network is the bit-wise AND of the IP address and the mask. The host ID is the bit-wise AND of the IP address and the complement of the mask.

Occasionally, a network node X needs to discover certain information from other nodes, but the node X does not know the addresses of these others. In such situations, X broadcasts using special destination IP addresses. The direct broadcast address of X is the address whose host ID is all ones, and whose network address equals that of X. The limited broadcast address is 255.255.255.255.

The following three blocks of the IP address space is intended for private internets:

$$10,000 \text{ to } 10,255.255.255 (10/8 \text{ prefix, Class } A)$$

$$172.16.0.0 \text{ to } 172.31.255.255 (172.16/12 \text{ prefix})$$

$$192.168.0.0 \text{ to } 192.168.255.255 (192.168/16 \text{ prefix, Class } C)$$

That is, on the Internet at large, there must never be IP packets whose source or destination addresses are from the above ranges.

Most operating systems are internally structured to depend on the presence of a network layer. To facilitate this, the address 127.0.0.1 is assigned as the so-called *address* of the localhost (spelled as one word) and 127.0.0.0 as the localnetwork (spelled as one word). Packets sent to this address do not actually travel onto the external network. They simply appear as received on the local (artificial) device.

When a machine is physically moved from one network to another, we must reassign an IP address that belongs to the new network. This is one of the problems that mobile IP solves.

IP Header. An IP header is a sequence of bytes that the IP layer software prefixes to the data it receives from the higher layers. The resulting IP header plus the data is given to the lower layer (e.g., the Ethernet card device driver). The byte layout of IP headers is shown in Fig. 3. The header may or may not have the IP Options filed. Except for this field, all other fields are fixed in length as shown. Minimally (i.e., without the options), the IP header is 20 bytes in length. With IP options, an IP header can be as long as 60 bytes.

IPv is the version number of the protocol; currently it is 4. IP version 6 is discussed later. The value of IHL multiplied by 4 is the length of the IP header in bytes. The Type of Service field specifies the "relative urgency" or importance of the packet. Total Length is a 2-byte field giving the length, in bytes, of the entire packet including the header, options (if any), and the packet data. Thus, the maximum length of an IP data gram is 65535 bytes. (IP over Ethernet limits this to 1500.) The Identification field, Flags, and Fragment Offset are used to keep track of the pieces when a datagram must be split up as it travels from one router to the next. IP fragmentation is discussed further below. The Time to live (TTL) is a number that is decremented by 1 whenever the datagram passes through a router node. When it goes to 0, the datagram is discarded, and an error message is sent back to the source of this packet. The Protocol field identifies the protocol of the data area. The Header Checksum field is the 16-bit one's complement

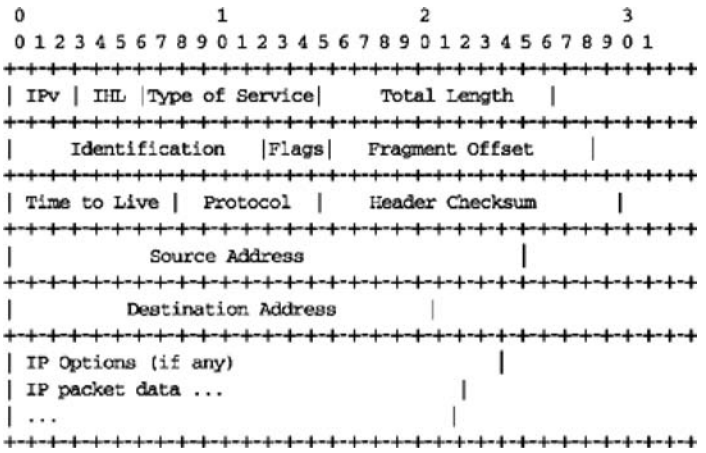

Fig. 3. IP Header

of the one's complement arithmetic sum of the entire header viewed as a sequence of 16-bit integers. The Source Address is the datagram's sender IP address, and Destination Address is the IP address of the intended recipient. The IP Options may or may not be present. When present, its size can be one or more bytes.

Routing Protocols. When the source S and the destination D are on the same network, we have a direct delivery of the packet that does not involve routers. When the two hosts are not on the same network, in general, there can be multiple paths between the source and destination. Because of failures, maintenance, and other reasons, the intermediate nodes known as routers may come on or off during the delivery of packets. Thus, consecutive packets sent by a host S to a destination D may (have to) travel entirely disjoint routes depending on how the network is connected. The typical network host has only one NIC, and hence is on only one network, and sending and receiving of network traffic is secondary to its main functionality. Routers are specialized computer systems whose primary function (often their sole function) is to route network traffic. Routers must have multiple NICs, each on a separate network. A router examines the destination IP address of a packet and consults its routing tables that record information regarding where to deliver a packet next so that definite progress is made in moving the packet closer to its final destination.

Every network host (including routers) has a routing table, which can be visualized as a table of two columns: To send the packet to a final destination given in column 1, send the packet to the next hop whose IP address is given in column 2. The size of such a table can be greatly reduced by parametrizing the column 1 by its network address, and also by including a default row in the table that acts as a catch-all. The default row indicates the next hop IP address for any packet whose destination network address does no match that of any other row. Once the next hop IP address is determined, the router uses the lower layer address (such as the Ethernet MAC) to deliver the packet to the next hop.

The routing table of an ordinary host rarely changes from boot-up to shut down. The tables of routers, however, must be dynamic and adjust to changing conditions, perhaps by the millisecond, of the Internet. Routing protocols keep the routing tables up-to-date.

The Internet is a network of autonomous networks. Interior gateway protocols (IGPs) maintain the routing tables within an autonomous network. RIP (routing information protocol) and OSPF (open shortest path first) are examples of IGPs. Border gateway protocol (BGP) is the most common protocol in use for routing among autonomous networks.

IP Fragments. When datagrams are too large to be sent in a single IP packet, due to interface hardware limitations for example, they can be split up by an intermediate router unless prohibited by the Don't Fragment flag. IP fragmentation occurs when a router receives a packet larger than the Maximum Transmission Unit (MTU) of the next network segment. All such fragments will have the same Identification field value, and the Fragment Offset indicates the position of the current fragment in the context of the pre-split-up packet. Intermediate routers are not expected to re-assemble

the fragments. The final destination will reassemble all the fragments of an IP packet and pass it to higher protocol layers (like TCP or UDP).

Domain Name Service. Because of the mnemonic value, humans prefer to work with host names such as gamma.cs.wright.edu. A host name in this form is known as a fully qualified domain name (FQDN); gamma is the name of the host, and cs.wright.edu is the name of the domain the host is in. Each network host maintains a short cache table of FQDNs to IP addresses. When a name is not found in this cache, the host enquires with a name server the domain name service (DNS) protocol. Each name server behaves recursively in this manner. Sometimes it is necessary to transfer the resource records of an entire DNS zone. A DNS query with Name = wright.edu, Class = IN, and Type = AXFR will trigger a zone transfer for all the host names in the wright.edu domain.

DNS uses a distributed database to delegate control of domain name hierarchies among zones, each managed by a group of name servers. Name servers are the repositories of information that make up the domain database. Each name server has authoritative information about one or more zones, but may also have cached, but non-authoritative, data about other parts of the database. The name server marks its responses to queries as authoritative or not.

Either TCP or UDP can be used for DNS, connecting to server port 53. Ordinary DNS requests can be made with TCP, although convention dictates the use of UDP for normal operation.

Mobile IP. As the mobile network host moves, its point of attachment may change, and yet in order to maintain existing transport-layer connections, it must keep its IP address the same.

The *mobile node* uses two IP addresses. The *home address* is static and is used to identify TCP connections. The *care-of address* changes at each new point of attachment. Whenever the mobile node moves, it *registers* its new care-of address with its home agent. The home agent redirects the packets to the current care-of address by constructing a new IP header that contains the care-of address as the destination IP address. This new header encapsulates the original packet, causing the home address to have no effect on the routing of the encapsulated packet until it arrives at the care-of address. When the packet arrives at the care-of address, the effect of this "tunneling" is reversed so that the packet once again appears to have the home address as the destination IP address.

Mobile IP discovery of the care-of address uses an existing standard protocol called Router Advertisement (RFC 1256). A router advertisement carries information about default routers, and in addition carries further information about one or more care-of addresses. Home agents and care-of agents typically broadcast these advertisements at regular intervals (say, once every few seconds). If a mobile node needs to get a care-of address in a hurry it multicasts a router solicitation. An advertisement also informs the mobile node whether the agent is a home agent, a care-of agent, or both, and therefore whether it is on its home network or a care-of network, and about special features provided by care-of agents, for example, alternative encapsulation techniques.

The registration of the new care-of address begins when the mobile node, possibly with the assistance of the care-of agent, sends a registration request to the home address. The home agent typically updates its routing table. Registration requests contain parameters and flags that characterize the tunnel through which the home agent will deliver packets to the care-of address. The triplet of the home address, care-of address, and registration lifetime is called a *binding* for the mobile node. The home agent authenticates that registration was originated by the mobile node.

Each mobile node and home agent compute an unforgeable digital signature using one-way hash algorithm MD5 (Message Digest 5, RFC 1321) with 128-bit keys on the registration message, which includes either a time stamp or a random number carefully generated.

Occasionally a mobile node cannot contact its home agent. The mobile node tries to register with another home agent by using a directed broadcast IP address instead of the home agent's IP address as the target for the registration request.

Transmission Control Protocol

TCP [RFC 793, RFC 3168] offers the client process a connection to a server process. This connection needs to be established, as needed. Once this connection is established, the TCP protocol guarantees the correct (both in content and in order) delivery of the data. TCP sends its message content over the IP layer, and can detect and recover from errors. TCP, however, does not guarantee any speed of delivery, even though it offers congestion control.

Ports and Connections. Port numbers are used by the transport layer for multiplex communication between several pairs of processes. To each message, this layer adds addresses, called port-numbers. The port numbers would have been assigned by the OS to certain processes. Thus, a connection is uniquely identified by four numbers: source and destination IP addresses, and source and destination port numbers. The IP addresses are supplied by the IP layer. The TCP and UDP port numbers are unrelated to the memory addresses often referred to as IO ports.

Reliable Transmission. TCP requires that every segment include an acknowledgment of the last data segment received in the other direction. TCP is a sliding window protocol with time-out and retransmits. If the sender does not receive an acknowledgment within the time-out period, it retransmits the segment. Acknowledgments are piggybacked on reply data. There is dynamically adjustable window size that specifies the number of bytes the receiver has as buffer space. The sender continues to send and slides the window ahead as long as acknowledgments are being received for bytes within the window.

TCP messages, called *segments*, are sent as one or more IP datagrams. A TCP header follows the IP header, supplying information specific to the TCP protocol. Figure 4 contains the details of the TCP segment.

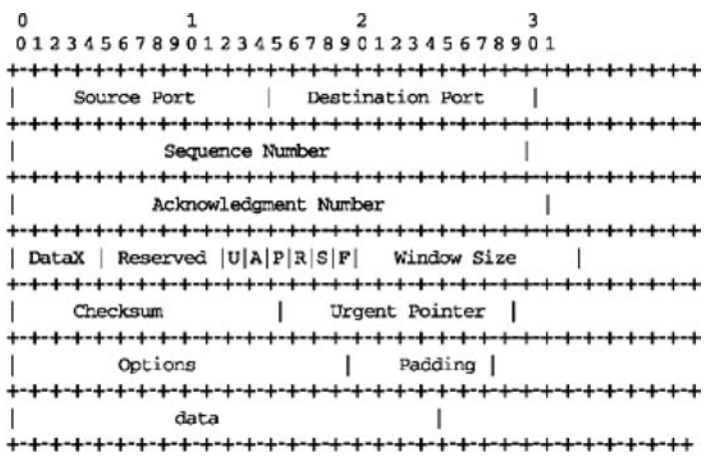

Fig. 4. TCP Header.

The letters |U|A|P|R|S|F| in the fourth row of the segment are abbreviated names for control bit flags: URG, Urgent Pointer field significant, ACK, Acknowledgment field significant; PSH, Push Function; RST, Reset the connection; SYN, Synchronize sequence numbers; and FIN, sender is finished with this connection. These are further explained below.

The Sequence Number, together with the Acknowledgment Number, serves as a ruler for the sliding window protocol. While establishing the connection, the SYN flag is set to 1, and the client and the server exchange their initial sequence numbers.

Acknowledgment Number is valid only when the ACK bit is set. This field contains the value of the next sequence number the sender of the segment is expecting to receive. Once a connection is established, this is always included. The DataX number multiplied by 4 is the number of bytes in the TCP Header. This indicates where the data begin. Window size is described in the section Congestion Control. Urgent Pointer is valid when URG is 1. Its value is a positive offset from the sequence number in this segment. Options, if any, are given at the end of the TCP header and are always a multiple of 8 bits in length. All options are included in the checksum. An option can be just a single byte, or it can be a byte of option-kind, followed by a byte of option-length, and the actual option-data bytes. The option-length counts the two bytes of option-kind and option-length as well as the option-data bytes.

State Diagram. A TCP server process starts its life by passively opening a port and starts to listen to connection attempts from clients. This process causes a number of changes in the information maintained by the TCP layer software. These transitions are described by the state diagram shown in Fig. 5. An active open causes a SYN = 1 segment to be sent out and the software enters the SYN-sent state.

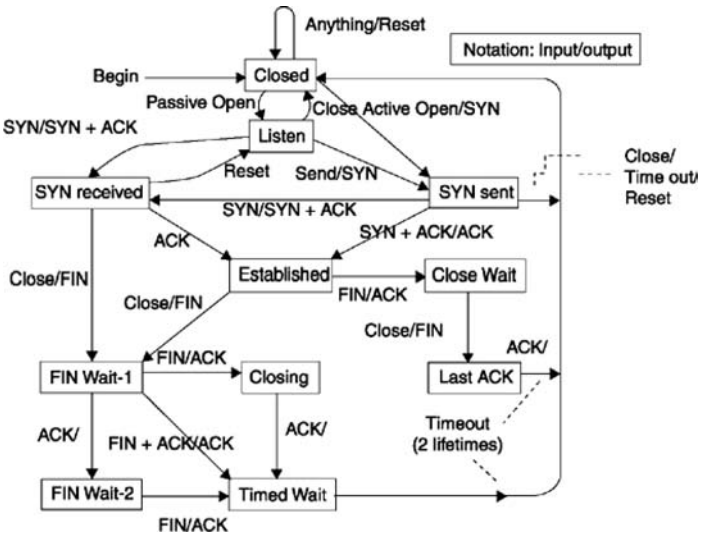

Fig. 5. TCP state diagram.

TCP Three–Way Handshake. This establishes the connection between the initiating node (say A, the client) and the receiving node (say B, the server) of packets as follows:

- A: "I would like to talk to you, B." A sends a packet with SYN = 1, and the initial sequence number to B.
- B: "OK, let's talk." B replies with a SYN–ACK packet (i.e., SYN = 1, ACK = 1, Acknowledgment number = sequence number received + 1, and SYN = 1 with sequence number set to the ISN of the server. If B was unwilling, it responds with a RST = 1 packet refusing the request for service.
- A: "Thanks!" A sends a packet with ACK = 1, Acknowledgment number = ISN of B + 1, SYN = 0, sequence number = previous sequence number +1.

The sequence number for SYN = 1 can be a zero, but that is not secure, so the sequence number is randomly chosen. Here is an example:

SYN	ACK	src	dst	Sequence-number	Acknowledgement-number
1	0	1037	80	102723769	0
1	1	80	1037	1527857206	102723770
0	1	1037	80	102723770	1527857207

where the client is on port 1037 establishing a connection with a service on port 80 (typically HTTP).

Four-Way Handshake. This terminates a previously established connection between say A and B as follows:

- A sends to B a packet with FIN = 1, which indicates "no more data from A." This flag is used when closing a connection down the normal way. The receiving host B enters the CLOSEWAIT state and starts the process of gracefully closing the connection. Each end of the connection sends a packet with the FIN = 1. The receiver is expected to acknowledge a received FIN packet by sending a FIN = 1 packet.
- B sends to A a packet with ACK = 1, acknowledging the FIN packet received.
- B sends to A another packet, but now with FIN = 1.
- A sends to B a packet with ACK = 1. No further packets are exchanged.

So four packets are used to close a TCP connection in the normal situation.

Closing a connection can also be done by using the RST flag set to 1, which indicates to the receiver that a reset should occur. The receiving host accepts the RST packet provided the sequence number is correct, and enters the CLOSED state and frees any resource associated with this instance of the connection. The RST packet is not acknowledged. A host H sends a connection resetting RST packet if host X requested a connection to a non-existent port p on host H, or for whatever reason (idle for a long time, or an abnormal condition, etc.), the host H (client or the sever) wishes to close the connection. Resetting is unilateral. Any new incoming packets for that connection will be dropped.

TCP Timers. TCP depends on many timers.

Connection Establishment Timer is started when the SYN is sent during the initial connection setup. Typical value of this timer is 75 s. If a time-out occurs, the connection is aborted.

FIN_WAIT timer is started when there is a transition from the *FIN_WAIT_1* state to the *FIN_WAIT_2* state. The initial value of this timer is 10 min. If a packet with FIN = 1 is received, the timer is canceled. On expiration of the 10 min., the timer is restarted with a value of 75 s. The connection is dropped if no FIN packet arrives within this period.

TIME_WAIT timer is started when the connection enters the *TIMED-WAIT* state. This is to allow all the segments in transit to be removed from the network. The value of the timer is usually set to 2 min. On expiration of the timer, the connection is terminated.

For the KEEP_ALIVE timer, we need to distinguish the silence caused because there are no data to send from that caused by a broken connection. Setting a keep-alive timer allows TCP to periodically probe the other end. The default value of this timer is 2 h. After the expiration of the timer, probes are sent to the remote end. The connection is dropped if the remote does not respond.

Congestion Control. The Acknowledgment segments from a receiver also contain an advertised window size that specifies the buffer size it has available. If the new size is larger, the sender can increase; if it smaller, the sender can decrease the sliding window size. TCP uses the sliding window mechanism to control the flow.

When a router begins to accumulate too many packets, it can send ICMP Source Quench messages to the senders of these packets. These messages should cause the rate of packet transmission to be slowed.

UDP, ICMP, and Other Protocols

User Datagram Protocol (UDP). UDP is a connectionless transport protocol. It is a thin protocol on top of IP, providing high speed but low functionality. Delivery of UDP datagrams is not guaranteed. Nor can it detect duplicate datagrams. The UDP protocol is mostly used by application services where squeezing the best performance out of existing IP network is necessary such as trivial file transfer (TFTP) and NFS, and by the DNS.

The port numbers appearing in the UDP header are similar to the TCP port numbers (see Fig. 6), but the OS support required by UDP ports is much simpler and less resource consuming than that of TCP ports. Source Port is the port of the sending process. When not meaningful, this field is set to 0. Destination Port is the UDP port on the receiving machine, whose

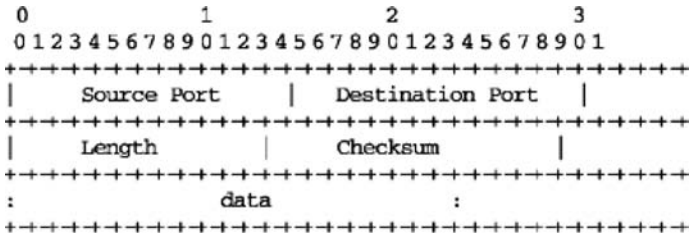

Fig. 6. UDP Header.

IP address is supplied by the IP layer. Length is the number of bytes in the datagram including the UDP header and the data. Checksum is the 16-bit one's complement of the one's complement sum of the UDP header, the source and destination IP addresses obtained from the IP header, and the data, padded with zero bytes at the end (if necessary) to make a multiple of 2 bytes.

Internet Control Message Protocol (ICMP). ICMP [RFC 792, 1981] manages and controls the IP layer, as in reporting network errors, such as a host or entire portion of the network being unreachable or a packet being directed at a closed port, reporting network congestion, assisting in trouble shooting, reporting time-outs, or forcing routing options. In general, much of the best-effort in delivering IP datagrams is associated with ICMP. The purpose of the ICMP messages is to provide feedback and suggestions about problems, for example, when a datagram cannot reach its destination, when the gateway does not have the buffering capacity to forward a datagram, or when the gateway can direct the host to send traffic on a shorter route. To avoid the infinite regress, no ICMP messages are sent about ICMP messages. Also ICMP messages are only sent about errors in handling fragment zero of fragmented datagrams.

An ICMP message is sent as the data portion of an IP datagram. These IP datagrams are treated like all other IP datagrams. Each ICMP message begins with a 1-byte ICMP type field, which determines the format of the remaining data, a one-byte code field, and a 2-byte checksum. If the ICMP message is reporting an error, these 4 bytes are followed by the first 8 bytes of the IP datagram causing the error.

The popular network utilities ping and traceroute use ICMP. The ping command sends several echo requests, captures their echo replies, and displays statistics about speed and datagram loss. The traceroute utility constructs IP datagrams with well-chosen TTL values and collects the time-exceeded ICMP messages to map a route from the source to a destination IP address.

ICMP helps improve the performance of the network. For example, ICMP redirect messages from a router inform a host that a different router is more optimal than it is for certain destinations.

Address Resolution Protocol (ARP). ARP [RFC 826, 1982] is used to determine the Ethernet MAC address of a device whose IP address is known. This needs to be done only for outgoing IP packets, because IP datagram must be Ethernet framed with the destination hardware address. The translation is performed with a table look-up.

Reverse ARP (RARP) [RFC 903] allows a host wishing to discover its own IP address to broadcast its Ethernet address, and expect a server to reply with its IP address.

The ARP cache accumulates as the host continues to network (see Table 1). If the ARP cache does not have an entry for an IP address, the outgoing IP packet is queued, and an ARP request packet that effectively requests "If your IP address matches this target IP address, then please let me know what your Ethernet address is" is broadcast. Once the table is updated as a result of receiving a response, all the queued IP packets can now be sent.

TABLE 1. A SMALL PORTION OF AN ARP CACHE

IP address	Ethernet address
130.108.2.23	08-00-69-05-28-99
130.108.2.1	00-10-2f-fe-c4-00
130.108.2.27	08-00-69–0d-99-12
130.108.2.20	08-00-69-11-cf-b9
130.108.2.10	00-60-cf-21–2c-4b
192.168.17.221	00-50-ba-5f-85-56
192.168.17.112	00-a0-c5-e5–7c-6e

The entries in the table expire after a set time period in order to account for possible hardware address changes for the same IP address. This change may have happened, e.g., due to the NIC being replaced.

ARP is an OSI layer-3 protocol, but it does not use an IP header. It has its own packet format as shown in Fig. 7. The ARP request packet has zeroes in the target Hardware Address fields. It is broadcast on the local LAN

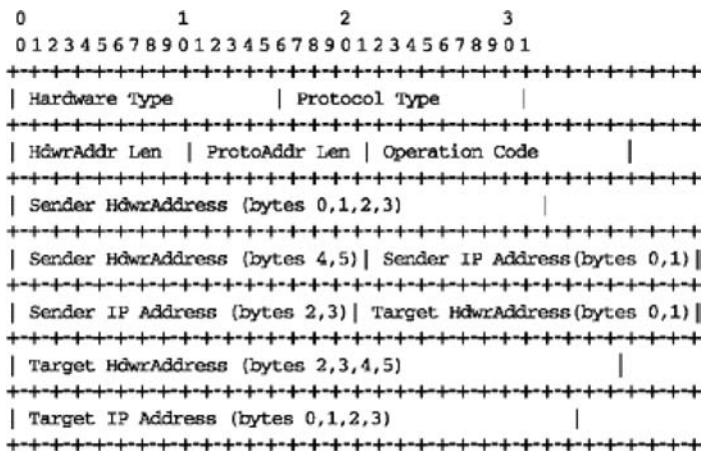

Fig. 7. An ARP request/response packet.

without needing to be routed. The destination host sends back an ARP reply with its hardware address so that the IP datagram can now be forwarded to it by the router. An ARP response packet has the Sender/Target field contents swapped as compared to the request.

TCP/IP Security

The TCP/IP suite had many design weaknesses so far as security and privacy are concerned, all perhaps due to the era (1980s) that the development took place. For example, the ICMP redirect message, intended to improve routing performance, has often been used maliciously. In this section, a summary of some of these issues is discussed. All major OS have made improvements in their implementations of the protocol stack that disable many of the attacks described below.

Covert Channels. A number of protocols permit covert channels. For example, ICMP echo request packets should have an 8-byte header and a 56-byte payload. ICMP echo requests should not be carrying any data. However, such ICMP packets can be significantly larger, carrying covert data in their payloads. Covert channels are prevalent in nearly all the protocols of the TCP/IP suite.

IP Address Spoofing. IP spoofing replaces the IP address of (usually) the sender or (in rare cases) the destination with a different address. Because the IP layer of the OS normally adds these IP addresses to a data packet, a spoofer must circumvent the IP layer and talk directly to the raw network device. IP spoofing is normally used to deposit another exploit on the target machine.

Note that the attacker cannot simply reassign the IP address of T to the host A using ifconfig or a similar configuration tool. Other hosts, as well as T, will discover (through ARP, for example) that there are two machines with the same IP address.

IP Fragment Attacks. Many firewalls do not perform packet reassembly. Attackers create artificially fragmented packets in order to fool such firewalls.

A well-behaving set of IP fragments is non-overlapping. However, a cleverly constructed second fragment packet can have an offset value that is less than the length of the data in the first fragment, so that upon packet reassembly it overrides several bytes of the first fragment.

In the IP layer implementations of nearly all OS, there are bugs in the reassembly code. An attacker can create and send a pair of carefully crafted but malformed IP packets that in the process of reassembly cause a server to "panic" and crash.

The Ping of Death attack sends fragments that when reassembled will be a packet larger than the maximum permissible length.

TCP Flags. TCP segments have a number of flags that have, collectively, a strong influence on how the segment is processed. However, not all the flags can be independently set or reset. For example, SYN FIN, SYN FIN PSH, SYN FIN RST, SYN FIN RST PSH are all illegal combinations. Past implementations have accounted only for valid combinations, ignoring the invalid combinations as simply "will not happen." Attackers

have written special programs that construct such illegal packets, and cause the network hosts to crash or hang.

The SYN Flood. In the TCP protocol as designed, there is no limit set on the time to wait after receiving the SYN. An attacker initiates many connection requests with spoofed source addresses to the victim machine. The SYN+ACK packets that the victim host sends are not replied to. Once the limit of the half-open connections is reached, the victim host will refuse further connection establishment attempts from any host until a partially opened connection in the queue is completed or times out. This effectively removes a host from the network for several seconds, making it useful at least as a stepping tool to other attacks, like IP spoofing.

TCP Sequence Number Prediction. TCP exploits are typically based on IP spoofing and sequence number prediction. In establishing a TCP connection, both the server and the client generate an initial sequence number from which they will start counting the packets transmitted. This sequence number is (should be) generated at random, and should be hard to predict. However, some implementations of the TCP/IP protocol make it rather easy to predict this sequence number. The attacker either sniffs the current SEQ/ACK of the connection or can algorithmically predict them.

Closing a Connection by FIN. The attacker constructs a spoofed FIN packet. It will have the correct SEQ numbers so that it is accepted by the targeted host connection. This host would believe the (spoofed) sender did not have any data left. Any packets that may follow would be ignored as bogus. The rest of the four-way handshake is also supplied by the attacker.

A similar connection killing attack using RST has also been seen.

Connection Hijacking. Host YY accepts the packets from XX only when correct SEQ/ACK numbers are used. The attacker ZZ can send one or two packets to YY spoofing the source address as XX, at a time when XX was silent. YY would accept these data, and update ACK numbers. XX would continue to send its old SEQ numbers, as it is unaware of the spoofed data. As a result, subsequent packets from XX are discarded by YY. The attacker ZZ could then impersonate to be XX, but using correct SEQ/ACK numbers from the perspective of YY. This results in ZZ hijacking the connection: host XX is confused while YY thinks nothing is wrong as ZZ sends "correctly synchronized" packets to YY.

Applications

Nearly all network applications are based on a client–server architecture where one process, the client, requests services from a second process, the server. Typically, the client and server processes are on different machines, but they need not be.

File Transfer Protocol (FTP), Telnet, and rlogin. The three application protocols described in this section are all based on TCP. They send authentication information and data in the clear (i.e., unencrypted), and hence are easily compromised by network sniffers. Also, their authentication of host is simply the IP address that they respond to. Consequently, utilities based on these protocols should not be used in situations where security is a concern. The SSH described later provides near equivalent functionality at a higher level of security.

Telnet. Telnet [RFC 854] establishes a TCP connection with a telnet server on the reserved port 23, and passes the keystrokes of the telnet client to the server, and accepts the output of the server as characters to be displayed on the client. The server presents these keystrokes as input received from a pseudo-terminal to the OS hosting the telnet server. Telnet defines a network virtual terminal (NVT) format as that which permits interoperability with machines that use different characters for common operations such as terminating a line and interrupting a run-away process. The telnet client typically maps the signal-generating keys of the keyboard to invoke the corresponding control functions of the NVT. The control functions are encoded as escape sequences of 2 bytes, the IAC (255), followed by the 1-byte code of the control function. Telnet uses the URGENT DATA mechanism of TCP to send control functions so that the telnet server can respond appropriately

File Transfer Protocol (FTP). FTP [RFC 959, 1985] uses two TCP connections, one called the *control* connection and the other the *data* connection. The client can issue a number of commands on the control connection that change various settings of the FTP session. All content transfer occurs on the data connection. The FTP client opens a control connection to port 21 of the FTP server machine. This connection persists the entire session. The format of data passed over the control connection is the same as that of telnet NVT. The GET command requests for the transfer of the contents that the server has (popularly known as *downloading*), and the PUT command requests the server to receive and store the contents that the client is about to send (popularly known as *uploading*).

The data connection can be opened in two modes. In the *active mode* FTP, the server initiates a data connection as needed from its port 20 to a port whose number is supplied by the client via the PORT command. In the *passive mode* FTP, the server informs the client a port number higher than 1024, to which the client initiates a data connection.

rlogin. The rlogin protocol [RFC 1282] is similar in functionality to telnet, and also operates by opening a TCP connection on the rlogin server machine at port 513. It is widely used between UNIX hosts because it provides transport of more of the UNIX terminal environment semantics than does the telnet protocol, and because on many UNIX hosts it can be configured not to require user entry of passwords when connections originate from trusted hosts.

Dynamic Host Configuration Protocol (DHCP). DHCP [RFC 2131, 1997] consists of a protocol for delivering host-specific configuration parameters from a DHCP server to a host, and a mechanism for allocation of IP addresses to hosts. The IP configuration parameters that DHCP can supply include subnet mask, a list of default routers, TTL, and MTU. A typical host will use DHCP soon after booting into the OS to configure its network. DHCP assumes that the IP layer software will pass the packets delivered to the NIC of the host even though the IP address has not been assigned yet. DHCP has three mechanisms for IP address allocation. In "automatic allocation," DHCP assigns a permanent IP address to a client. In "dynamic allocation," DHCP leases an IP address to a client for a limited period of time (or until the client explicitly relinquishes the address). In "manual allocation," a client's IP address is manually assigned but uses DHCP to convey the assigned address to the client. Dynamic allocation is the only one of the three mechanisms that allows automatic reuse of an address that is no longer needed by the client to which it was assigned.

Hypertext Transfer Protocol (HTTP). HTTP [RFC 2616, 1999] is at the core of the World Wide Web. The Web browser on a user's machine and the Web server on a machine somewhere on the Internet communicate via HTTP using TCP usually at port 80. HTTPS [RFC 2660, 1999] is a secure version of HTTP.

A Web browser displays a file of marked-up text with embedded commands following the syntactic requirements of the hypertext markup language (HTML). There are several ways of invoking these commands, the most common one being the mouse click. Most of the clickable links displayed by a Web browser are the so-called links that associate a URL (universal resource locators) with a visible piece of text or graphic. URLs have the following syntax: scheme://[userName[:password@]] serverMachineName[:port]/[path][/resource][?parm1 = parma&parm2 = parmb]. A simple example of the above is http://www.cs.wright.edu/~pmateti/InternetSecurity where the scheme was chosen to be http, the port defaults to 80, and the path given is ~pmateti/ InternetSecurity. A click on such a link generates a request message from the browser process to the Web server process running on the remote machine whose name www.cs.wright.edu is obtained from the link clicked.

HTTP Message Format. The request and response are created according to the HTTP message format, which happens to be a sequence of lines of text. The first line identifies the message as a request or response. The subsequent lines are known as header lines until an empty line is reached. Following the empty line are lines that constitute the "entity body." The header lines have a left-hand side that names various parameters separated from the right-hand side that provides values with a colon. The request line has three components: a method (one of GET, POST, or HEAD), a URL, and the version number of HTTP (either 1.0 or 1.1) that the client understands. Of the methods GET is the most common. The POST method is used when the client sends data obtained from a user-filled HTML form. The HEAD method is used in program development. The response line also

contains three components: HTTP/version-number, a status code (such as the infamous 404), and a phrase (such as Not Found, OK, or Bad Request). The entity body in a response message is the data, such as the content of a Web page or an image, which the server sends.

Authentication and Cookies. Web servers requiring user authentication send a WWW-Authenticate: header. The Web client prompts the user for a username and password, and sends this information in each of the subsequent request messages to the server. HTTP is stateless in that the HTTP server does not act differently to request based on previous requests. Occasionally, a Web service wishes to maintain a minor amount of historical record of previous requests. Cookies [RFC 2965] create a stateful session with HTTP requests and responses. The response from a server can contain a header line such as "Set-cookie: value." The client then creates a cookie stored on the client's storage. In subsequent requests sent to the same server, the client includes the header line "Cookie: value."

Secure Shell (SSH). SSH provides the functionality of telnet and rlogin but with greater security. The user name and password are sent encrypted after establishing a TCP connection on port 22, authenticating that the connection is indeed to the server. The SSH client maintains a database of server names and their authentication keys that the server offers the first time an SSH session is opened to the server. All subsequent SSH sessions compare the authentication key offered by the server with that stored in the client database. The SSH provides for other methods of authentication.

PRABHAKER MATETI, Wright State University, Dayton, OH

TRANSMISSION GRATING. A diffraction grating ruled on a transparent base. Most transmission gratings are plastic replicas of reflection gratings. The radiation is transmitted through, rather than reflected from such a grating.

TRANSMISSION LEVEL. The level of the signal power at any point in a transmission system which is the ratio of the power at that point to the power at some point in the system chosen as a reference point. This ratio is usually expressed in decibels.

TRANSMISSION LIMIT. A limiting wavelength or frequency above or below which a given type of radiation is practically all absorbed by a given medium. If the limits are sharply defined, the medium acts as a sharp cutoff light filter for that radiation.

TRANSMISSION LOSS. The power lost in transmission between one point and another. It is measured as the difference between the net power passing the first point and the net power passing the second. (See also **Standing-Wave Ratio**.) In underwater sound, the transmission loss H is defined to be $H = S - L$, where S is the sound level in decibels, and L is the sound pressure level in decibels above root mean square pressure of 1 dyne per square centimeter.

TRANSMISSION MODE. The various transmission modes in a waveguide are characterized by the electric and magnetic field patterns in a plane normal to the guide axis. When the magnetic vector is perpendicular to the direction of travel, the wave is *transverse magnetic*, or a TM-wave. When the electric vector is perpendicular, it is a *transverse electric*, or TE-wave. If both vectors are perpendicular to the direction of travel, the wave is *transverse electromagnetic*, or a TEM-wave. There are an infinite number of transmission modes in a guide, but each mode possesses a cut-off frequency; waves of lower frequency cannot be propagated by the corresponding mode. The lowest of these frequencies is the absolute cut-off frequency of the guide, and the corresponding mode is the dominant transmission mode. Note that a pair of parallel wires is a waveguide possessing a cut-off frequency of zero, i.e., direct current is propagated.

TRANSMISSION (Pneumatic). Use of compressed air to communicate the values of instrumental-measurement information from one location to the next. Also referred to as pneumatic telemetering, the system is usually confined to relatively short distances within a processing and manufacturing facility, generally not exceeding a thousand feet. The distance over which pneumatic signals may be transmitted is limited by the amount of added lag that the tubing will contribute to the system. The output tubing includes capacitance proportional to the volume of the tube and is distributed along the length of the tubing. The tubing also includes resistance, similarly distributed. Usually transmission tubing is about $\frac{3}{16}$ inch (~5 millimeter) in inside diameter. For tubing of this diameter, the dynamic response for a 350-foot (105-meter) length, terminating in a 1-cubic-inch (~16 cubic centimeters) volume will be approximated by a time constant of 1 second and a dead period of $\frac{1}{3}$ second. For a length of 1,000 feet (300 meters) of tubing, the time constant would be 7 seconds and dead period 1 second.

A pneumatic transmitter provides air output pressure proportional to the value of the variable being measured. Usually, the output-pressure range is from 3 to 15 pounds/square inch (0.2 to 1 atmosphere). Air supply pressure is usually 20 pounds/square inch (1.4 atmospheres). The lowest pressure in the line, corresponding to a minimum instrument reading (often zero on the scale), is 3 psi (0.2 atmosphere). In an instrument calibrated — say from 0° to 100 °C — the transmitted pressure for the high reading would be 15 psi (1 atmosphere). The relationship is reasonably linear. An elementary pneumatic transmitter is shown in the Fig. 1. In this case, it is assumed that a transducer is used to provide an input pressure that is directly related to the variable being measured. As in a pneumatic controller (see also **Pneumatic Controller**), a flapper-nozzle arrangement may be used to vary the output pressure. A feedback element is used to maintain the flapper-nozzle clearance constant. In so doing, more or less air pressure is

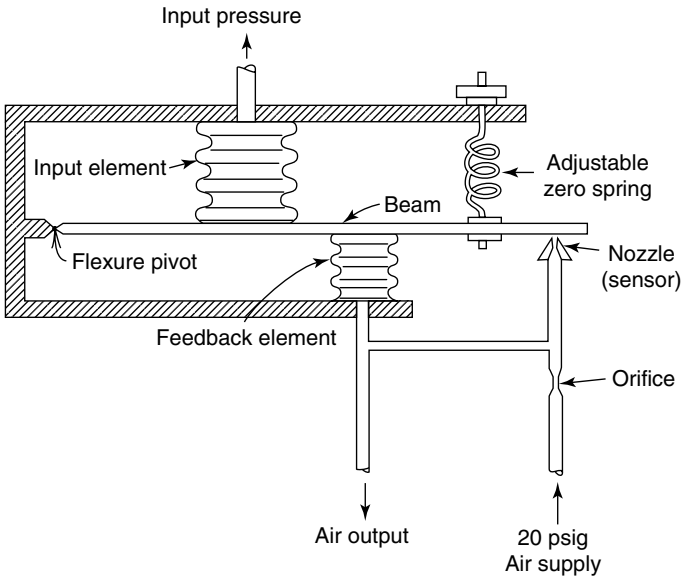

Fig. 1. Elementary type of pneumatic transmitter.

required, and this is reflected by the transmitter air-output pressure. Where transmission distance is relatively long, a pneumatic relay also will be used in the system.

TRANSMISSOMETER. An instrument for measuring the extinction coefficient of the atmosphere and for the determination of visual range. Also called *telephotometer*, *transmittance meter*, or *hazemeter*.

TRANSMITTANCE. Consider a beam of electromagnetic radiation of intensity or radiant power I_0 incident upon a sample and let I be the intensity of the beam transmitted by the sample. Then, the ratio $I/I_0 = T$ is called the transmittance. Experimental measurements of transmittance must usually be corrected for reflection, scattering, and other effects (see also **Bouguer and Lambert Law**). Formerly, such a corrected transmittance result was designated an internal transmittance. Such usage is now discouraged as a reported value of T should be understood as one upon which all appropriate corrections have been made. For solutions, the absorbance $A = \log 1/T$ is more closely related to concentration (see also **Beer's Law**) and many spectrometers record A rather than T.

TRANSMITTANCE (Directional Luminous). The ratio of the luminance of the surface at which light leaves a diffusing object to the illuminance of the surface at which the light is incident upon the object; provided that (1) the luminance of the emergent surface is expressed in lamberts and the illuminance of the incident surface in lumens/square centimeter, or (2) the luminance of the emergent surface is expressed in foot-lamberts and the illuminance of the incident surface in foot-candles.

TRANSMITTANCY. The ratio of the internal transmittance of a solution to that of the pure solvent in equivalent thickness. This ratio was supposed to correct for certain unwanted effects in transmittance experiments (see also **Bouguer and Lambert Law**). However, the term is now discouraged since presumably a reported transmittance result has been corrected for all extraneous factors.

TRANSMITTER. 1. A device for converting sound waves into corresponding electrical oscillations, e.g., a microphone or telephone transmitter. 2. In radio communications, the complete group of equipment utilized in converting sound, or an audio-frequency electrical signal into the modulated radio-frequency signal fed to the antenna. The usage varies somewhat and may connote the modulators and radio-frequency stages, or may be applied to more or less of the equipment constituting the complete broadcasting system.

TRANSMUTATION. The natural or artificial transformation of atoms of one element into atoms of a different element as the result of a nuclear reaction. The reaction may be one in which two nuclei interact, as in the formation of oxygen from nitrogen and helium nuclei (β-particles), or one in which a nucleus reacts with an elementary particle such as a neutron or proton. Thus, a sodium atom and a proton form a magnesium atom. Radioactive decay, e.g., of uranium, can be regarded as a type of transmutation. The first transmutation was performed by the English physicist Rutherford in 1919.

TRANSONIC. Pertaining to that which occurs or is occurring within the range of speed in which flow patterns change from subsonic to supersonic or vice versa, about Mach 0.8 to 1.2.

TRANSONIC FLOW. In aerodynamics, flow of a fluid over a body in the range just above and just below the acoustic velocity. Transonic flow presents a special problem in aerodynamics in that neither the equations describing subsonic flow nor the equations describing supersonic flow can be applied in the transonic range.

TRANSOSONDE. See **Meteorology**.

TRANSPIRATION. Transpiration is the evaporation of water from the plant to the atmosphere. All plants require water for their continued existence and most kinds of plants require it in considerable quantities. In spite of the absolute indispensability of water for their growth and metabolism, plants in general are very inefficient in their use of water. An overwhelmingly large proportion of the water absorbed by most kinds of terrestrial plants escapes from them as water vapor. This process of the loss of water vapor from plants is called transpiration. Although some water vapor loss may occur from any organ of a plant exposed to the atmosphere, in the vast majority of plants most transpirational water loss occurs from the leaves. There are two kinds of foliar transpiration: (1) stomatal transpiration in which water vapor loss occurs through the stomates; and (2) cuticular transpiration, in which evaporation of water takes place directly through the surface of the epidermal cells through the cuticular layer into the atmosphere. Figure 1 shows that the water vapor in a stomatal aperture diffuses to the atmosphere through the stomata and the boundary layer of a leaf, in the case of the open stomata. In most species, stomatal transpiration represents 90% or more of the total foliar transpiration.

Stomatal transpiration involves the two physical processes of evaporation and diffusion. Evaporation of water takes place from the moist cell wall surfaces into the air-filled intercellular spaces between mesophyll cells. (See also **Leaf**.) If the stomates are closed this soon results in the saturation of the intercellular spaces with water vapor. If, however, the stomates are open, diffusion of water vapor takes place through them into the outside atmosphere except when the vapor pressure of the surrounding atmosphere is equal to that of the intercellular spaces. This latter condition rarely prevails, however, during the daylight hours of clear days when the stomates are most likely to be open.

Meteorological factors significantly affect the transpiration. Several experimental results have been published about the relationships between the meteorological factors and the transpiration. Transpiration completely depends on the physiological activities as long as stomatal aperture does not change. However, the plant may regulate stomatal opening and transpiration. A temporary reduction of stomatal aperture is often caused by a decrease of light intensity, dry air, water deficit, high temperature, and toxic gases. Haseba showed by a simulation analysis between meteorological factors and physiological activity that the transpiration rate increases with increasing a wind speed under a high air temperature, a low relative humidity, a low solar radiation, and a large stomatal conductance and that decreases in an adverse condition. He also showed that the transpiration may not change between two extreme conditions even if a wind speed increases.

The increase in a solar radiation and an air temperature makes the transpiration increase because the saturated water vapor pressure in the stomatal pore (e_s) increases by rising leaf temperature. On the other hand,

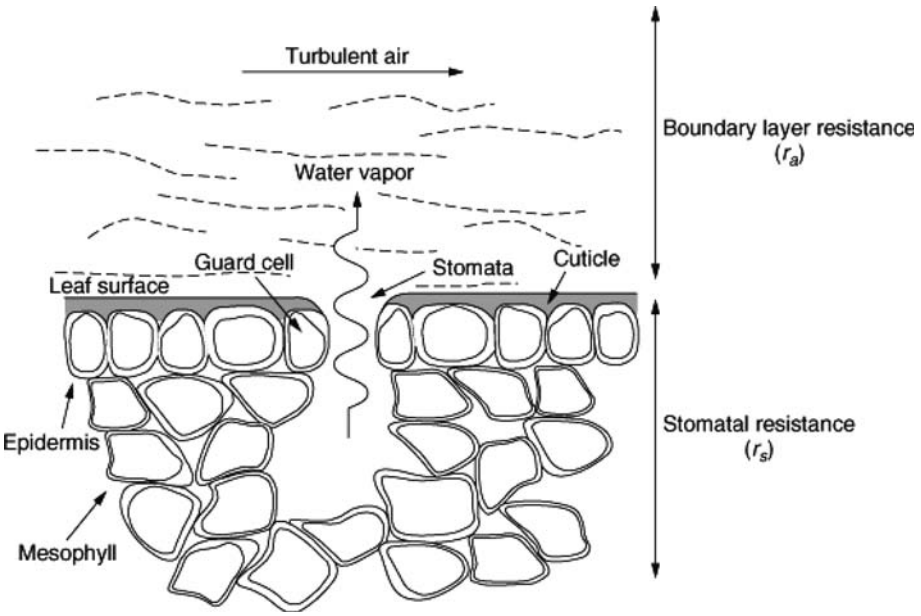

Fig. 1. Conceptual diagram of the transpiration from a leaf in case of the open stomata. The curvilinear arrow is the flow of a water vapor from the stomatal aperture to the atmosphere.

the transpiration rate is inhibited as the relative humidity of the ambient air is great and the water vapor deficit decreases.

For example, transpiration is also influenced by deficit of the soil moisture. Transpiration does not change if the soil moisture slightly decreases. However, if the soil water content greatly decreases, to keep the water content plant regulate stomatal aperture decreases transpiration.

Transpiration is necessary for the growth of plants. The flow of water through the plant by transpiration increases the absorption of minerals from the soil. Changes in the water balance and the amount of water available in the soil can be crucial for plants. There is a rising concern that the worldwide water resources may be exhausted by global warming. Under the drought stresses, a plant does not only decrease the transpiration along with the decrease of stomatal conductance, but also it often may cause damage. Miyashita et al. showed that the recovery level of transpiration in the kidney bean after drought stress gradually decreased as the periods of water stress.

The other effect of transpiration is to decrease the leaf temperature. In particular, the adjustability of a leaf temperature prevents too high of a temperature of a plant from the strong solar radiation. It is well known that the leaf temperatures are different among the plant species even if meteorological conditions are the same, which is mainly the difference of transpiration.

The differences (Ts-Ta) between leaf temperature (Ts) of worldwide barley cultivars (north America cvs, north African cvs, Chinese cvs, Ethiopian cvs, southwest Asiatic cvs, Japanese cvs, Korean cvs, Nepalese cvs, Turkish cvs, and European cvs) and ambient air temperatures (Ta) were measured under the same field. The temperature differences (Ts-Ta) of barley cultivars in the habitats with the cool meteorological phenomena such as Europe were large under high-temperature conditions. These show the differences of capability in the transpiration among the geographical varieties. Not only the plant species, but also the relationships between transpiration and the meteorological conditions at the places of origin are recognized.

For the plant canopy, such as a forest or an agricultural land, the transport of water vapor from the canopy to the atmosphere includes both the transpiration from plants and the evaporation from the wetted surfaces of plants and soils. Total of transpiration and evaporation is known and described as evapotranspiration. Transpiration of plant canopy is approximately proportional to the green mass, although the transpiration rate of individual leaves decreases with increasing leaf densities because of shielding of radiation and wind. Therefore, transpiration from the canopy is affected by development of the foliar mass. Canopy transpiration has the seasonal and diurnal patterns. Total annual and daily transpiration of stands of plant in various climatic regions, which are obtained from data of numerous authors, are summarized. Community transpiration of tropical rainforest is $1500 \sim 2000$ mm/year, that of grain fields $400 \sim 500$ mm/year and that of open vegetation in arid desert $0.01 \sim 0.4$ mm/day. Under similar climatic conditions, forests with greater mass transpire more than grass lands, which in turn transpire more than heath. In addition to accurate observational data, the detailed simulation models, which include all basic hydrological parameters, are now available in calculation of stand transpiration. These quantitative data about transpiration of plant vegetations are important for forestry and landscape management, irrigation management, and prediction of climatic change.

As high CO_2 in the future decreases stomatal aperture (or stomatal conductance), transpiration may decrease if CO_2 increases and leaf temperature is constant. However, high leaf temperature at higher ambient temperature may partly counteract the expected suppression of transpiration. Despite higher leaf temperature, water-use efficiency (the ratio of photosynthesis to transpiration) increases at high CO_2 mainly because of increased photosynthesis. See also **Hydrology**.

Measurement of Transpiration

Transpiration in the single leaf, the individual plant, and the canopy level measured by many methods is as follows: (1) The weighing method. The total weight of a plant with a pot is precisely measured at a constant time. The amount of a drop of a weight is comparable with the transpiration. As similar methods, there are the leaf cutting method for a single leaf and the lysimeter method for many plants. (2) The chamber method. The plant is covered by a transparent box with an inlet and an outlet port for the air flow. The humidity of an outlet port increases by the transpiration if an air flows. Transpiration rate can be calculated from the difference of an absolute humidity and an air flow rate. This method can be widely used for a single leaf, an individual plant, and a canopy. (3) The sapflow method. There is a transpiration stream within a plant vessel from a root to a leaf. It is in proportion to the increasing amount of a stem temperature when a stem is warmed by a constant quantity of heat. This method is used for plants (tomato, soybean, sugarcane, sweet potato, and etc) or trees. (4) Micrometeorological method. Evapotranspiration from a canopy is measured by a micrometeorological observation. Also, the Bowen ratio energy balance method; the aerodynamic method; the turbulent transport method; and so on is available. See also **Evapotranspiration**; and **Lysimeters**.

TRANSPLANTATION. The ability to transplant tissues and organs between individuals has been long sought, but not successfully achieved until in the latter half of the twentieth century. The concept is relatively straightforward, and sufficient technical skills have often been available for the transfer of some organs, but the attempts have been defeated by the recipient's own immune system. In an attempt to protect the body from "foreign" cells in the sense of infectious agents, the immune system is unable to distinguish between the presence of "good foreign" and "bad foreign" cells. Essentially, the immune system of the recipient views the transfer of even beneficial foreign cells as a threat, and attempts to destroy the transplant. The increasing success in transplantation has been due to two general discoveries: (1) the role of genetics in determining what the immune system views as foreign, leading to an ability to optimally match donors and recipients, and (2) the development of techniques to inhibit the ability of the immune response to damage or destroy transplanted grafts.

History

The transplantation of organs to replace those lost or damaged through injury, disease or deliberate mutilation has been practiced longer than most people realize. Legend has it that Saints Cosmas and Damian, in the third century, replaced an entire gangrenous leg removed from Justinian, a church elder in Constantinople, with one taken from a recently deceased corpse. While it is highly unlikely that this actually happened, records dating back many centuries show that physicians on the Indian subcontinent developed techniques for moving flaps of skin from an individual's forehead downward on to their face to reconstruct noses lost through injury, infection or legal penalties involving mutilation. The first scientifically documented successful case in Western medical literature was described in 1596 by Gaspari Toggliacozzi at the University of Bologna who, knowing that transplants between individuals had little or no hope of success and decided against using a wooden or metal substitute, transferred a piece of skin from a man's arm on to his face to reconstruct the patient's nose.

The paramount importance of the genetic relationship between the host and the donor to the success of a transplant was not definitively recognized until the late 1920s when Little and Tyzzer noted a pattern in the rejection of transplanted tumors in mice. Grafts exchanged between closely related donors and hosts had a far greater chance of success than those done between unrelated individuals. Utilizing transplantable tumors in mice, George Snell formulated the basic laws of transplantation in the 1940s and began to identify and analyze the roles of specific histocompatibility genes. Following World War II, Sir Peter Medawar extended these principles to the transplantation of normal tissues. Both Snell and Medawar received Nobel Prizes in recognition of their work. See also **Medawar, Peter Brian (1915–1987)**; and **Snell, George Davis (1903–1996)**.

Auto-, Allo- and Xenografts

Grafts are often classified on the basis of the genetic relationship between the host and the donor. Grafts exchanged from one part of an individual to another part of the same individual are called autografts. In this case, the graft and recipient are genetically identical. A comparable degree of matching between different individuals is possible only in the case of siblings derived by splitting of a zygote (e.g. identical twins) or between members of the same inbred strain of experimental animal. In fact, the advances in understanding the basis for transplantation was in large part dependent upon the development of such inbred strains, permitting genetics to be a controlled experimental variable rather than an uncontrolled one. Grafts exchanged between different individuals of identical genetic constitutions (e.g., identical twins) are termed isografts (or syngeneic grafts), to distinguish them from autografts.

Grafts exchanged between nonidentical members of the same species are allografts (or allogeneic grafts), while xenografts (or xenogeneic grafts) are those exchanged between members of different species. Best known are the use of chimpanzees or baboons as heart donors. More recently, because of the close physiological similarities of the two species, miniature swine have been increasingly explored as potential donors. Because xenografts are particularly susceptible to rapid attack by naturally occurring antibodies and complement, the insertion of certain human genes into the genomes of the donor swine has made it possible to increase the chances of the donated organs.

The immune system of the graft recipient can recognize genetically encoded molecules on a graft that may be new or different ("foreign") from those already present on the cells of the recipient, and proceed to attack and destroy that graft. The molecules on transplanted cells and tissues that are recognized by the immune system are called histocompatibility antigens, and are encoded by histocompatibility genes.

Histocompatibility antigens are co-dominantly expressed, i.e. they are fully expressed on the surface of a cell carrying either one or two copies of the gene encoding them. Autografts and syngeneic grafts should bear no histocompatibility antigens that are foreign to the recipient, and therefore should succeed unless there are technical problems that damage the graft or its interface with the recipient. Depending upon the particular combination used, allografts can vary from the recipient across a wide spectrum — from as little as a single amino acid within a single histocompatibility antigen to differences involving scores of different histocompatibility antigens. Xenografts, obviously, also bear many histocompatibility antigens differing from those of the recipient.

Histocompatibility genes/antigens are typically divided into two categories–major and minor. The major histocompatibility antigens are those encoded by the class-I and class-II loci within a small chromosomal segment, termed the major histocompatibility complex (MHC) (Fig. 1). The class-I and -II histocompatibility antigens are usually highly polymorphic (i.e. having numerous alleles per locus) within each species, but bear strong similarities in general structure and function across species. In humans, the MHC is termed the human leucocyte antigen (HLA) complex and is located on chromosome 6 (Fig. 2). In mice, the other mammalian species most intensively studied for genetic and immunological phenomena, the MHC is termed the H2 complex and is located on chromosome 17. In general, the class-I histocompatibility antigens are particularly strong barriers to transplantation, and grafts bearing class-I histocompatibility antigens foreign to the host are typically rejected vigorously, unless there is therapeutic intervention to interfere with the recipient's immune system.

Whereas the major histocompatibility loci are limited in number, typically in the range of 6–12 (depending upon the species), the minor histocompatibility genes represent a large number of loci, scattered across all of the chromosomes, encoding a wide range of molecules against which the immune system can potentially react. Immune responses against minor histocompatibility antigens are highly variable, depending upon the specific antigen in question, but are generally slower and less vigorous than responses against MHC encoded histocompatibility antigens. However, the sheer number of minor histocompatibility genes, probably several scores at minimum, makes the sum of the responses against them a potent threat to their survival.

Major Types of Organ Transplant

Transplants can involve cells (e.g., suspension of bone marrow cells), tissues (e.g. corneas), or partial/whole organs (e.g., kidney, liver, heart, skin, etc.). While blood transfusion is a form of transplantation, it is usually dealt with as a separate specialty called hematology. When the transplanted tissue/organ is placed into its natural anatomical location, it is considered an orthotopic graft; when placed into a location other than its natural one, the graft is referred to as heterotopic.

The placement of transplanted organs depends upon their particular anatomy and function. Some, such as kidneys and hearts, require numerous direct connections with the host vasculature in order to survive and function. Others, such as skin and numerous endocrine organs, need only to be secured in place, where they establish new vascular connections with

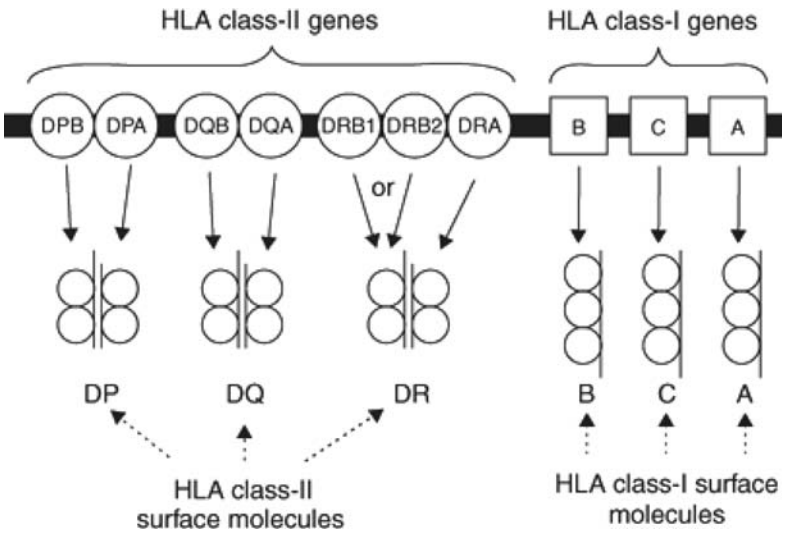

Fig. 1. The histocompatibility antigens encoded by the class-I and class-II loci of the HLA complex. The class-I molecules are expressed on the surface of all nucleated cells in the body; class-II molecules are expressed on a subset of cells, primarily those, such as dendritic cells, macrophages and B lymphocytes that are engaged in antigen processing and presentation. The class-I and class-II loci are highly polymorphic.

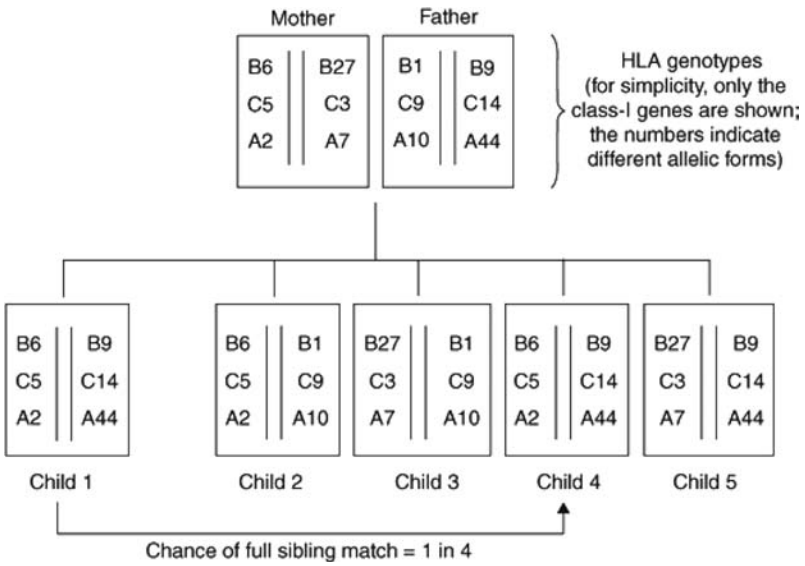

Fig. 2. Segregation of HLA genes within a family. Because the HLA genes are so closely linked, those present on a given member of a chromosome pair are usually transmitted to the next generation as a unit (called a *haplotype*). The genes are inherited in a Mendelian fashion so that a given offspring has approximately a one-fourth chance of having a full sibling inheriting the same combination.

the host. In the least complex type of transfer, bone marrow transplants are simply injected intravenously as single cell suspensions.

Transplants of heart, kidney, liver, lung, intestine, bone and cartilage, skin and bone marrow are possible, and many of them are now done quite routinely.

Bone marrow transplantation presents a special challenge. As the source of stem cells that produce the hematopoietic system, the ability to transplant bone marrow permits the cure of a variety of chronic conditions, including many forms of anaemia, immunodeficiencies, and even some autoimmune conditions. However, because the bone marrow is the source of the stem cells that ultimately produce T and B lymphocytes, bone marrow transplants are different from other types of transplanted tissue in that they represent the transplantation of immunologically competent tissue. Thus the graft is capable of recognizing histocompatibility antigens on host cells as foreign and attacking the host tissues, leading to graft-versus-host disease (GVHD). Because the recipients of bone marrow transplants are often naturally or therapeutically immunosuppressed, the transplanted cells can attack host tissues vigorously, without any opposing host-versus-graft responses. See also **Immunodeficiency**; and **Lymphocytes**.

Organ Datasource

Kidney. The kidneys are a pair of reddish-brown organs located on either side of the spine just below the diaphragm, behind the liver and stomach. They are bean-shaped and measure about 4 and one half inches long (11.4 centimeters), 2 and one half inches wide (6.4 centimeters), and 1 inch thick (2.5 centimeters). The primary function of the kidneys is to remove waste from the body through the production of urine. They also help to regulate blood pressure, blood volume, and the chemical (electrolyte) composition of the blood.

Renal failure is the inability of the kidneys to remove wastes and maintain electrolyte balance. Acute renal failure, characterized by inability to produce urine and an accumulation of wastes, is often associated with trauma, burns, acute infection, or obstruction of the urinary tract; its

treatment depends on the cause and often includes antibiotics and reduced fluid intake. Chronic kidney failure, which may occur as a result of many systemic disorders, causes fatigue and sluggishness, diminished urine output, anemia, and often complications of hypertension and congestive heart failure. The treatment depends on the cause, often involving the use of diuretics, restricted protein intake, and, if the kidney failure cannot be otherwise treated, dialysis and/or transplantation. See also **Kidney and Urinary Tract**.

A kidney transplant may involve one or both kidneys if the donor is deceased and only one kidney if the donor is living. In most transplants, only one kidney is transplanted. But, in certain circumstances, particularly if the donor is less than ideal, two kidneys may be transplanted. There is also some experimental work being done on splitting kidneys prior to transplanting them, resulting in two recipients per kidney, but this is still extremely rare in practice.

Pancreas. The pancreas is a 5 to 6 inch (12.7 to 15 centimeter) gland located behind the stomach; it extends horizontally between the duodenum and the spleen. One function of the pancreas is to produce enzymes that are used for digestion. It also produces insulin, which is essential for life because it regulates the use of blood sugar throughout the body. See also **Pancreas**.

A pancreas transplant may involve either the whole pancreas or a pancreas segment. Whole organ transplants are far more common but a segmental transplant is possible. Segmental transplants are done if a living donor is involved. Many pancreas transplants also involve transplantation of the duodenum.

The kidney is frequently transplanted with the pancreas in the U.S. Many people suffering from pancreas failure also have renal failure. In most cases a kidney-pancreas transplant is performed from a deceased donor. But there have been several transplants performed using a living donor, with one kidney and a pancreas segment being donated.

Liver. The liver is one of the largest and most complex organs in the body. It weighs approximately 1,500-1,800 grams (or about three to four pounds) and is made up of a spongy mass of wedge-shaped lobes. The liver has numerous functions that are necessary for life. The liver helps process carbohydrates, fats, and proteins, and stores vitamins. It processes nutrients absorbed from food in the intestines and turns them into materials that the body needs for life. For example, it makes the factors that the blood needs for clotting. It also secretes bile to help digest fats, and breaks down toxic substances in the blood such as drugs and alcohol. See also **Liver**.

A liver transplant may involve the whole liver, a reduced liver, or a liver segment. Most transplants involve the whole organ but segmental transplants have been performed with increasing frequency in recent years. This would allow two liver recipients to be transplanted from one cadaveric donor or to allow for living donor liver donation. A reduced liver transplant may result if the donor liver is too large for the recipient.

Heart. The heart is a strong and muscular, cone-shaped organ that is about the size of a fist. It pumps blood throughout the body and is located behind the breastbone between the lungs. Deoxygenated blood flows from the heart to the lungs where it gives up wastes and is freshly oxygenated. From there, the blood returns to the heart and is pumped to the rest of the body. Heart failure is the inability of the heart to pump enough blood to maintain normal body requirements. Birth defects or any condition that damages or overloads the heart muscle can cause it. Treatment depends on the cause of heart failure and the age and condition of the patient. See also **Heart and Circulatory System (Physiology)**.

Most heart transplants involve replacing the patient's heart with the heart from a cadaveric donor. In certain situations, the patient's native heart is not removed; this is known as a heterotopic transplant. There have also been a few transplants in the U.S. involving a living heart donor. This may occur if one patient receives a heart-lung combination transplant but their heart is in good condition. This patient's heart may then be subsequently transplanted into another recipient. This is known as a "domino" heart transplant.

Lung. Lungs are a pair of highly elastic and spongy organs in the chest. They are the main organs involved in breathing. They take in air from the atmosphere and provide a place for oxygen to enter the blood and for carbon dioxide to leave the blood. The lungs are divided into lobes, with three on the right and two on the left. See also **Respiratory System**.

Lung transplants may involve two lungs, a single lung or a lobe of a lung. Most of the lung lobe transplants have been performed for patients with cystic fibrosis and have involved the donation of a lung lobe from each of two living donors.

Intestine. The intestine is the lower part of the alimentary canal. It extends from the stomach to the anus. The upper part, the small intestine, is narrow and convoluted. It provides further digestion of food and absorbs nutrients from the digested food. The lower part, the large intestine, is wider and reabsorbs water from the digested foods and sends it back into the blood stream.

An intestine transplant may involve the whole intestine or an intestine segment. Most of the intestine transplants are whole organ transplants and are performed in conjunction with a liver transplant. Intestine transplants usually involve a cadaveric donor though it is possible for a living donor to donate an intestine segment.

Requirements for Organs

Transplantation presents a solution to a wide range of clinical problems. Patients born with missing or defective organs can gain the missing functions through transplanted organs. Vital organs lost to injury or deterioration — corneas, kidneys, hearts, livers, etc. can be replaced to enhance the quality and length of life. Transplantation can even be used to elevate the efficiency of treatment for other diseases, as in the case of cancer therapy. The use of radiation and chemical agents to kill tumors faced limitations because of the devastating effect such treatments could have on tissues that generate the hematopoietic system responsible for oxygen transport and immune defenses. However, the ability to transplant bone marrow and replace these tissues has permitted an elevation in the levels of anticancer agents that can be utilized.

Since the inception of organ transplantation in the 1950s, it has been increasingly used and the total number of transplants performed, on a worldwide basis, now exceeds half a million (Table 1). The increased reliance on transplantation has been possible because of constant improvements in surgical technique, in optimizing the matching of donors and recipients, and in the ability to manage the host immune system to permit graft survival without overwhelming sepsis. For many major internal organs, the survival rates are excellent and often exceed 90% (Table 2).

The increasing ability of transplantation to cure or alleviate many diseases has resulted in an increasing imbalance between the number of

TABLE 1. WORLDWIDE TRANSPLANTS OF SOLID ORGANS[a]

	No of transplants performed[a]	
Organ	During 1997	Cummulative since 1950s
Kidney	24 225	415 854
Liver	7183	62 502
Heart	3685	46 277
Lung	810	7689
Pancreas	378	2260
Lung and kidney	143	2172

[b] All candidates will be less than the sum due to candidates waiting for multiple organs.

patients awaiting donated organs and the number of available organs. Data illustrating the imbalance in the USA during 2006–2007 are given in Table 3. While organ donation has increased, it still falls far short of the need. In addition, there are numerous cultural and religious objections that drastically inhibit the donation of organs.

Finally, it should be mentioned that transplantation is a valuable experimental tool in analyzing the embryonic origins, development and function of numerous cells and organs.

Immunosuppression

Most available grafts are allografts because of the genetic diversity among humans. Individuals who need to acquire donated kidneys, hearts, livers, etc. may be fortunate enough to obtain them from closely related first degree relatives (parent, child or sibling). However, unless the donor is an identical twin, there is almost certain to be some degree of genetic mismatch of histocompatibility genes/antigens. Therefore, the alternative solution to an attack by the immune system upon the graft is to employ some method of minimizing the capacity of the immune system to do so.

Therapeutic intervention in the immune system can be approached in two different ways — immunosuppression and the induction of specific immune tolerance. Immunosuppression is the generalized inhibition of the immune system without reference to the specificity of the rejection response. The induction of specific immune tolerance is an attempt to inactivate or eliminate the part of the immune system that is capable of responding to a particular antigen. While deliberate immunosuppression is possible through the application of a wide range of physical or chemical agents, specific immune tolerance requires the knowledge of specific antigens involved and manipulations in advance of the transplant, and is therefore still largely confined to the experimental arena.

Generalized immunosuppression is usually achieved by the application of irradiation, chemical agents or antibodies directed against cells of the immune system. The cells of the immune system, particularly lymphocytes, are sensitive to radiation as well as to a variety of chemical agents, such as cyclophosphamide. Thus, treating a transplant recipient with such agents can greatly reduce the ability of the immune system to attack a foreign graft. However, the general nature of the damage inflicted on the immune system by these agents also reduces the ability to respond to infection, and such infections are the major cause of mortality in transplant recipients. In addition, the elevated levels of irradiation used for immunosuppression can have devastating effects on other cells/tissues such as erythrocytes, the intestinal lining and the nervous system. More recently, drugs have been developed that, while not specific, have a more restricted effect on the immune system because their effects are directed primarily at some of the cells involved in immune responses. Drugs such as cyclosporin, tacrolimus (FK506) and rapamycin target their effects on those T lymphocytes that are most actively proliferating and responding at the time of application (presumably those that are attacking the graft), leaving the remaining quiescent T and B lymphocytes relatively unaffected and available for use in the future if needed. While a great improvement over earlier, more general drugs, even these more limited agents have their limitations. For example, should an active infection be ongoing at the time of application, the parts of the immune system responding to that infectious agent would also be damaged by the suppressive agent and the patient would have great difficulty in coping with the infection. In addition, the drugs often have to be used over an extensive period of time and their long-term application has been shown to have adverse effects on some internal organs (e.g., liver). Much effort is currently going into the identification of new, more effective drugs for immunosuppression that also have fewer unfavorable side effects.

Another approach to inhibit the immune responses has been the use of antibodies directed at molecules present on the surface of the cells, particularly CD8+ and CD4+ T lymphocytes, involved in responses against grafts. The antibodies binding to the molecules on the lymphocytes can lead to their inactivation or destruction. Thus, the portion of the immune system reacting against the graft can be inhibited without damaging the ability to respond to other future stimuli (e.g. infectious agents). However, applications of antibodies against T lymphocytes, or subsets of T lymphocytes, have many of the same problems as immunosuppressive drugs in that their use, especially over an extended time span, reduces the ability to respond to infectious agents.

Experimentally, it is possible to make the immune system of a potential recipient tolerant of the histocompatibility antigens of a future allogeneic or xenogeneic donor, so that a subsequent graft from such a donor will not become the target of a rejection response. A variety of means can be used to induce this specific tolerance, but these have not yet been successfully transferred to the clinical setting for reasons of time, technical considerations and ethical issues.

Graft Survival

Graft survival depends upon several factors–the most important of which are the degree of genetic matching between host and donor and the specific genes by which they may differ, prior exposure to the foreign antigens of the graft and the status of the recipient's immune system (normal or impaired).

Probably the single most important factor for improving the chances of graft survival (in the absence of therapeutic intervention) is the genetic relationship of host and donor. Identical twins are identical for 100% of their genes. First degree relatives are identical (on average) for 50% of their genes, second degree relatives (grandparents, grandchildren, aunts, uncles, nieces and nephews) are identical for 25% of their genes, etc. Unrelated donors, whether living or cadaver, are likely to share fewer genes. Thus the more closely related the graft donor, the lower the likely frequency of foreign histocompatibility antigens on the graft that can be targeted by the recipient immune system. In the case of MHC genes, it is possible to type recipients and potential donors in advance and select those that are the closest match. Among full siblings, there is generally a 1 in 4 chance that one sibling may be identical to another at all of the MHC genes (which are located so close together on the chromosome that they are usually transmitted from parent to child as a unit). The chances of identity across all of the MHC genes is considerably lower when unrelated donors are used, but the ability to type the MHC permits the selection of the best possible match among those available. No comparable typing system is available for minor histocompatibility antigens and the only beneficial strategy is to try to use the most closely related donor.

Like other antigens, histocompatibility antigens can sensitize a recipient so that future exposures to the same antigen can result in faster, more vigorous rejections ("second set" rejections). While this phenomenon is largely confined to the experimental setting, it can present difficulties in rare clinical cases where repeated donations of cells from a sole donor or limited number of donors may be necessary.

Finally, the functional status of the recipient's immune system is an important factor. Thus, patients whose immune systems are naturally or artificially suppressed are able to retain grafts that would be readily rejected by normal recipients. However, as discussed above, such immunosuppression has a number of undesirable side effects — primarily putting the patient at high risk of succumbing to opportunistic infections.

The patterns of graft rejection are often categorized on the basis of the speed, vigor and immune mechanisms involved.

- Chronic rejections are those in which the graft establishes a vascular connection with the host and usually gains normal function. However,

after a period of many weeks, months, or even years, the graft may begin gradually to deteriorate. Chronic rejections are usually associated with cell-mediated immune responses involving T lymphocytes.

- Acute rejections are those in which the graft establishes a vascular connection with the host and may even gain function for a short period of time. However, after a short time, usually 1 to 3 weeks, the graft begins to deteriorate rapidly and may be lost altogether within a day or two of the onset of deterioration. Acute rejections are also usually associated with cellular responses involving T lymphocytes.
- Hyperacute rejections are those in which the graft is destroyed so rapidly that it often fails even to establish an initial vascular connection with the recipient. Such grafts may be lost within a very few days of placement. Hyperacute grafts are usually associated with humoral immune responses involving antibodies and the complement system.

Privileged Sites

Privileged sites are places in the body where genetically disparate grafts, which would be readily rejected if placed at most locations, have an enhanced chance of survival. Usually, these are sites that are, in some manner, sheltered from the immune system. A number of sites within the body are considered privileged — the anterior chamber of the eye, the central nervous system, the testicular lumen and the uterus. The fluid-filled anterior chamber of the eye provides an opportunity for cells (or small tissue pieces) to grow without making a direct vascular connection to the rest of the body. Thus the immune system may be slow to recognize their presence. Transplanted allogeneic corneas can often survive permanently, being an essentially nonvascular piece of tissue. The immune system's ability to monitor the brain and spinal cord is reduced by the blood–brain barrier that inhibits the passage of cells and large molecules from the vasculature into the central nervous system under normal circumstances. The lumen of the testicular tubule is closed and sheltered by the Sertoli cells from the vasculature.

Although there is a debate over whether the uterus should be termed an immunoprivileged site, it deserves mention here. The fetus, where a substantial fraction of the paternally inherited histocompatibility antigens are likely to be foreign to the mother, is essentially a type of allograft residing within the mother's body. The maternal immune system, in conjunction with the placenta, utilizes a number of poorly understood mechanisms to spare the developing fetus from immune attack. When such protective mechanisms fail, the consequences can be fatal. This protection cannot be absolute, however, as some antibodies must be able to cross the placenta from the maternal circulation to the fetal circulation to provide protection from infection both *in utero* and for the first several months after birth, until the infant's own immune system matures to the point where it can adequately protect the newborn on its own.

Future Directions

With natural limitations upon the number of identical twins or close relatives who can serve as potential donors, it is likely that future increase in donor availability will require four types of future developments: (1) improvements in immunosuppression, (2) increased availability and improved distribution of human organs, (3) increased availability of xenogeneic organs and (4) increased sophistication of practical mechanical substitutes for tissues and organs.

Testing of numerous new drugs is in progress to identify those with greater immunosuppressive capacity and fewer undesirable side effects than those currently in wide use, and there is increasingly sophisticated use of monoclonal antibodies to manipulate host immune cells. Often, however, such testing trials require long-term testing before side effects can be evaluated properly. Campaigns are underway to increase public awareness and acceptance of organ donation, but it is unclear how much impact they will have. Changes are also being explored for improved schemes of distribution to be sure that available organs are distributed in a way that is both fair and provides optimal host–donor matching. Xenogeneic donor species, such as swine and nonhuman primates, are the focus of considerable attention. However, it is more difficult to achieve sufficient immunosuppression for survival of xenografts than allografts, and genetic engineering of the donor animals is often needed to permit even short-term survival. In addition, there is concern that xenogeneic grafts may introduce potentially dangerous infectious organisms. Finally, technical improvements in bioengineering may make it increasingly possible to employ mechanical substitutes such as artificial bone, blood vessels, heart valves and even entire hearts for more extended periods of time. See also **Monoclonal Antibodies**.

TRANSPORT EQUATION (Boltzmann). Consider the evolution of the velocity distribution function f. This evolution proceeds through mechanical changes (flow) and collision.

In gases at low densities, the effect of collisions involving more than two molecules is negligible. If the collisions with the walls can also be neglected, the evolution of the molecular distribution function $f_i(\mathbf{r}, \mathbf{v}, t)$ is given by the Boltzmann integro-differential equation:

$$\frac{\partial f_i(\mathbf{r}, \mathbf{v}, t)}{\partial t} + \mathbf{v}_i \frac{\partial f_i(\mathbf{r}, \mathbf{v}, t)}{\partial \mathbf{r}_i} + \mathbf{X}_i \frac{\partial f_i(\mathbf{r}, \mathbf{v}, t)}{\partial \mathbf{v}_i} = 2\pi \iint (f_i' f_j' - f_i f_j) g_{ij} b \, db \, d\mathbf{v}_j \tag{1}$$

b is the impact parameter, g_{ij} is the relative velocity. $\partial f/\partial t$ is the local variation of the distribution function. Equation (1) results from three

causes: (1) $\mathbf{v}_i(\partial f_i/\partial \mathbf{r}_i)$, often called the *Streaming Term*, is the variation of the distribution function caused by the movement of the particles in and out of the volume element under consideration; (2) $\mathbf{X}_i(\partial f_i/\partial \mathbf{v}_i)$ is the variation of the distribution function resulting from the external forces $\mathbf{X}_i$ acting on the molecules; (3) finally, the term on the right-hand side of Equation (1) expresses the variation of f_i that results from the binary collisions between the molecules, f_i increases when a collision between two molecules having initial velocities $\mathbf{v}_i'$ and $\mathbf{v}_i'$ creates a molecule of the proper velocity $\mathbf{v}_i$. It decreases when a molecule of velocity $\mathbf{v}_i$ collides with a molecule of velocity $\mathbf{v}_j$. The term on the right-hand side of Equation (1) is called the *Collision Integral* of the Boltzmann equation.

TRANSURANIUM ELEMENTS. The chemical elements with an atomic number higher than 92 (uranium), commencing with 93 (neptunium) and through 103 (lawrencium) frequently are termed Transuranium elements. Any additional elements that may be identified will be a part of this series. See also **Actinide Series**.

TRAP. 1. A general term for fine-grained, basic and therefore dark-colored igneous rocks, having a relatively high specific gravity. The term is derived from an old Scandinavian word meaning a stair, because these rocks, as particularly well displayed in the 3,000-foot (900-meter) cliffs of the Faroe Islands, develop architectural forms simulating colossal stairways. The term is also used as a synonym for basalt, especially by contractors who use it for road metal.

2. In electronics, a trap is an absorption filter used to trap or remove an undesired signal from a receiver, as in the sound trap used in the video amplifier of a television receiver to prevent the sound signal from interfering with the picture.

3. In a diffusion pump system, a trap is a device designed to reduce the effect of vapor pressure of the mercury or oil in the pump, on the high-vacuum side of the system.

4. Trap is a word also used in connection with the trapping of atoms and ions. See also **Trapped Ions** and also check alphabetical index.

TRAPEZIUM. See **Quadrilateral**.

TRAPEZOIDAL RULE. A special case of the Newton-Cotes formula for numerical integration

$$\int_a^b f(x)\,dx = h\left[\frac{y^0}{2} + y_1 + y_2 + \cdots + y_{n-1} + \frac{y_n}{2}\right]$$

where h is the interval between equally spaced values of x, the independent variable. This is the simplest, but least accurate, of the numerical integration rules. It is often used, however, and can give quite satisfactory results.

TRAP (Geology). See **Natural Gas**; and **Petroleum**.

TRAPPED IONS. Charged particles, including electrons and atomic ions, can be stored for long periods of time (days are not uncommon) without the usual perturbations associated with confinement (for example, the frequency shifts associated with the collisions of ions with buffer gases in a more traditional optical pumping experiment). Ions that are stored in electromagnetic "traps" can provide the basis for extremely high-resolution spectroscopy. By using lasers, the kinetic energy of the ions can be cooled to millikelvin temperatures, thus suppressing Doppler frequency shifts. Potential accuracies of frequency standards and clocks based on such experiments are anticipated to be better than one part in 10^{15}. The current time standard (cesium clock) has an accuracy of one part in 10^{13} or less. See also **Mass Spectrometry**.

Storage has mainly been achieved in four types of traps: (1) the radio frequency or Paul trap; (2) the Penning trap; (3) the Kingdon electrostatic trap; and (4) the magnetostatic (magnetic bottle) trap. The principles, advantages, and disadvantages of these traps are detailed by D.J. Wineland (*Science*, **226**, 395–400, Oct. 26, 1984).

TRAPPING. An electron in the conduction band of a semiconductor or insulator may be caught by any irregularity in the crystal lattice and trapped there until it can be released by thermal agitation. The rate of release will depend on $\exp(-E/kT)$ where E is the depth of the trap — hence a material containing large numbers of deep traps may show reduced photoconductivity, for example, and a slow decay as the electrons are released after the light has been removed.

TRAUMA. A physical injury, the term often signifying a severe wound; or a psychic trauma, representing the psychological consequences of emotional shock.

TRAVELING-WAVE TUBE. See **Microwave Tubes**.

TRAVERSE. A series of connected straight lines, forming the outline of a plot of land or the center line of a roadway or railway. A traverse that forms a closed figure is a closed traverse. A traverse that is not closed is an open traverse. The traverse is obtained by means of a survey. Ordinarily, the transit and tape are used, the transit being successively set up over each point constituting the junction of two adjacent lines. The distances between transit stations (the length of the straight lines) are measured by taping with a graduated tape or chain. The bearings of the lines or the angles between the lines, as well as the length of the lines, are noted by the instrument man at the time of the survey in a field book. These field notes are later employed to map the traverse by one of the several methods available, such as tangent offsets, latitudes and departures, coordinates, etc.

A traverse that follows the shoreline of a body of water is a meander line. The general outline of the shore is found by taking offsets from the transit lines at regular intervals and also at points where there is an abrupt change of shape.

TRAVERSE TABLES. In many problems in surveying and navigation (e.g., the important navigational problem of dead reckoning), the solution of a plane right-triangle becomes necessary. In traverse tables, the plane right-triangle is solved without using tables of trigonometric functions. The tables are constructed by tabulating for successive values of one apex angle the two sides of the triangle as functions of the hypotenuse. The traverse tables, as published for navigational purposes, solve the dead-reckoning problem by tabulating difference of latitude and departure as functions of the distance for each course, either in quarter points of the compass or every degree. Since the tables must contain pages for each value of the apex angle, they are more bulky than ordinary trigonometric tables. However, the rapidity with which the plane triangle may be completely solved more than compensates for the time lost in turning pages, particularly when extreme accuracy is not required in the solution.

See also **Course**; and **Navigation**.

TRAVERTINE. Carbonated waters dissolve large amounts of calcium carbonate, especially under high temperature. Such waters reaching the earth's surface as hot springs often deposit the calcium carbonate, in great quantities. This material is called travertine from the ancient name for Tivoli, Italy, where a very thick deposit occurs. Travertine may be compact, crystalline, fibrous or, if rapidly deposited, spongy and porous. The less compact varieties are known as tufa. Travertine is being formed at the Mammoth Hot Springs, Yellowstone National Park and at many other localities. A banded travertine used as an ornamental stone is called onyx marble or Mexican onyx.

TREE. Numerous specific trees are described in this volume — as indicated by the listings of Table 1. One of the most difficult problems in connection with persons conducting literature research on trees involves the naming of trees. Often, material will be listed only under Latin family or genus names. The listings of Table 2 are designed to render assistance in this regard. The names of Table 3 are further expanded to include the major genera within various families, including common name examples for the various genera. Included with many of the specific tree descriptions in this volume are lists of specifications of so-called champion trees in the United States. Over the years, these champion trees have

TABLE 1. SPECIFIC TREES DESCRIBED IN THIS VOLUME

Title of Entry	Tree Family	Title of Entry	Tree Family
Acacia Tree	*Leguminosae*	**Holly Trees and Shrubs**	*Aquifoliaceae*
Alder Trees	*Betulaceae*	**Hornbeam Trees**	*Carpinaceae*
Allspice Tree	*Myrtaceae*	**Juniper Trees**	*Cupressaceae*
Angiosperms	—	**Kentucky Coffee Tree**	*Gymnocladus*
Araucarias	*Araucariaceae*	**Larch Trees**	*Pinaceae*
Arborvitae	*Cupressaceae*	**Laurel Family**	*Lauraceae*
Ash Trees	*Oleaceae*	**Lignum Vitae**	*Guaiacum*
Balsa Tree	*Bombaceceae*	**Litchi Tree**	*Sapindaceae*
Baobab Tree	*Bombaceceae*	**Locust Trees**	*Leguminosae*
Basswood Trees	*Tiliaceae*	**Logwood Tree**	*Caesalpiniaceae*
Bayberry Shrubs and Trees	*Myricaceae*	**Macadamia Tree**	*Proteaceae*
Beech Trees	*Fagaceae*	**Magnolia Trees**	*Magnoliaceae*
Birch Trees	*Betulaceae*	**Mahogany Trees**	*Meliaceae*
Bladdernut Tree or Shrub	*Staphleaceae*	**Maidenhair Tree**	*Ginkgoaceae*
Boswellia Tree	*Burseraceae*	**Mangrove Tree**	*Rhizophoraceae*
Box Trees and Shrubs	*Aquifoliaceae*	**Maple Tree**	*Aceraceae*
Brazil-Nut Tree	*Lecythidaceae*	**Mesquite Tree**	*Prosopis*
Brazilwood	*Caesalpiniaceae*	**Mulberry Family**	*Moraceae*
Buckeye and Horse Chestnut Trees	*Hippocastanaceae*	**Nutmeg Tree**	*Myristicaceae*
Buckthorn Shrubs and Trees	*Rhamnaceae*	**Nux Vomica Tree**	*Loganiaceae*
Cacao Tree	*Sterculiaceae*	**Oak Trees**	*Fagaceae*
Caesalpinia Tree	*Caesalpiniaceae*	**Olive Tree**	*Oleaceae*
Cashew and Sumac Trees	*Anacardiaceae*	**Palm Trees**	*Palmae*
Casuarina Tree	*Casuarina*	**Papaya Tree**	*Caricaceae*
Catalpa Trees	*Bignoniaceae*	**Pepper**	*Piperaceae*
Cedar Trees	*Cupressaceae; Pinaceae; Araucariaceae; Simaroubaceae*	**Persimmon Trees**	*Ebenaceae*
		Pine Trees	*Pinaceae*
Chestnut Trees	*Fagaceae*	**Plumeria Tree**	*Gentianaceae*
Citrus Trees	*Rutaceae*	**Podocarps**	*Podocarpaceae*
Clove Tree	*Myrtaceae*	**Poinciana**	*Delonix*
Coffee Tree and Coffee	*Rubiaceae*	**Pomegranate Tree**	*Myrtaceae*
Comminphora Tree	*Burseraceae*	**Poplar Trees**	*Salicaceae*
Conifers		**Quassia**	*Simaroubaceae*
Coral Tree	*Leguminosae*	**Redwood (Coast)**	*Taxodiaceae*
Corkwood Tree	*Leitneriaceae*	**Redwood (Dawn)**	*Taxodiaceae*
Cypress Trees	*Cupressaceae; Taxodiaceae*	**Rose Family**	*Rosaceae*
Dogwood Shrubs and Trees	*Cornaceae*	**Sapodilla**	*Sapotaceae*
Elder Trees and Viburnums	*Caprifoliaceae*	**Schinus Tree**	*Schinus*
Elephant Tree		**Silk Cotton Trees**	*Bombaceceae*
Elm Trees	*Ulmaceae*	**Spruce Trees**	*Pinaceae*
Eucalyptus Trees	*Myrtaceae*	**Sweetgum Tree**	*Liquidambar*
Fir Trees	*Pinaceae*	**Sycamore and Plane Trees**	*Platanaceae*
Giant Sequoia	*Taxodiaceae*	**Teak Tree**	*Verbenaceae*
Ginseng	*Araliaceae*	**Tung**	*Euphorbiaceae*
Guava Trees	*Myrtaceae*	**Tupelo Trees**	*Davidiaceae*
Hackberry and Zelkova Trees	*Ulmaceae*	**Walnut Trees**	*Juglandaceae*
Hazelnut Shrubs	*Corylaceae*	**Willow Trees**	*Salicaceae*
Heather Shrubs and Trees	*Ericaceae*	**Witch Hazel**	*Hamamelis*
Hemlock Trees	*Pinaceae*	**Yew Trees**	*Taxaceae*
Hickory and Wingnut Trees	*Juglandaceae*		

TABLE 2. ALPHABETICAL LIST OF FAMILY TREE NAMES — LATIN AND ENGLISH

English	*Latin*	*Latin*	English	English	*Latin*	*Latin*	English
Basswood	*Tiliaceae*	*Aceraceae*	Maple	Magnolia	*Magnoliaceae*	*Leguminosae*	Pea

TABLE 3. ABRIDGED ALPHABETICAL LIST OF TREE GENERA VERSUS FAMILIES

Genus	Name of Family		Examples[a]
	English	Latin	
Abies	Pine	*Pinaceae*	Fir
Acacia	Pea	*Leguminosae*	Acacia, cootamundra, wattle, mimosa
Acer	Maple	*Aceraceae*	Maple, sycamore
Aesculus	Horse Chestnut	*Hippocastanaceae*	Buckeye, horse chestnut
Ailanthus	Quassia	*Simaroubaceae*	Tree of heaven
Albizia	Pea	*Leguminosae*	Silk tree
Alnus	Birch	*Betulaceae*	Alder
Amelanchier	Rose	*Rosaceae*	Service-berry
Aralia	Bignonia	*Bignoniaceae*	Japanese angelical tree, Hercules club, Devil's walking stick
Araucaria	Chile Pine	*Araucariaceae*	Parana pine, Chile pine, Norfolk island pine
Arbutus	Heather	*Ericaceae*	Strawberry tree, madrona
Archonotophoenix	Palm	*Palmae*	King palm
Arecastrum	Palm	*Palmae*	Queen palm
Asimina	Laurel	*Lauraceae*	Pawpaw
Athrotaxis	Chile Pine	*Araucariaceae*	Tasmanian cedar, King William pine
Austrocedrus	Cypress	*Cupressaceae*	Chilean incense cedar
Betula	Birch	*Betulaceae*	Birch
Broussonetia	Mulberry	*Moraceae*	Paper mulberry
Buxus	Holly	*Aquifoliaceae*	Common box
Callitris	Cypress	*Cupressaceae*	Cypress pine
Calocedrus	Cypress	*Cupressaceae*	Incense cedar
Camellia	Tea	*Theaceae*	Camellia, tea tree
Carpinus	Hornbeam	*Carpinaceae*	Hornbeam
Carya	Walnut	*Juglandaceae*	Bitternut, pignut, pecan, mockernut, shagbark hickory
Castanea	Beech	*Fagaceae*	Chestnut
Castanopsis	Beech	*Fagaceae*	(Cross between oak and chestnut)
Casuarina	Myrtle	*Myrtaceae*	Dwarf oak or she-oak
Catalpa	Bignonia	*Bignoniaceae*	Catalpa, Indian bean tree
Cedrela	Mahogany	*Meliaceae*	Chinese toon
Cedrus	Pine	*Pinaceae*	True cedars
Celtis	Elm	*Ulmaceae*	Hackberry
Cephalotaxus	Yew	*Taxaceae*	Chinese plum yew; Cow's tail pine; Japanese plum yew
Ceratonia	Pea	*Leguminosae*	Carob
Cercidiphyllum	Witch Hazel	*Hamamelidaceae*	Katsura
Cercis	Pea	*Leguminosae*	Redbud, Judas tree
Chamaecyparis	Cypress	*Cupressaceae*	False cypress
Chamaerops	Palm	*Palmae*	European fan palm
Chionathus	Olive	*Oleaceae*	Fringe tree
Chrysolepis	Beech	*Fagaceae*	Golden chinkapin
Cinnamomum	Laurel	*Lauraceae*	Camphor tree
Citrus	Citrus	*Rutaceae*	Lime, limequat, orange, lemon, grapefruit, mandarin orange, orangequat, sweet orange, Ugli tree
Cladrastis	Pea	*Leguminosae*	Yellow-wood
Clethra	Heather	*Ericaceae*	Clethra
Cocos	Palm	*Palmae*	Coconut palm
Cornus	Dogwood	*Cornaceae*	Dogwood; Cornelian cherry
Corylus	Hazel	*Corylaceae*	Hazel
Cotinus	Cashew	*Anacardiaceae*	Smoke tree
Cotoneaster	Rose	*Rosaceae*	Cotoneaster shrubs
Crataegomespilus	Rose	*Rosaceae*	Bronvaux medlar
Crataegus	Rose	*Rosaceae*	Hawthorn, cockspur thorn
Cryptomeria	Swamp Cypress	*Taxodiaceae*	Japanese cedar
Cunninghamia	Swamp Cypress	*Taxodiaceae*	Chinese fir
Cupressocyparis	Cypress	*Cupressaceae*	Leyland cypress
Cupressus	Cypress	*Cupressaceae*	Cypress
Cydonia	Rose	*Rosaceae*	Quince
Cytisus	Pea	*Leguminosae*	Moroccan broom
Dacrydium	Podocarp	*Podocarpaceae*	Rimu (red pine); Houn pine
Davidia	Davidia	*Davidiaceae*	Dove tree; black gums
Diospyros	Ebony	*Ebenaceae*	Persimmon

(*continued*)

TABLE 3. (*Continued*)

Genus	Name of Family		Examples[a]
	English	Latin	
Disanthus	Witch Hazel	*Hamamelidaceae*	*Disanthus cercidifolius*
Elaegnus	Oleaster	*Elaegnaceae*	Russian olive
Embothrium	Protea	*Proteaceae*	Chilean firebush
Erica	Heather	*Ericaceae*	Tree heath
Eucalyptus	Myrtle	*Myrtaceae*	Eucalyptus or gum
Eucommia	Elm	*Ulmaceae*	Hardy rubber tree
Eucryphia	Horse Chestnut	*Hippocastanaceae*	*Eucryphia cordifolia*
Euodia	Citrus	*Rutaceae*	Korean euodia
Fagus	Beech	*Fagaceae*	Beech
Ficus	Mulberry	*Moraceae*	Common fig
Fitzroya	Cypress	*Cupressaceae*	Chilean Fitzroya cypress
Fortunella	Citrus	*Rutaceae*	Nagami kumquat
Franklinia	Tea	*Theaceae*	Franklinia
Fraxinus	Olive	*Oleaceae*	Ash (not mountain ash)
Genista	Pea	*Leguminosae*	Mount Etna broom
Ginkgo	Ginkgo	*Ginkgoaceae*	Maidenhair tree
Gleditsia	Pea	*Leguminosae*	Locust
Glyptostrobus	Swamp Cypress	*Taxodiaceae*	Chinese cypress
Gordonia	Tea	*Theaceae*	Similar to camellia
Grevillea	Protea	*Proteaceae*	Silk oak
Gymnocladus	Pea	*Leguminosae*	Kentucky coffee tree
Hakea	Protea	*Proteaceae*	Sea urchin
Halesia	Snowbell	*Styracaceae*	Snowdrop tree; mountain silverbell
Hamemelis	Witch Hazel	*Hamamelidaceae*	Witch hazel
Hippophae	Oleaster	*Elaegnaceae*	Buckthorn
Hoheria	Lime or Basswood	*Tiliaceae*	Ribbonwood
Idesia	Mahogany	*Meliaceae*	Chinese Idesia
Ilex	Holly	*Aquifoliaceae*	Holly, possumhaw, tarajo
Jacaranda	Bignonia	*Bignoniaceae*	Jacaranda
Jubaea	Palm	*Palmae*	Chilean wine palm
Juglans	Walnut	*Juglandaceae*	Walnut
Juniperus	Cypress	*Cupressaceae*	Juniper; pencil cedar
Kalopanax	Bignonia	*Bignoniaceae*	Castor aralia
Koelreuteria	Horse Chestnut	*Hippocastanaceae*	Golden rain tree; Prize of India
Laburnum	Pea	*Leguminosae*	Laburnum
Larix	Pine	*Pinaceae*	Larch
Laurus	Laurel	*Lauraceae*	Laurel; sweet bay; willow-leaf bay
Ligustrum	Olive	*Oleaceae*	Ligustrum lucidum
Liquidambar	Witch Hazel	*Hamamelidaceae*	Sweet gum
Liriodendron	Magnolia	*Magnoliaceae*	Tulip tree
Lithocarpus	Beech	*Fagacae*	Tanbar oak
Livistona	Palm	*Palmae*	Australian palm
Maackia	Pea	*Leguminosae*	*Maackia amurensis; M. sinensis*
Maclura	Mulberry	*Moraceae*	Osage orange
Magnolia	Magnolia	*Magnoliaceae*	Magnolia; cucumber tree; pink tulip tree; swamp bay; sweet bay; umbrella tree
Malus	Rose	*Rosaceae*	Crab apple; orchard apple
Maytenus	Willow	*Salicaceae*	Mayten tree
Mespilus	Swamp Cypress	*Taxodiaceae*	Medlar
Metasequoia	Swamp Cypress	*Taxodiaceae*	Water larch
Morus	Mulberry	*Moraceae*	White, black mulberry
Myrtus	Myrtle	*Myrtaceae*	Myrtle
Nothofagus	Beech	*Fagaceae*	Beeches of southern hemisphere
Nyssa	Davidia	*Davidiaceae*	Sour gum, black gum, tupelo
Olea	Olive	*Oleaceae*	Olive
Ostrya	Hornbeam	*Carpinaceae*	Hop hornbeam
Oxydendrum	Heather	*Ericaceae*	Sorrel tree
Parrotia	Elm	*Ulmaceae*	Parrotia (Persian ironwood)
Paulownia	Bignonia	*Bignoniaceae*	Paulownia; empress tree
Phellodendron	Citrus	*Rutaceae*	Amur cork tree
Phillyrea	Olive	*Oleaceae*	*Phillyrea latifolia*
Phoenix	Palm	*Palmae*	Canary island palm; date palm
Photinia	Rose	*Rosaceae*	Chinese photinia
Picea	Pine	*Pinaceae*	Spruce

TABLE 3. (*Continued*)

Genus	Name of Family		Examples[a]
	English	Latin	
Pinus	Pine	*Pinaceae*	Pine
Pistacia	Cashew	*Anacardiaceae*	Chinese pistachio
Pittosporum	Witch Hazel	*Hamamelidaceae*	Pittosporums
Platanus	Plane	*Platanaceae*	Plane
Podocarpus	Podocarp	*Podocarpaceae*	Podocarp
Poncircus	Citrus	*Rutaceae*	Japanese bitter orange
Populus	Willow	*Salicaceae*	Poplar, cottonwood, aspen
Prunus	Rose	*Rosaceae*	Almond, apricot, gean, mazzard, various cherry, peach, Sloe, blackthorn, Portugal laurel
Pseudolarix	Pine	*Pinaceae*	Golden larch
Pseudotsuga	Pine	*Pinaceae*	Douglas firs
Ptelea	Citrus	*Rutaceae*	Hop tree
Pterocarya	Walnut	*Juglandaceae*	Wing-nut
Pterostyrax	Snowbell	*Styracaceae*	Epaulette tree
Pyrus	Rose	*Rosaceae*	Pear
Quercus	Beech	*Fagaceae*	Oak
Rhododendron	Heather	*Ericaceae*	Rhododendron, rose acacia, great laurel, rose bay
Rhus	Cashew	*Anacardiaceae*	Sumac; varnish tree
Robinia	Pea	*Leguminosae*	Black locust; mop-head acacia clammy-locust
Rosa	Rose	*Rosaceae*	Musk rose
Roystonia	Palm	*Palmae*	Royal palm
Sabal	Palm	*Palmae*	Caribbean cabbage palmetto
Salix	Willow	*Salicaceae*	Willow
Sambucus	Elder	*Caprifoliaceae*	Common elder; elderberry
Sassafras	Laurel	*Lauraceae*	Sassafras
Saxegothaea	Yew	*Taxaceae*	Prince Albert's yew
Schinus	Cashew	*Anacardiaceae*	California pepper tree
Sciadopitys	Pine	*Pinaceae*	Japanese umbrella pine
Sequoia	Swamp Cypress	*Taxodiaceae*	Coast redwood
Sequoiadendron	Swamp Cypress	*Taxodiaceae*	Giant Sequoia ("Big Tree")
Sophora	Pea	*Leguminosae*	Sophora
Sorbus	Rose	*Rosaceae*	Whitebeam; mountain ash; service tree
Stewartia	Tea	*Theaceae*	Stewartias (similar to camellia)
Styrax	Snowbell	*Styracaceae*	Snowbell
Taxoidium	Swamp Cypress	*Taxodiaceae*	Pond cypress; bald cypress; Mexican cypress
Taxus	Yew	*Taxaceae*	Yew
Tetraclinis	Cypress	*Cupressaceae*	North African cypress
Thuja	Cypress	*Cupressaceae*	Arborvitae; white cedar; thuja
Thujopsis	Cypress	*Cupressaceae*	False arborvitae
Tilia	Lime or Basswood	*Tiliaceae*	Basswood; linden; common lime (not to be confused with the citrus lime)
Torreya	Yew	*Taxaceae*	California nutmeg; Japanese kaya
Trachycarpus	Palm	*Palmae*	Chinese windmill palm
Tsuga	Pine	*Pinaceae*	Hemlock
Ulmus	Elm	*Ulmaceae*	Elm
Umbellularia	Laurel	*Lauraceae*	California laurel
Viburnum	Elder	*Caprifoliaceae*	Wayfaring tree; Gueldar rose
Washingtonia	Palm	*Palmae*	Petticoat palm
Yucca	Palm	*Palmae*	Joshua tree
Zelkova	Elm	*Ulmaceae*	Elm zelkova; Japanese zelkova

[a]Examples given in many cases are abridged. Also it is possible for some species of trees given in examples to appear in more than one genera because common names are not always scientifically specific.
Latin names appearing in Example column indicate no common English name.

been selected annually by American Forests. Pictures of many of the champion trees also are included. A champion among champions is the record white oak (*Quercus alba*) located at Wye Mills, Maryland. See Fig. 1 on p. 192.

The magnitude of the millions of trees growing on the earth is dramatized by Table 4 which lists the forested areas of the principal forested nations of the world.

TREE CLIMATE. See **Climate**.

TREE HOPPER *(Insecta, Homoptera)*. An insect of moderate size with a peculiarly formed thorax, prolonged over the hinder part of the body and in many species with other projections of bizarre form. These insects make up the family *Membracidae*, related to the leaf hoppers and spittle bugs.

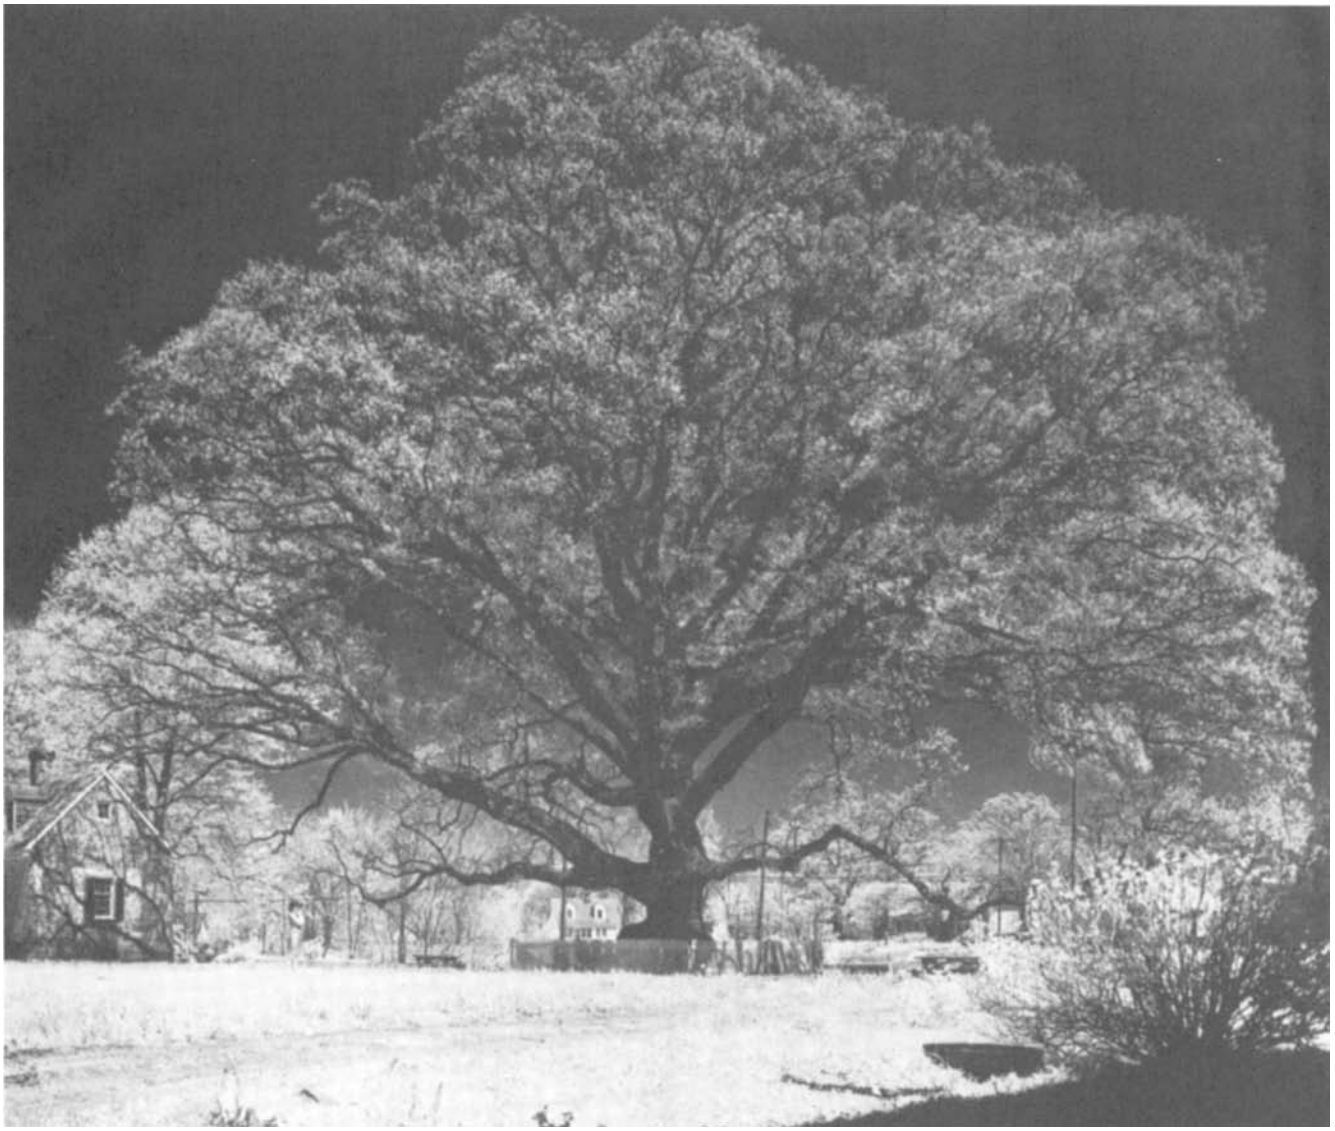

Fig. 1. Record white oak (*Quercus alba*) located at Wye Mills, Maryland. The tree measures 31 feet, 10 inches (9.4 meters, 25 centimeters) in circumference at 41/2 feet (1.4 meters) above the base; is 96 feet (29.4 meters) high; and has a spread of 119 feet (36.3 meters). Selected as champion of species by American Forests in 1996. (*Maryland Department of Economic Development*.)

TABLE 4. PERCENT FORESTATION OF VARIOUS NATIONS

The buffalo tree hopper, *Ceresa bubalus*, sometimes damages twigs of fruit trees by laying eggs in the bark and is occasionally troublesome in the garden through sucking the juices of young seedlings. Clean cultivation is an effective control.

TREE (Mathematics). A connected subgraph of a connected graph which contains all the vertices of the graph but is free of circuits. Occasionally the phrase "complete" tree is used but the definition given here is more in accord with modern engineering terminology. A graph can possess

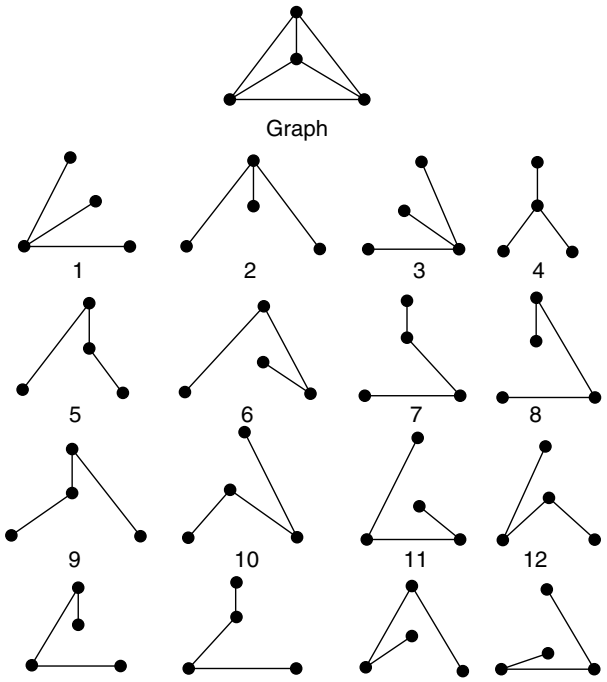

Fig. 1. Examples of graphs.

many trees. In Fig. 1 is an example of a graph with 4 vertices, 6 edges and 16 trees. See also the discussion under **Digraph**.

It can be shown that every finite connected graph G contains at least one tree. A tree contains v vertices and $v-1$ branches where v is the number of vertices in G.

See also **Graph (Mathematics)**.

TREE OF HEAVEN. See **Mahogany Trees**.

TREE TOAD *(Amphibia, Anura).* Small animals like the other frogs and toads in form but largely of arboreal habits. The toes are provided with adhesive disks at the tips. The spring peeper and the cricket frog, each about an inch in length, are well known North American species. Our tree frogs deposit their eggs in the water but in some species the larval stage is passed in the egg, which is attached to a leaf. The extensive family *Hylidae* includes tree frogs of every continent.

TRELLIS DRAINAGE. The type of drainage pattern which is similar to a trellis or fireman's ladder. Trellis drainage is characteristic of the canoe-shaped valleys of the Appalachians.

TREMATODA. The flukes, a class of flatworms (Phylum *Platyhelminthes*). They are very variable in size, are flattened or rounded in cross section, and are exclusively parasitic. Flukes resemble the free-living flatworms (*Turbellaria*) more closely than tapeworms, but in addition to their parasitic habits they differ in having the mouth usually near the anterior end of the body and the intestine usually forked and sometimes provided with anal openings. The body is covered with a cuticle and bears suckers and in some species hooks or spines by which the worm attaches itself to the host.

Many flukes hatch from the egg as free-swimming larvae and pass through a life cycle in two or more hosts before attaining maturity. The passage from host to host is associated with particular larval stages.

Some flukes attach themselves to the gills or skin of fishes while others live in the internal organs of various animals. Man is affected by four types, the liver, lung, blood, and intestinal flukes, found chiefly in tropical and Oriental countries. Since some of these parasites pass some stages of their metamorphosis in fishes, the eating of uncooked or imperfectly cooked fish is dangerous in regions where they occur.

TREMBLEY, ABRAHAM (1710–1784). Born in Geneva, to an officer belonging to the oligarchy, Trembley was educated in philosophy, completing a thesis on infinitesimal calculus in 1731. He left Geneva for Holland and became tutor to Count Bentinck's two sons in 1736. Greatly influenced by A.-F. Réaumur's *History of Insects*, in August 1740 he collected a green organism from aquatic lentils, which he started to observe very accurately as he realized that it was attracted by light. In order to determine to which kingdom these 'organized bodies' belonged, he started a long series of experiments, showing that they always regenerate and live after being cut in every conceivable way and even after being turned inside out like a glove. On Charles Bonnet's advice, he began corresponding with Réaumur, who proposed the name *Polyp* for the animal, and communicated Trembley's discovery to the Paris Academy of Sciences in 1741. Trembley also published some papers in *Philosophical Transactions*. Henry Baker forestalled Trembley's major publication of 1744 with a book (published in 1743) where he displayed many techniques and discoveries of the Genevoise naturalist. Yet Trembley was elected Fellow of the Royal Society and received the Copley Medal in 1743. See also **Bonnet, Charles (1720–1793)**.

His discovery resulted in a stream of European microscopical research on *Hydra* and infusoria, awakening also a metaphysical interest about the nature of the soul. He returned to Geneva and married Miss von der Strassen in 1757 by whom he had five children. For them he wrote books on education and religion. He was also politically active. Many historians of science consider him among the founders of experimental biology.

M.J. RATCLIFF, Wellcome Institute for the History of Medicine, London, UK

TREMBLOR. See **Earth Tectonics and Earthquakes**.

TREMOLITE. [CAS: 1332-21-4]. The mineral tremolite is a calcium-magnesium silicate corresponding to the formula $Ca_2Mg_5Si_8O_{22}(OH)_2$, belonging to the amphibole group. The replacement of magnesium by ferrous iron causes tremolite to approach actinolite in composition. Tremolite is monoclinic, developing bladed prismatic crystals, but it is frequently found in compact columnar, granular, or fibrous masses. The perfect prismatic cleavage at angles of 56° and 124° typical of this group is to be noted; hardness, 5–6; specific gravity, 2.9–3.1; luster, vitreous to silky; color, varies from white or whitish-gray through shades of green or greenish-yellow; transparent to opaque. Tremolite is formed as a result of contact metamorphism and occurs in marbles, dolomites, and schists. It may alter to talc. Tremolite is found in Switzerland, in the St. Gotthard region, being named for the Tremola Valley, and is common elsewhere in Europe. In the United States it occurs in Maine, Pennsylvania, and New York. In Canada tremolite has been found in Quebec and Ontario.

Hexagonite is a pinkish-purple variety of tremolite which contains a small amount of manganese. So called because it was at first believed to be hexagonal. It has been since shown to be monoclinic, and is found in St. Lawrence County, New York. Some nephrite and asbestos is tremolite.

TRENCH FOOT. A serious disease of the foot usually precipitated by lack of attention to the feet as may be encountered by military personnel. Exposure of limbs to low temperatures, particularly under moist conditions, in the range of freezing to about 41 °F (5 °C) produces a constriction of blood vessels. A net result after prolonged periods of exposure is an edema and blistering which the victim may not sense because of numbness at the low temperature. Infection or gangrene may follow. Persons who must be exposed in this manner to wet, cold conditions over prolonged periods should wear specially-designed footwear and should warm and thoroughly dry the feet as frequently as possible. In very serious situations, antibiotics may be administered to counter infection, accompanied by rest during which the feet should be elevated. Frequent removal of wet socks and replacing with clean, dry socks is an excellent preventive measure.

R. C. V.

TRENCH (Ocean). See **Earth Tectonics and Earthquakes**.

TREPANNING. Originating a hole by removing an annular ring of material, instead of reducing to chip form the entire volume of the material originally within the hole.

TREPHINE. 1. A hollow, circular, saw-tooth, drill-like instrument that is used for removing a disk of bone from the skull. This opening may then be enlarged or several of these drill holes may be made or connected so as to raise a piece of bone to expose a portion of the brain.

2. To open the skull with a trephine. The skull is usually operated upon for removal of an intracranial tumor, to relieve intracranial pressure, or to drain a brain abscess.

TRIANGLE. A polygon with three sides and three angles. If the three angles all lie in the same plane, the triangle is called plane; if not, so that a spherical polygon is involved, the triangle is also called spherical. The word *triangle*, however, is usually taken to mean a plane triangle. From their properties, they are named as follows: acute, all interior angles acute; congruent, two or more triangles which may be superimposed and which then become equal in all of their properties; equal, with equal areas but not necessarily congruent; equiangular, with three equal interior angles and therefore also equilateral with three equal sides; isosceles, two sides are equal; oblique, containing no right angle; obtuse, containing one obtuse interior angle; right, one angle is $\pi/2$ (the opposite side is the hypotenuse and the other sides are the two legs); scalene, no sides are equal; similar, the angles are equal and the corresponding sides are proportional.

Given a sufficient number of parts of a triangle (sides and angles), the remaining parts may be found, a process called solving the triangle. This is the main concern of plane trigonometry, as taught in elementary courses.

If two arcs of a great circle intersect, a spherical angle is formed. It is measured by the plane angle between the tangents to the circles at their intersection. A polygon with three sides and three spherical angles is a spherical triangle. It may be right, oblique, equilateral, isosceles, or scalene, similar to the corresponding plane triangle. The sum of its angles is greater than π (180°) but less than 3π (540°). The difference between the sum of its angles and π is the spherical excess, E. If the triangle is cut from a sphere of radius R, the area of this spherical triangle is $S = \pi R^2 E/180$, where E is expressed in degrees.

If the vertices of a spherical triangle are taken as poles and arcs of great circles are drawn through them, a second spherical triangle results. It is called the polar triangle of the first.

Spherical triangles, like plane triangles, may be solved. The methods of spherical trigonometry, a generalization of plane trigonometry, are used.

See also **Polygon**; **Trigonometric Function**; and **Trigonometry**.

TRIANGULATION. In surveying, the field work necessary to obtain the angular measurements between the sides of a series of connected triangles, and the length of one or more of the sides, is known as triangulation. The system of connected triangles is called a triangulation system. The topographic surveying of land requires the establishment of control points of known position and elevation. This control usually takes the form of a series of surveyed triangles, with the apices located on prominent points in the area, such as peaks, mounds, cliffs. In laying down a network of triangles, a fairly level region is selected on which to measure a straight base line. The transit is then set over one end of this base line, and the angles between pairs of selected control points taken. The transit is then taken to the other end of the base line, and the angles are again taken to the same points. By occupying, progressively, advancing triangulation points the network may be extended over as large an area as necessary. These angles are read to a high degree of precision by very accurate instruments, using the method of repetition. Even then the angular data as taken in the field will not be consistent, one triangle with another or with the whole. Such small errors or inconsistencies as exist must be adjusted, or balanced, by distributing the error. This is a fairly specialized and intricate process but must be executed to obtain a consistent system of triangles of highest probable accuracy. Upon the completion of this process the position of any triangulation point with respect to any other or with respect to the base line may be very accurately computed. The United States Coast and Geodetic Survey has covered the country with a triangulation system, the sides of the triangles often being many miles in length. The accuracy of triangulation depends upon the accuracy with which the instrument is constructed and read, and the precision with which the base line is measured. The precision of triangulation is classified as first order, second order, third order, etc., first order triangulation being that in which the base line is required to be measured to an accuracy of 1 part in 25,000, and the average triangle closure being only one second. The geodetic surveying calls for first and second order triangulation, but ordinary intermediate work is satisfactory with third or fourth order triangulation.

An early map of India (Fig. 1) exemplifies the "Great Trigonometrical Survey" of India completed in the mid-1870s. The survey commenced in Madras and included the great mountain peaks of the Himalayas. On the master map, 1 inch (2.54 cm) was equal to 96 miles (154.5 km). (*Republic of India, New Delhi*.)

TRIANGULUM AUSTRALE. A southern constellation of a triangular configuration and located near Circinus.

TRIANGULUM (the triangle). A northern constellation that lies between Andromeda and Aries.

TRIASSIC PERIOD. The earliest, major subdivision of the Mesozoic Era of the geologic time-scale. One of the oldest systemic terms and denoting a three-fold division of the German formations into the lower or Bunter sandstones, the middle or Muschelkalk limestones, and the upper or Keuper copper-bearing shales. The term Triassic was proposed by Alberti in 1834. The period began about 200 million years ago and lasted for about 50 million years. The maximum thickness of formations, 25,000 feet (7,500 meters), occurs in the Alps. In eastern North America, especially in Massachusetts, Connecticut, and New Jersey, occurs a thick series of red sandstones, arkoses, shales, and argillites of freshwater origin, containing the footprints of the earliest known dinosaurs. Interbedded with the sedimentary formations are numerous basalt lava flows and sills. This eastern facies of the Triassic is called the Newark Series after the type locality in New Jersey. In Arizona and New Mexico occur freshwater clastic sediments containing the prostate fossil trunks of ancestral Sequoias in which the original body structures have been perfectly replaced by silica. Some of the tree trunks are over 150 feet (45 meters) long and 3–6 feet (0.9–1.8 meters) in diameter. In the Cordilleran region, the Triassic formations are marine. Triassic rocks also occur in South America, British Isles, Western Europe, Asia, Africa, and Australia. During this period there were great changes in the plants and animals, as disclosed by the fossils. Ferns, cycads, and conifers predominated among the plants. The modern corals, hexacoralla, predominate over the earlier tetracoralla of the Paleozoic, Cystoids and Blastoids have become extinct. The brachiopods are less abundant, their place being taken by the pelecypods. Modern insects begin their development in this period, and the modern (bony) fishes are ascendant. Among the terrestrial animals, the Paleozoic amphibia (*Stegocephalia*) are replaced by the dinosaurs. The highest types of marine invertebrates are ammonites. Marine reptiles, called Ichthyosaurs, and flying reptiles called Pterosaurs, first appeared in Europe. Small reptilian-like mammals also made their first appearance. The economic products of this period are chiefly salt, gypsum, and copper. In eastern North America the period closed with relatively slight uplift and block-faulting of the Newark Series, called the Palisades Disturbance. In the Pacific Coast region there was a withdrawal of the marine waters to mark the close of the period.

TRIBE. See **Taxonomy**.

TRIBOLOGY. Tribology is defined as *the science of interacting surfaces in relative* motion and of related subjects and practices. The word *tribology* comes from the Greek *tribos*, which means *rubbing*.

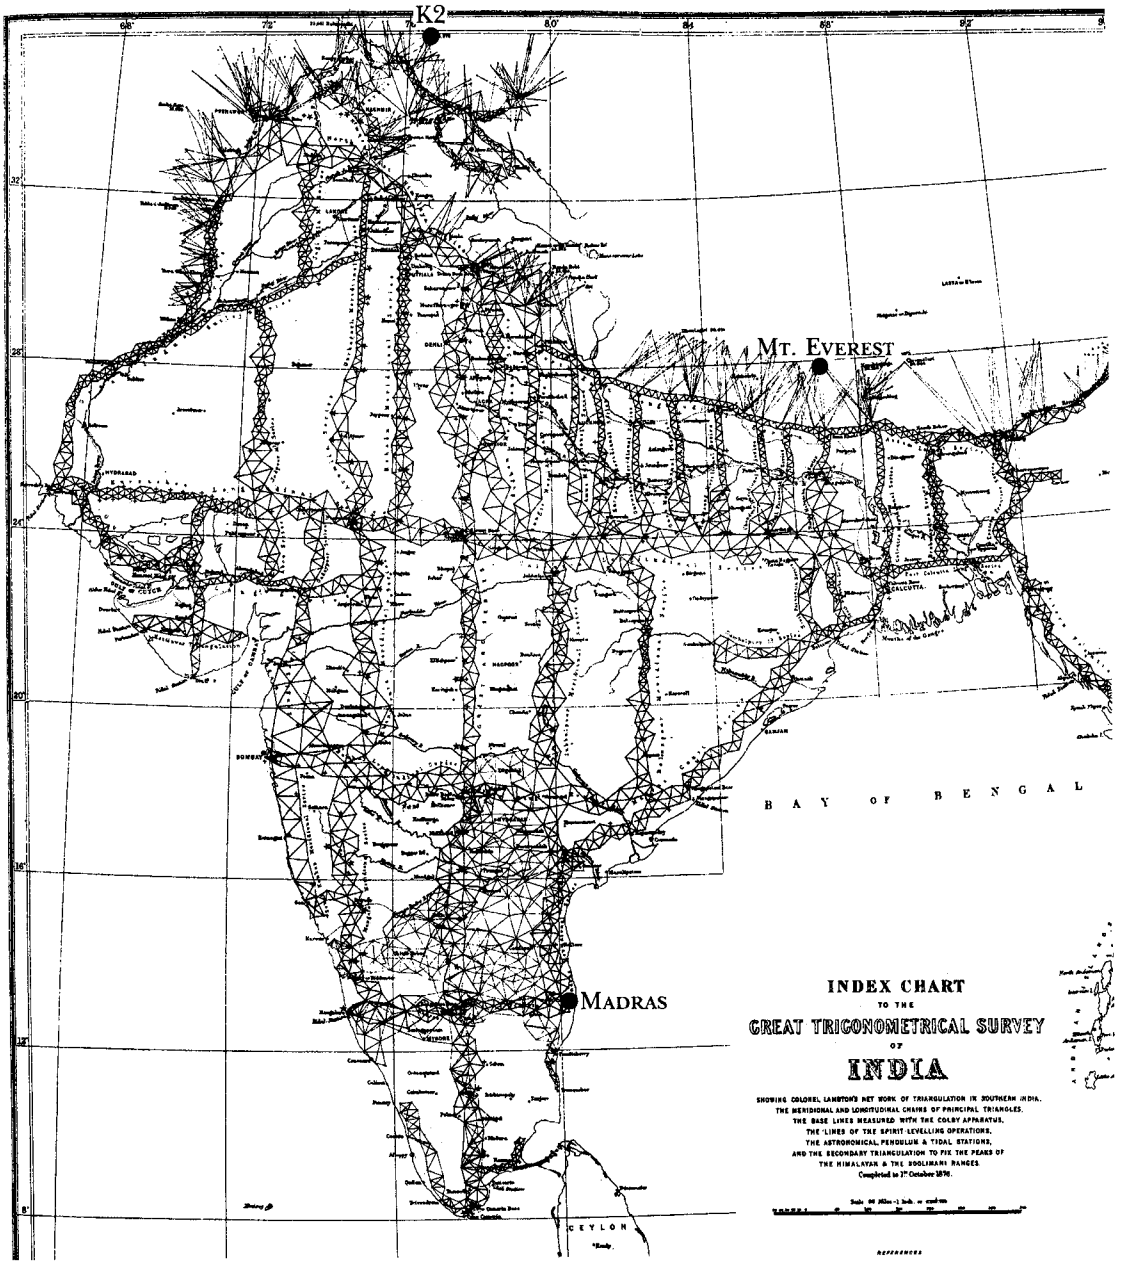

Fig. 1. Mid-1870s triangulation map of India, referred to as the "Great Trigonometrical Survey." (*Republic of India, New Delhi*.)

A typical example of relative motion is sliding. The lateral force due to sliding is friction; the process of a surface being worn down by friction is wear; and the action of applying oil or some other substance in order to decrease friction and wear is lubrication. Decreasing the friction enables a machine to run more easily and reduces its energy consumption. Decreasing wear extends a machine's working life. On the other hand, brakes and friction-drive mechanisms, such as traction-drive transmissions and ultrasonic motors, make use of frictional forces. Tribology is a key technology for mechanical systems, because almost all machines have sliding mechanisms.

Sliding mechanisms have a very long history. Wheels having bearings were invented about 5000 years ago. The ancient Egyptians used liquid lubricants to slide sledges loaded with huge stones or statues. However, scientific studies of friction began much more recently than these ancient empirical applications.

In the 17th century, Amonton discovered the two basic laws of friction: The frictional force is proportional to the load and independent of the area of the sliding surfaces. These laws were verified in the 18th century by Coulomb and are now known as the Amonton–Coulomb laws. However, Leonardo da Vinci had already foreseen these laws through his scientific experiments in the 15th century. There were two different theories about the origin of friction. Coulomb concluded that friction was due to the interlocking of surface asperities. On the other hand, at about the same time, Desaguliers proposed that friction was due to molecular adhesion between the surfaces. It took about 200 years to establish the scientific theory of friction. The interlocking theory cannot explain the energy dissipation calculated from the friction force. From the end of the 19th century to the beginning of the 20th century, researchers including Hardy and Tomlinson systematized the adhesion theory. However, this theory requires a friction force proportional to the contact area, which conflicts with experimental results that the friction force is independent of the contact area. In about 1940, several researchers including Holm, Bowden, and Tabor found that the real contact area is very small compared with the geometrical contact area, and Bowden and Tabor explained the empirical Amonton–Coulomb laws using deformations of contacting asperities and adhesion of the real contact areas. This theory is now generally accepted. On the other hand, molecular dynamics studies in the 1990s have led to a new interlocking theory of friction being evaluated as an atomistic friction mechanism without wear.

In the 19th century, Tower showed that a rotating journal bearing generates high pressure in the oil film between the bearing and the spindle. This hydrodynamic pressure sustains the bearing load. Reynolds

formulated an equation expressing the pressure in 1886. This lubrication equation is called the Reynolds equation. Around the turn of the 20th century, Stribeck experimentally studied the influence of variables such as load and velocity on friction. A curve of friction versus a combination of such variables is known as a Stribeck curve.

The scientific study of wear started in the 1930s. In 1953, Archard found the empirical rule that the wear volume is proportional to the load and the sliding distance, and inversely proportional to the hardness. At about the same time, Burwell classified the physical mechanisms of wear. However, there are many kinds of interactions between sliding surfaces, such as mechanical, chemical, thermal, and fluidic interactions. The effects of these interactions depend on the sliding conditions and materials, and they affect each other. Furthermore, wear is made more difficult to understand by wear processes being irreversible. Although a lot of engineering data on wear has been accumulated, scientific explanations are still insufficient.

In 1938, Siebel suggested that joint research was needed by physicists, chemists, metallurgists, theorists, designers, and engineers because of the complexity of wear processes. This suggestion is still important for tribology today. In many cases, metals have been used for sliding surfaces, but new materials, such as ceramics and hard coatings, are beginning to be used widely. For progress in materials, we need much more scientific knowledge to understand friction, lubrication, and wear processes and to develop materials and machines having higher tribological performance. Not only engineering data but also scientific understanding of phenomena are needed for tribology. Thus, tribology ranges from basic physics and chemistry to machine development — it is an interdisciplinary research area.

Tribophysics. Tribophysics depends on the dynamics of continuum bodies, and several important mechanisms have been clarified, such as deformation, friction, lubrication, and wear. Another approach is from physics at atomic and molecular scales. This approach is to reveal fundamental physical information that is important for understanding the origin of friction and wear and learning the limits of continuum-body dynamics.

Tribochemistry. Liquid lubricants are a mixture of a base oil and additives, which are mainly composed of organic compounds. Under boundary lubricating conditions, the lubricating performance of liquid lubricants is closely related to their chemical behavior.

Tribochemistry includes chemical reactions and chemical phenomena such as chemisorption under tribological processes. Tribological behavior is strongly affected by tribochemical reactions — for example, the formation of lubricating surface films from lubricant additives, chemical or corrosive wear, and degradation of lubricants.

Tribochemical phenomena occur under the effect of mechanical contacts. Chemical reactions are enhanced by the mechanical effect at sliding contacts. There are two main causes for tribochemical reactions: (1) temperature and pressure rise at sliding contacts and (2) enhanced activity of mechanically contacting surfaces.

Tribomaterials. *Tribomaterials* include sliding materials facing each other and coatings of solid or liquid films between the sliding materials. They are required to reduce, or in some cases to control, adhesion, friction, and wear of mechanical components. During sliding, they are subjected to mechanical, thermal, and chemical attack depending on the operational conditions and environments. Friction and wear of tribomaterials are therefore very complicated phenomena involving various mechanisms and factors. Suitable selection of tribomaterials depending on the operating conditions plays an important role in controlling the life of mechanical components.

TRIBOLUMINESCENCE. See **Luminescence**.

TRICHLOROMETHANESULFENYL CHLORIDE. See **Sulfur Compounds**.

TRICHOMES. A *trichome* (or hair) is an outgrowth derived from the shoot or root epidermis of a plant. The form and distribution of trichomes differs between plant species or genera, but recent molecular work reveals that there are common regulatory pathways for trichome development of different types within the same plant species and possibly also across plant species. See also **Epidermis (Plant Science)**.

Trichome Form and Function

Trichome function is usually inferred from their form and physiology and often lacks experimental evidence. In a few cases the presence of trichomes is correlated with an increased resistance against insects. They have also been implicated in controlling leaf surface temperature and transpiration rate by increasing reflection and by reducing air exchange near the surface. Some trichomes, i.e. root hairs, are involved in anchoring and in absorption of nutrients. Different types of trichomes are classified according to their form and physiological properties [Uphof, 1962].

Nonglandular trichomes are unicellular or multicellular outgrowths that are either unbranched or stellate (Figure 1**a**–**c**). This type of trichome is thought to protect young plant parts. In some climbing plant species nonglandular trichomes serve to anchor the growing plant. In other plants, trichomes facilitate the transport of fruits and seeds by animals. See also **Seed**.

Glandular trichomes are specialized unicellular or multicellular hairs that secrete a wide variety of low- or high-molecular weight substances. The secreted material is either stored beneath the outer cuticle (Figure 1**d**) or discharged to the surface. Depending on the composition of the secreted material, glandular trichomes may play a role in plant defense against herbivores or in more general protection such as secretion of mucilage. In some cases glandular trichomes have adopted highly specific roles, such as digestive glands of insectivorous plants or nectary glands that secrete large amounts of sugar into the ovary.

Absorption hairs are usually root hairs (Figure 1**e**), although a few other examples exist. Root hairs function to anchor the plant in the ground and to generate a larger surface area to absorb water and nutrients. Root hairs are generally less diverse than aerial trichomes. However, they may grow straight or curved, and sometimes branch.

Origin and Distribution of Trichomes

The regulation of trichome initiation includes three spatial aspects; these are discussed below.

Organ Specificity. During embryogenesis, plants establish three different tissue layers that are maintained separately throughout development. Trichomes originate from the outermost tissue layer, the epidermis. Recent genetic experiments in *Arabidopsis* reveals that two key genes needed for trichome initiation are sufficient to trigger trichome formation in the subepidermis. This indicates that trichome-specific genes act downstream of tissue layer-specific cues.

Patterning. The trichome pattern in roots and shoots differs significantly. While shoot trichomes are regularly distributed on the epidermal surface and separated by other epidermal cells, root hairs are arranged in cell files that are initiated next to each other. This suggests that the underlying patterning mechanisms are different. See also **Epidermis (Plant)**; and **Shoots and Buds**.

Trichome initiation on aerial surfaces usually takes place on young primordia of the respective organ and trichomes are often the first cells that appear to differentiate. In some cases, additional trichomes are initiated between preexisting trichomes, suggesting that trichome initiation takes place with respect to other trichomes. In some monocots, i.e., *Anemarrhena*, trichome formation is correlated with asymmetric cell divisions, suggesting that the trichome pattern is generated by a series of cell divisions that segregates trichomes and epidermal cells. In other cases asymmetric cell divisions are not observed. Here trichome patterning is thought to be generated by lateral inhibition in the neighborhood of preexisting trichomes.

Root hair formation occurs in a narrow zone close to the root tip. The distribution of root hair and nonroot hair cells varies in different plant species. In some species no ordered arrangement is found and root hairs may develop randomly from any epidermal cell. In other plant species asymmetric cell divisions produce a large and a small cell, with the small cell differentiating into a root hair cell. A position-dependent root hair

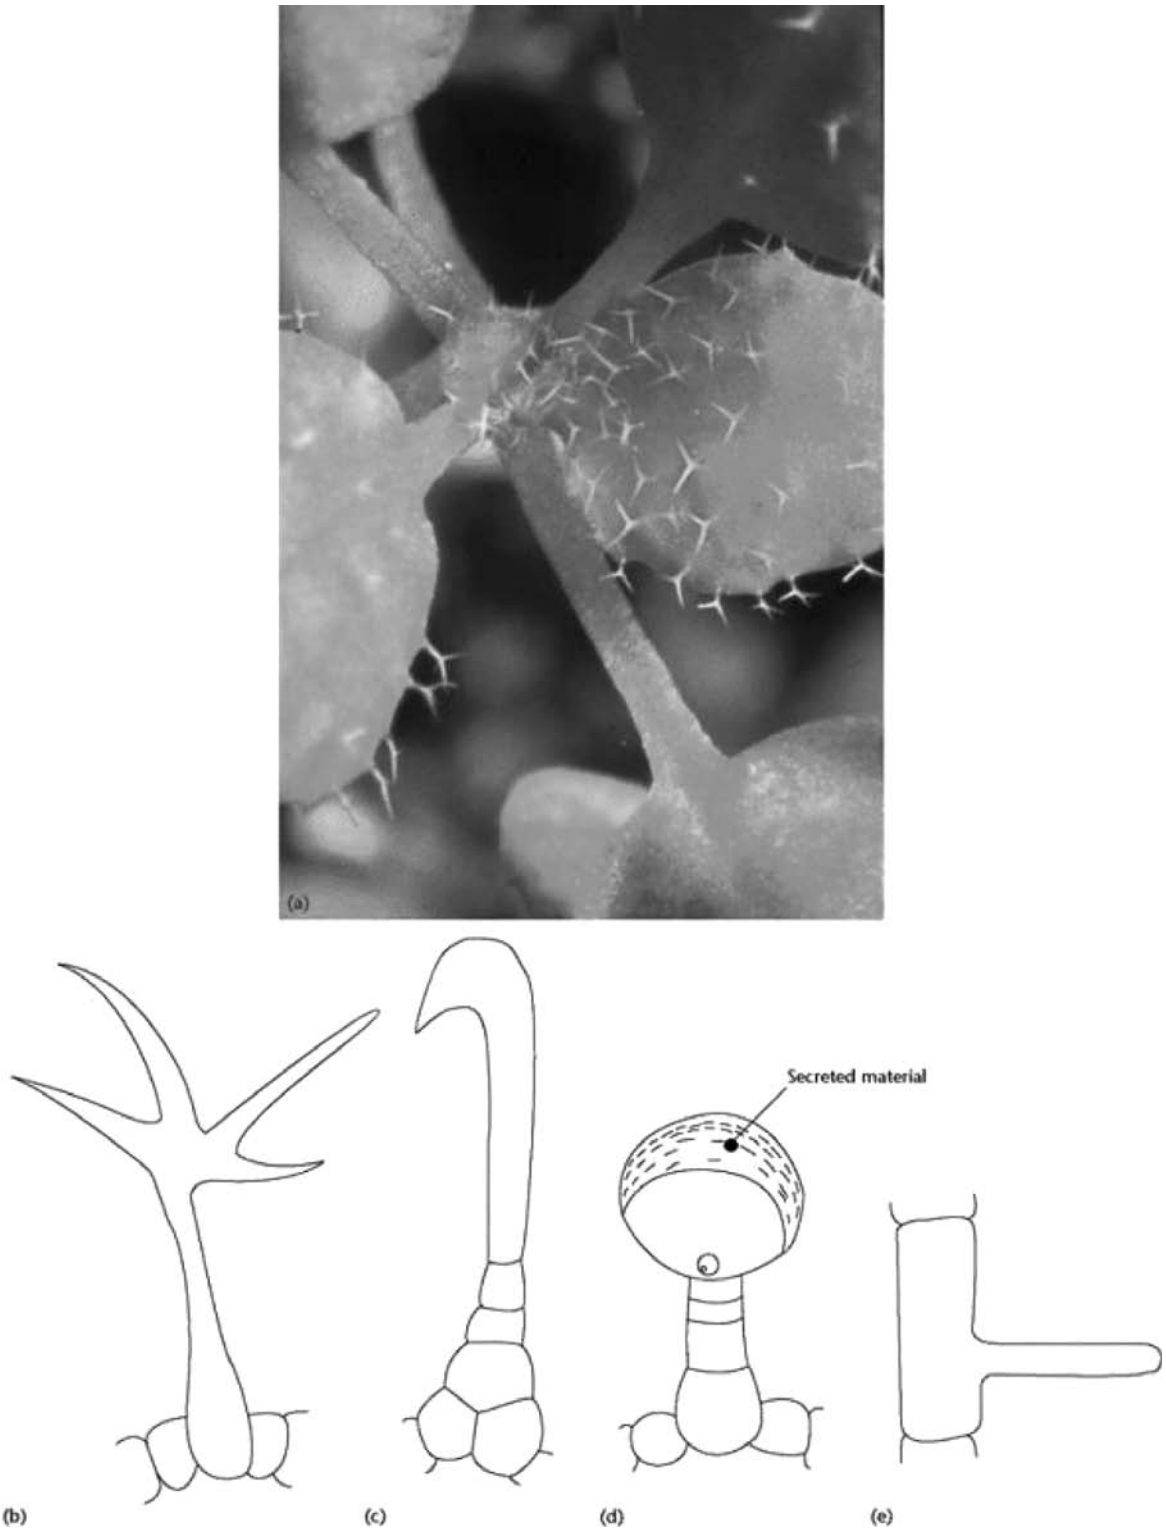

Fig. 1. (**a**) Rosette of a young *Arabidopsis thaliana* plant. Note the regular distribution of leaf trichomes. (**b**) Unicellular branched trichome of *Arabis alpina*. (**c**) Multicellular unbranched trichome of *Tricyrtis hirta*. (**d**) Glandular trichome of *Pelargonium zonale*. (**e**) Root hair of *Arabidopsis thaliana*.

pattern is found in most *Brassicaceae*, where root and nonroot hair cells are specified with reference to underlying cortex cells.

Genetic Pathways

In *Arabidopsis*, the systematic search for mutants affecting trichome and root hair development resulted in the identification of most of the genes involved in the initiation and differentiation of trichomes. The regulatory pathways underlying trichome initiation were further clarified by the analysis of genetic interactions, the cloning of several genes and subsequent molecular characterization.

Trichome Initiation. The development of leaf trichomes in *Arabidopsis* is tightly linked to leaf development. When incipient trichomes are initiated in the young leaf primordium they are separated by three to four epidermal cells. During leaf expansion trichomes become further separated owing to cell divisions of the intervening epidermal cells. Several genes have been shown to function at different regulatory steps of trichome initiation [Marks, 1997; Hülskamp, et al., 1999].

Trichome initiation is positively regulated by the plant hormone GA. GA-deficient mutants lack trichomes completely. Over expression of one positive regulator of trichome initiation, the *GLABRA1* gene (*GL1*, see below), can suppress the GA-deficient trichome phenotype, indicating that GA acts upstream of trichome-specific genes.

The relative timing of trichome initiation with respect to leaf development is regulated by the *REDUCED TRICHOME NUMBER* (*RTN*) gene. In *rtn* mutants trichome initiation ceases earlier than in the wild-type, resulting in a reduced number of trichomes.

At least five genes play a role in the generation of the spacing pattern. Two genes appear to act as positive regulators of trichome initiation: *GL1* and *TRANSPARENT TESTA GLABRA* (*TTG*). Both *gl1* and *ttg* mutants lack trichomes on aerial surfaces. The *GL1* gene encodes a *myb*-related transcription factor. The *TTG* gene encodes a protein with four WD40 repeats and is related to Gβ subunits of heterotrimeric G proteins, suggesting a role in signal transduction. A *myc*-related transcription factor appears to act downstream of *TTG* since overexpression of the heterologous *R* gene from maize, a *myc*-related transcription factor, can suppress the *ttg* mutant in *Arabidopsis*. *CAPRICE* (*CPC*), *TRIPTYCHON* (*TRY*) and *COTYLEDON TRICHOME1* (*COT1*) act as negative regulators of trichome initiation. *cpc* mutants produce more trichomes than wild-type and the *CPC* gene encodes a *myb*-related transcription factor that lacks a transactivation domain. *try* mutants produce trichome clusters containing between two and four trichomes. The *cot1* mutation causes ectopic trichome formation on cotyledons in plants overexpressing *GL1*, and hence is a suppressor of overexpressed *GL1*, whereas *cot1* mutants in a wild-type background show no phenotype.

The selection of single trichome cells among equivalent epidermal cells in *Arabidopsis* does not appear to involve cell lineage but is rather based on cellular interactions. This is suggested by the finding that cells in immediate contact with the mature trichome cell are not clonally related. In addition, it has been shown that trichomes in a *try* cluster are not clonally related; suggesting that one of the key patterning genes is not involved in cell lineage.

The current model to explain the generation of the spacing pattern assumes that epidermal cells are initially equivalent and compete with each other by the action of *GL1, TTG, TRY* and *CPC* (Figure 2a). *GL1* acts mostly downstream and is positively regulated by *TTG*. Cell–cell interactions are mediated by *TRY*, with *TRY* being regulated by *TTG* and acting as a negative regulator of *GL1*. These interactions constitute a feedback system that amplifies small fluctuations in the activities of the factors. Eventually one cell differentiates into a trichome cell, which then suppresses the differentiation of surrounding cells.

After trichome selection the first trichome-specific gene activated is *GLABRA2* (*GL2*). *GL2* encodes a homeobox transcription factor and is thought to control subsequent steps of trichome cell morphogenesis.

Root Hair Initiation. In *Arabidopsis*, cell divisions at the root apex generate cell files along the length of the root. The epidermal cells overlying the clefts between the underlying cortex cells are trichoblasts and differentiate to root hairs. The cells that are in contact with only one cortical cell file are atrichoblasts; these cells do not differentiate into root hairs. Trichoblasts and atrichoblasts are already cytologically distinct within the meristematic region long before root hair development begins. Mutants affecting correct root hair initiation suggest a stepwise but not strictly hierarchical regulation (Figure 2**b**) [Schiefelbein, et al., 1997; Schneider, et al., 1997]. See also **Root (Plant)**.

Three genes, *ROOT HAIRLESS 1* (*RHL1*), *RHL2* and *RHL3*, are required for trichoblast development in epidermal cell files. These three genes act genetically upstream of other root hair patterning genes.

In a second step the decision as to whether cells become trichoblasts or atrichoblasts is controlled by *EXTRA ROOT HAIRS 1* (*ERH1*), *ERH3* and *TTG*. In the corresponding mutants root hairs are formed in all cell files, indicating that *ERH1, ERH3* and *TTG* suppress trichoblast development.

Following the specification of trichoblasts and atrichoblasts, *GL2* is specifically expressed in atrichoblasts suppressing root hair differentiation. The expression of *GL2* in trichoblasts is likely to be suppressed by *CPC* since the *gl2cpc* double mutant exhibits the same phenotype as *gl2* alone. The *ERH2* gene is thought to act after the atrichoblast and trichoblast fate has been established.

The plant hormone ethylene acts further downstream in the root hair initiation pathway as a positive regulator. Mutations or drug treatments that reduce the ethylene levels or the ethylene perception cause a loss of root hairs; conversely, increased ethylene levels are sufficient to trigger root hair formation in atrichoblasts.

Despite the apparently different mechanisms operating in cell-type specification of shoot trichomes and root hairs, the two genetic regulatory pathways overlap substantially. The genes acting in both pathways affect

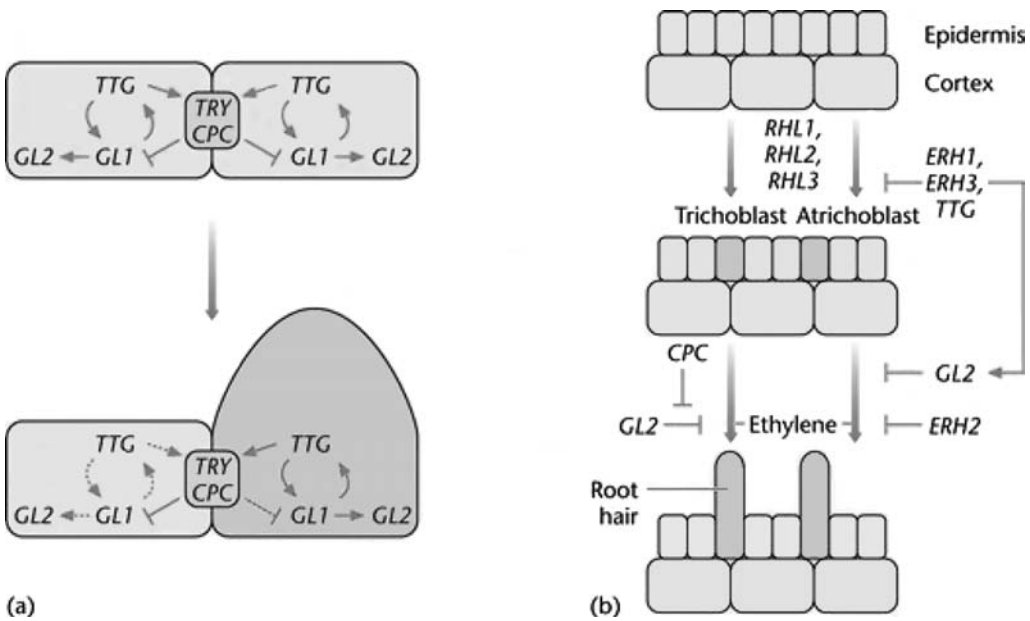

Fig. 2. **(a)** Genetic model for the selection of a trichome cell in *Arabidopsis*. Initially, both cells are equivalent and compete with each other (upper drawing). Owing to small fluctuations the system becomes biased; here the right cell develops to become a trichome cell (lower drawing).
(b) Genetic model for root hair initiation. Initially all root epidermal cells are competent to become a trichoblast (pink). The cells not overlying the cleft between the cortex cells are suppressed and become atrichoblasts (blue). In addition, root hair differentiation in atrichoblasts is suppressed by *GL2* and promoted by the plant hormone ethylene.

epidermal hair formation in opposite ways: *TTG* and *GL2* appear to be positive regulators of trichome formation but negative regulators of root hair formation. By contrast, *CPC* acts as a negative regulator of trichome formation and as a positive regulator of root hair formation. This indicates that in shoot tissues the default state is epidermal cells, while in root tissues the default state is root hair cells.

Molecular Evolution of Trichome Development

The general picture emerging from several genetic and molecular studies of trichome development in different plant species is that members of two classes of transcription factors, the *myb*- and *myc*-related transcription factors, coregulate trichome initiation. In one case it was demonstrated that the function of the maize *R* gene in the regulation of anthocyanin biosynthesis is evolutionarily conserved, and also has a role in trichome development in *Arabidopsis*. It has been shown that *myb*-related transcription factors acquire specific and separate functions in the initiation of subclasses of trichomes within a given species and may or may not be functionally conserved between different species. One representative example is the *MIXTA* gene, which in *Antirrhinum majus* is required for the development of conical cells in the epidermis of petals, but not for the formation of any other trichomes. Overexpression of *MIXTA* in *Nicotiana tabacum* results in not only the induction of conical cells, but also the formation of multicellular trichomes, indicating that these two cell types share a common regulation. By contrast, overexpression of the *MIXTA* gene in *Arabidopsis* has no effect [Glover, et al., 1998]. Thus, although trichome initiation in different plant species appears to be regulated by the same families of transcription factors, it remains to be determined to what extent this reflects the idea that the regulatory pathways underlying trichome development are evolutionarily conserved.

TRICHOMONIASIS. Trichomoniasis is a widespread disease of the urogenital tract caused by the protozoan *Trichomonas vaginalis*. This sexually transmitted disease affects humans only and has no known animal reservoirs. While it primarily affects women, *T. vaginalis* can infect men as well. The disease is marked in women by the development of purulent, frothy, vaginal discharge with a highly disagreeable odor. The role of *T. vaginalis* in producing inflammation of the male genital tract is not fully understood. The protozoan primarily invades the urethra, but may also enter the seminal vesicles or prostate. In a vast majority of infected males, the disease is asymptomatic, perhaps because they are protected by the high zinc content of prostatic secretions. Successful invasion of the prostate by the protozoan can lead to painful urination.

Treatment by the 5-nitroimidazole class of antiprotozoal agents can destroy most strains of *T. vaginalis*; however, some strains have been reported to be resistant to these drugs. The agent of choice is orally administered metronidazole (1, [CAS: 443-48-1] $C_6H_9N_3O_3$), the first systemic antitrichomonal agent, introduced in 1960. Other members of this therapeutic group include niridazole (2, [CAS: 61-57-4] $C_6H_6N_4O_3S$), tinidazole (3, [CAS: 19387-91-8] $C_8H_{13}N_3O_4S$), and ornidazole (4, [CAS: 16773-42-5] $C_7H_{10}ClN_3O_3$) but, in general, they offer no distinct advantage over metronidazole. It is recommended that both female and male sexual partners be treated simultaneously to avoid reinfecting one another. Nitroimidazoles have been demonstrated to be mutagenic in bacteria and carcinogenic in high doses in laboratory animals. It is advised that pregnant women in the first trimester of pregnancy refrain from taking these drugs even though there is no clinical evidence of fetal abnormalities being caused by them. Other nitro-heterocycles have been synthesized in large number and many show promising *in vitro* activity.

TRICHROISM. The property of exhibiting three different colors when viewed in as many different directions.

TRICHROMATIC COEFFICIENTS. Three coefficients, based on the response of the standard eye to the spectral distribution of light from a standard source, which may be used to describe the chromaticity of a source.

TRICKLE IRRIGATION. See **Irrigation**.

TRIDOP. A continuous-wave trajectory measuring system using the Doppler shift caused by a target moving relative to a ground transmitter and three or more receiving stations.

TRIDYMITE. The mineral tridymite is, like quartz, silicon dioxide, SiO_2, but is a high-temperature variety, probably stable above 870°C. It has a conchoidal fracture; is brittle; hardness, 7; specific gravity, 2.28–2.33; vitreous luster; usually colorless and transparent. It is found chiefly in volcanic rocks of the more acidic types like rhyolite, tachyte, and andesite. It is not a particularly uncommon mineral, occurring in Germany, France, Italy, Japan, the Island of Martinique, Mexico, and in the United States in Wyoming and Washington. Tridymite is hexagonal but when heated to about 1,470°C passes into an isometric form, cristobalite, which was first noted in the andesitic lavas of the Cerro San Cristobal, Pachuca, Mexico, together with tridymite. Cristobalite has been found also in California and in Germany.

TRIGONOMETRIC CURVE. Plots of the trigonometric functions are shown in Figs. 1–6. See also **Inverse Trigonometric Function**; **Trigonometric Function**; and **Trigonometry**.

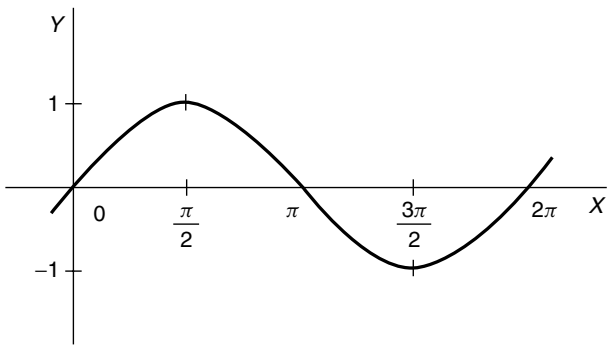

Fig. 1. $y = \sin x$.

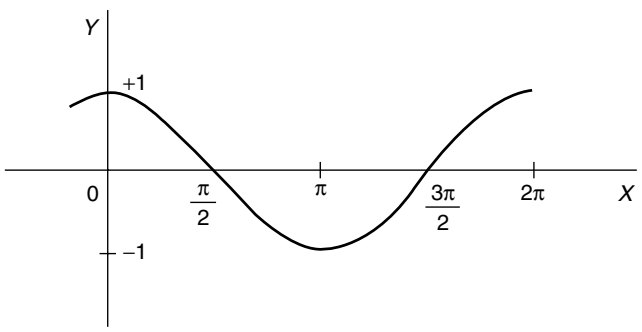

Fig. 2. $y = \cos x$.

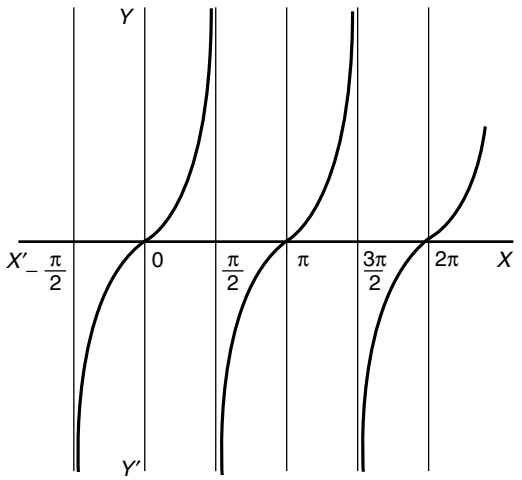

Fig. 3. $y = \tan x$.

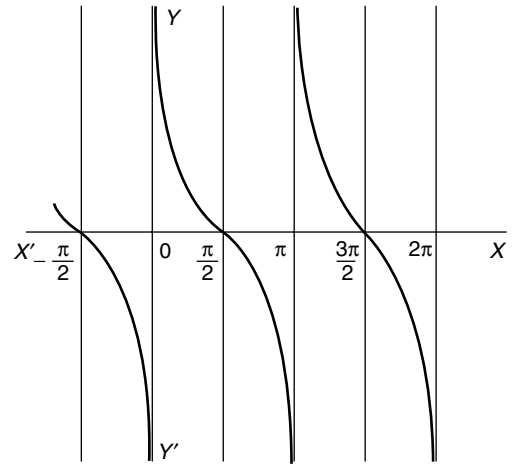

Fig. 4. $y = \cot x$.

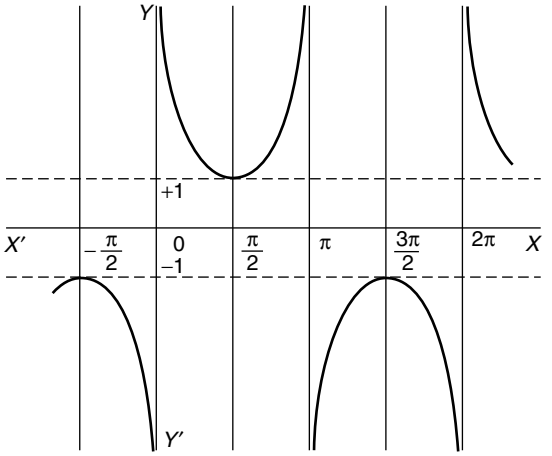

Fig. 5. $y = \csc x$.

TRIGONOMETRIC FUNCTION. If q is one of the acute angles in a right-angle triangle, x is the side of the triangle nearest to θ, y the side opposite the angle, and r the hypotenuse, the trigonometric functions are:

$$\sin\phi = y/r; \cos\phi = x/r$$

$$\tan\phi = y/x; \csc\phi = 1/\sin\phi$$

$$\sec\phi = 1/\cos\phi; \cot\phi = 1/\tan\phi$$

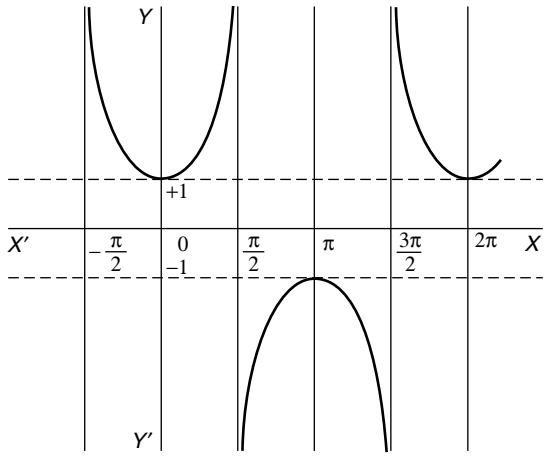

Fig. 6. $y = \sec x$.

Other quantities, but not often used, are:

$$\text{vers}\,\phi = 1 - \cos\phi; \text{covers}\,\phi = 1 - \sin\phi$$

$$\text{hav}\,\phi = \tfrac{1}{2}\text{vers}\,\phi; \text{exsec}\,\phi = \sec\phi - 1$$

The names of these functions are, respectively: sine, cosine, tangent, cosecant, secant, cotangent, versine, coversine, haversine, exsecant.

In the general case, where ϕ is not an acute angle in a right-angle triangle, the same definitions, with slight modification, can be used. Place the angle ϕ in a right-handed rectangular coordinate system with its vertex at the origin and its initial side on the positive OX-axis. The terminal side of the angle may lie in any one of the four quadrants but select any point on it (x, y) and draw a radius vector r to the point from the origin. The three letters x, y, r will then determine the trigonometric functions by the previous definitions.

There are many relations between these functions and only a few of them can be given here. We generally omit equations involving $\csc\phi$, $\sec\phi$, $\cot\phi$ for these are, respectively, the reciprocals of the relations for $\sin\phi$, $\cos\phi$, $\tan\phi$ and simple algebraic manipulation will give equations involving them, if they are wanted.

1. *Complementary, Negative, and Multiple Angles*. It will be recalled that two angles, A and B are complementary, if $A + B = 90^\circ$. From the defining relations in terms of a right-angle triangle, it follows that $\sin A = \cos(90^\circ - A) = \cos B$. The prefix "co" in cosine, cotangent, cosecant indicates this relationship, so that if A and B are complementary, $\sin A = \cos B$, $\tan A = \cot B$, $\sec A = \csc\ B$.

If the angle A is defined by the values of x, y, r and its negative $(-A)$ by x', y', r' a simple figure will show that $x = x'$, $y = -y'$, $r = r'$, hence $\sin(-A) = -\sin A$, $\cos(-A) = \cos A$, $\tan(-A) = -\tan\ A$.

Reference to a curve of the trigonometric functions (see also **Trigonometric Curve**) will show that they are periodic, repeating their values in multiples of 360°. In addition, the tangent and cotangent have periods of 180°. All of the functions also change their signs as the angles move through these periods. The correct sign can, however, be found by reducing a given angle to the first quadrant where all of the functions are positive. This can be done readily from Table 1, which also contains the information from the first part of this section, as well as numerical values for the functions of some frequently used angles.

2. *Fundamental Identities*. These relations, eight in number, make it possible to derive all of the equations in the following sections. Easily proved from the definitions of the functions, they are: (a) the three reciprocal relations for $\sin\phi$, $\cos\phi$, $\tan\phi$; (b) the quotients, $\tan\phi = \sin\phi/\cos\phi$ and its reciprocal; (c) the Pythagorean equations, $\sin^2\phi + \cos^2\phi = 1$, $\sec^2\phi = \tan^2\phi + 1$, $\csc^2\phi = 1 + \cot^2\phi$.

3. *The Addition Formulas*. If A and B are any angles $\sin(A \pm B) = \sin A\cos B \pm \cos A\sin B$; $\cos(A \pm B) = \cos A\cos B \mp \sin A\sin B$; $tan(A \pm B) = \tan A \pm \tan B)/(1 \mp \tan A\tan B)$.

TABLE 1. FUNCTIONS OF FREQUENTLY USED ANGLES

	$-A$	$90^\circ \pm A$	$180^\circ \pm A$	$270^\circ \pm A$	$360^\circ \pm A$
sin	$-\sin A$	$\cos A$	$\mp\sin A$	$-\cos A$	$\pm\sin A$
cos	$\cos A$	$\mp\sin A$	$-\cos A$	$\pm\sin A$	$\cos A$
tan	$-\tan A$	$\mp\cot A$	$\pm\tan A$	$\mp\cot A$	$\pm\tan A$

	0°	30°	45°	60°	90°
sin	0	1/2	$\sqrt{2}/2$	$\sqrt{3}/2$	1
cos	1	$\sqrt{3}/2$	$\sqrt{2}/2$	1/2	0
tan	0	$\sqrt{3}/3$	1	$\sqrt{3}$	∞

4. *Double-angle Formulas* These are special cases of (3). $\sin 2A = 2\sin A\cos A$, $\cos 2A = \cos^2 A - \sin^2 A$, $\tan 2A = 2\tan A/(1 - \tan^2 A)$.

5. *Half-angle Formulas*. These can be obtained from (4). $\sin^2 A/2 = (1 - \cos A)/2$, $\cos^2 A/2 = (1 + \cos A)/2$, $\tan A/2 = (1 - \cos A)/\sin A$.

6. *Product Formulas*. $2\sin A\cos B = \sin(A + B) + \sin(A - B)$, $2\sin A\sin B = \cos(A - B) - \cos(A + B)$, $2\cos A\cos B = cos(A + B) + cos(A - B)$.

7. *Sums and Differences*. These may be found from (6). $\sin A \pm \sin B = 2\sin(A \pm B)/2\cos(A \mp B)/2$, $\cos A + \cos B = 2\cos(A + B)/2\cos(A - B)/2$, $\cos A - \cos B = -2\sin(A + B)/2\sin(A - B)/2$.

8. *Series for the Functions*. Taylor series, or other methods, can be used to obtain the infinite series:

$$\sin x = x - \frac{x^3}{3!} + \frac{x^5}{5!} - \frac{x^7}{7!} \pm \cdots; x^2 < \infty$$

$$\cos x = 1 - \frac{x^2}{2!} + \frac{x^4}{4!} - \frac{x^6}{6!} \pm \cdots; x^2 < \infty$$

$$\tan x = x + \frac{x^3}{3} + \frac{2x^5}{15} + \cdots + \frac{2^{2n}(2^{2n} - 1)}{(2n)!} \times B_{2n-1}x^{2n-1} + \cdots; x^2 < \pi^2/4?\text{VS, \%}$$

In the last equation, the coefficients are the Bernoulli numbers. If x is small, these series show that approximate values are $\sin x \approx x$, $\cos x \approx 1 - x^2/2$, $\tan x \approx x$, where, as in the three expansions above, x must be expressed in radians.

See also **Inverse Trigonometric Function**; **Spherical Trigonometry**; and **Trigonometry**.

TRIGONOMETRY. The mathematical study of the triangle, normally the plane triangle. The subject seems to have been invented by the Greek Hipparchus, born about 160 B.C., and further developed by Ptolemy of Alexandria, who died in 168 A.D., and by the Hindu and Arabian mathematicians.

The main problem of trigonometry is the finding of unknown parts of a triangle from given data. For a right triangle, two parts must be given in addition to the right angle and one of them must be a side. Let A, B, C be the angles and a, b, c the sides opposite them, respectively. Then if the right angles is C, the remaining parts of the triangle are found from the relation $A + B = 90^\circ$, and the Pythagorean theorem, $a^2 + b^2 = c^2$. Alternatively, suitable combinations of the trigonometric functions may be used.

For an oblique triangle, three of the six parts may be found if three others are given, including one side. One possibility is the division of the oblique triangle into two right triangles and the solution of each of these as described in the preceding paragraph. One could also use:

(1) the law of sines, $a/\sin A = b/\sin B = c/\sin C$; (2) the law of cosines, $a^2 = b^2 + c^2 - 2bc\cos A$; (3) the law of tangents,

$$(a - b)/(a + b) = \frac{\tan(A - B)/2}{\tan(A + B)/2};$$

(4) the half-angle formula, $\tan A/2 = r/(s-a)$, where the perimeter of the triangle, $2s = (a+b+c)$ and r is the radius of a circle inscribed in it, $sr^2 = (s-a)(s-b)(s-c)$. Additional relations can be obtained for (2)–(4) by cyclic permutation of the letters a, b, c and A, B, C.

There are four special cases for an oblique triangle, as follows:

Case	Given	Equation to Use
I	A, B, a	(1)
II	a, b, A	(1)
III	a, b, C	(3) for A, B (1) for c
IV	a, b, c	(2) or (4)

Case II, which is called the ambiguous case, may give two, one, or no solutions. The possibilities are: no solution, $A < 90°$, $a < b \sin A$ or $a \leq b$; one solution, an oblique triangle, $A < 90°$, ab or $A > 90°$, $a > b$, a right triangle, $A < 90°$, $a = c \sin A$; two solutions, oblique triangle, $A < 90°$, $b > a > b \sin A$.

The solution of an oblique triangle is conveniently checked by the Mollweide formulas:

$$(a+b)/c = \frac{\cos(A-B)/2}{\sin C/2}; (a-b)/2 = \frac{\sin(A-B)/2}{\cos C/2}$$

and two other equations, found by cyclic permutation of the letters, a, b, c and A, B, C.

The area of a triangle is given by $2H = \text{base} \times \text{altitude}$. Equivalent expressions are:

(5) $$H^2 = s(s-a)(s-c);$$

(6) $$2H = ab \sin C;$$

(7) $$2H = a^2 \frac{\sin B \sin C}{\sin(B+C)}.$$

Again, other relations may be obtained by cyclic permutations. To find the area in case I, use (7); case III, (6); case IV, (5).

Tables of logarithms are available for the trigonometric functions and triangles are usually solved by logarithmic calculations.

For further relations between angles, see also **Trigonometric Function**. See also **Spherical Trigonometry** for the solution of spherical triangles.

TRILOBITA (TRILOBITES). Trilobites are a distinctive group of fossil marine arthropods. Their earliest representatives are known from rocks of lower Cambrian age (545 million years old (Ma)), and the latest died out in upper Permian times (~245 Ma). Like all arthropods, they have an external skeleton (exoskeleton) and that of trilobites is characteristically divided transversely into three components, a head (cephalon), a thorax of separate articulated segments, and a tail or pygidium (Fig. 1). Longitudinally there is a central raised axis and two lateral flanking areas, giving the body the trilobed form from which the group takes its name. Mature individuals range from about 1 mm in length to 700 mm.

The cephalon is an arched plate with a central raised area (the glabella), which usually has paired sets of transverse furrows. Lateral to this are the "cheek" regions upon which are set a pair of compound eyes; these have lenses made of calcite and are the oldest known visual system in the animal kingdom. Lines of weakness, the facial sutures, run across the cephalon from front to rear, passing along the top of the eye; these facilitated splitting of the exoskeleton into separate components during moulting. Below the glabella is a swollen plate, the hypostome, which may be fixed to the cephalon at the front or may lie freely below it.

Each thoracic segment has a central axial ring and a pair of lateral pleura, usually bearing an oblique furrow. A pair of ventrally projecting apodemes on each segment were probably sites of limb attachment. The pygidium, which likewise has its own small apodemes, may be large or small, rounded, pointed, or spinose. Its external surface often carries impressions of furrows like those of the thorax, but fading out posteriorly. In trilobites that were able to roll up in a ball for protection (usually Ordovician and later forms), the front edge of each thoracic segment forms

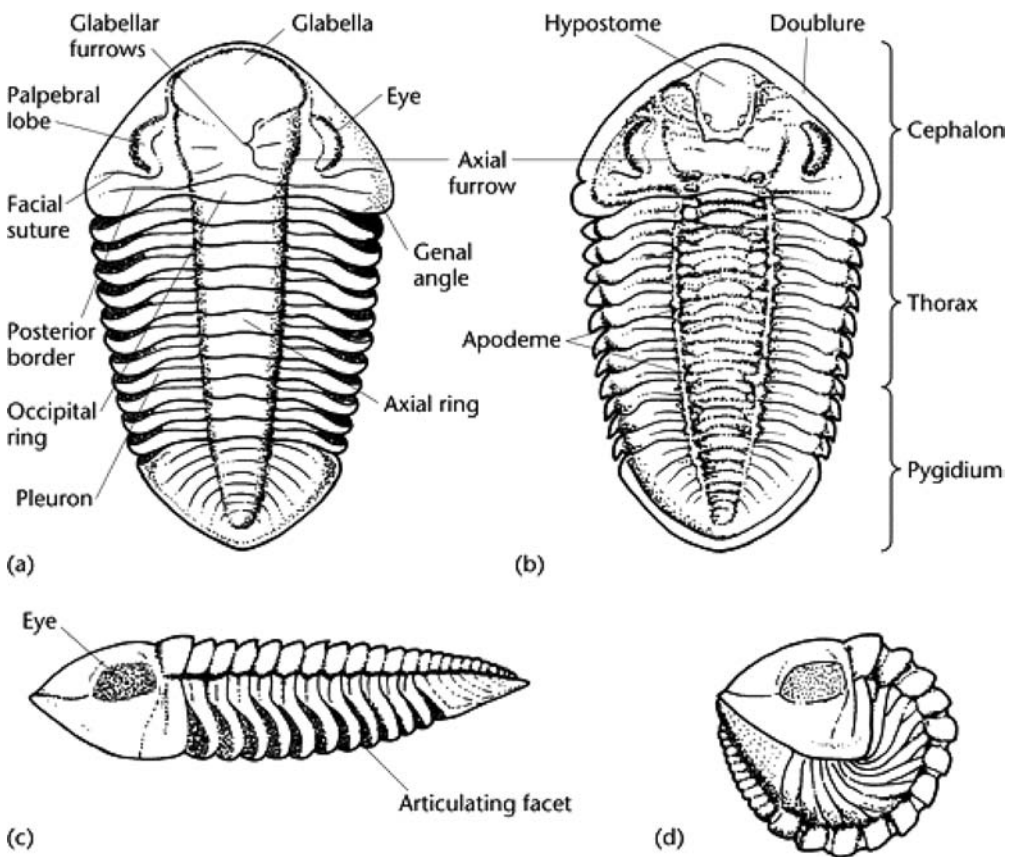

Fig. 1. *Acaste downingiae*, Silurian, England: (**a**) dorsal surface; (**b**) ventral surface; (**c**) side view in natural life position; (**d**) enrolled specimen.

an oblique articulating facet that enables the segments to fit together, and some of these enrolment systems show a remarkable perfection.

Little is known of the internal organization of trilobites. From rare specimens in which the shape of the gut is preserved by mud infilling, it appears that the mouth lay behind the hypostome and an oesophagus ran forwards to a large stomach between the glabella and hypostome, from which the straight, simple gut ran under the axis to terminate at an anus below the pygidium. Some kind of ventral membrane must have bounded the internal organs from below. The delicate ventral appendages are seldom preserved. In the few cases where they are well known the cephalon bears a pair of anterolaterally directed antennae, followed by three pairs of two-branched (biramous) limbs, each with a filamentous gill branch, used in respiration and swimming, and a jointed walking leg. A similar pair of limbs is found in each thoracic segment and usually there are progressively smaller pairs in the pygidium. Spiny gnathobases projecting inwards may have acted as jaws. See also **Fossil Record**.

Life Histories. The breeding habits of trilobites are poorly known, though several examples of large clusters of mature individuals, overwhelmed by sediment, may indicate that these trilobites came together for reproduction, and probably moulting at the same time. A few examples of trilobite embryos have been reported, but our knowledge of development comes mainly from later stages.

Trilobites, like other arthropods, grew by moulting (ecdysis). A new soft shell was secreted by epidermal cells below the old exoskeleton, which was then cast off as the individual swelled up with water, breaking along the suture lines. Exoskeletal elements left undisturbed in particular configurations, and so preserved, showed that different kinds of trilobites had different ways of exuviation. The cast-off exuviae, arranged in a gradational size series, allow the reconstruction of the whole ontogeny. The earliest stage, seldom preserved, is a phaselus, a tiny ovoid button. More commonly, a protaspis, a cambered disc, represents the earliest ontogenetic stage. Subsequently, a transverse split appears, defining a head and "transitory pygidium"; this is the earliest meraspis stage. With successive molts, thoracic segments are budded off anteriorly one by one from a generative segment at the front of the transitory pygidium, until the full adult complement is reached. This is the holaspis stage, but it may still be very small by comparison with the mature adult. Some trilobite protaspides are weakly cambered, and were probably benthic. Globular protaspides, on the other hand, often with very spiny hypostomes, indicate a planktonic habit for the early larval stages.

The study of trilobite ontogeny is of intrinsic interest, but in evaluating ancestor–descendant lineages it is important also in demonstrating how often heterochrony, and especially pedomorphosis, was a primary control of evolutionary change.

Diversity and Habits. The life habits of trilobites can often be inferred by study of (a) the form of the exoskeleton, (b) the sedimentary environment in which the fossils are preserved, and (c) the nature of the ventral appendages and tracks and trails made by moving trilobites.

Most, if not all Cambrian genera were probably vagrant benthos, walking on or swimming above a muddy sea floor. In the Ordovician, however, many other ecological niches were invaded, and the form of the body became modified accordingly, in response to the increased number of habitats available. Various sea floor ecological niches were colonized, including reefs, and there is clear evidence of the pelagic habitat being colonized for the first and only time. Pelagic trilobites of the Ordovician usually have enormous compound eyes, which may be fused anteriorly, and a body of streamlined form, which as seen in lateral view was not designed to rest on the sea floor. Such trilobites are found independently of facies, which tallies with a mode of life in the upper waters of the sea, and possibly as diurnal vertical migrants. Two unrelated groups made the transition from a benthic to a pelagic habitat, one in cold waters bordering the southern continent of Gondwanaland, the other, contemporaneously, in the tropics. Some of the other morphological characters that arose in Ordovician times, however, remain imperfectly understood.

Locomotion in trilobites was probably accomplished by the limbs moving together in metachronal rhythm, as in modern arthropods; that is by progressive waves of movement running forwards along the body, with each pair of walking legs being put down in sequence on the sea floor, immediately followed by the pair in front, thus carrying the body forwards. Trace fossils attributed to trilobites confirm that this was the standard mode of progression. Traces are formed where tenacious mud on the sea floor took the imprints of the legs of a trilobite walking over the surface, but they are only preserved where these imprints were shortly afterwards filled by silt or sand from a sedimentary suspension flow. When the sand layer subsequently lithified, the imprints were preserved for posterity, and sometimes these can be matched directly with the known structure of the limbs of a particular trilobite genus. In some trace fossils the imprints are closely spaced on one side and spread out on the other, suggesting forward movement with the body somewhat oblique to the axis of the trail. Possibly the trilobite braced itself against a lateral current as it walked. Interestingly, at least some trilobites were able to walk sideways like a crab, and some large trails show initial crabwise movement changing into normal forward walking. There are also resting traces, scooped out by an individual in the mud, and preserved to show the marks of the underside and limb bases of the trilobite. Similar, though much longer, trails were probably made by trilobites ploughing though the upper surface of organic-rich mud, feeding on small worms as they did so, and there are several examples of traces made by a foraging trilobite that located a larger worm lying horizontally within the sediment and pulled it up to the surface using all the legs on one side, then devoured it. There is thus a clear testimony to a versatile range of behavior patterns in these ancient arthropods.

Phylogeny and Geological History

The earliest trilobites appear abruptly in the lower Cambrian. They may have had ancestors with an organic exoskeleton, and their sudden appearance may be the result of greatly increased preservation potential as a result of this becoming reinforced with calcite. On their first appearance they are already differentiated into several groups, the small agnostids that have only two thoracic segments and the rather similar eodiscids that have two or three, contrasting with the many kinds of "polymerids" that have several thoracic segments. Throughout the Cambrian, different groups of trilobites appeared, flourished and became extinct, often with a high rate of turnover; as a result, Cambrian biostratigraphy is largely based on trilobites. Cambrian trilobites often occur in bands, with unfossiliferous sediments in between, but in some areas they are extraordinarily abundant, as in the middle and upper Cambrian of Scandinavia, where the rock seems to consist almost entirely of trilobite fragments. Most Cambrian trilobites are of relatively "standard" form, and on the whole had limited facility for enrolment. Some, however, were quite specialized and of extraordinarily spinose form. At the end of the Cambrian there was a major crisis in the history of trilobites, and most of the typically Cambrian types became extinct. This may have been due to changing environmental conditions, including a global fall in sea level, but was also due to the rise of predatorial cephalopods. Quite early in the succeeding Ordovician, virtually all post-Cambrian groups were established, and trilobites reached their maximum diversity and colonization of different habitats, including the pelagic realm. Many new features of construction were established: spinosity, superior enrolment ability, and the "schizochroal" eye in which the lenses are few but relatively enormous (and which bring light to a sharp focus despite being made of birefringent calcite). In many groups the mechanisms of enrolment reach mechanical perfection, with interlocking "press-studs" or ridges ensuring defense against the shearing potential of predatory cephalopods. The rate of turnover of various groups continued to be high, and the biostratigraphical value of Ordovician trilobites remains undiminished.

Then, at the end of the Ordovician, there came a further crisis in the form of cooling of the shelf seas and oceans, and loss of habitat through sea-level lowering during the short but intense Hirnantian glaciation. Silurian and Devonian faunas were relatively impoverished by comparison, lacking the trinucleid and other typical Ordovician elements; the ranges of individual taxa were longer and their biostratigraphical value lessens. Curiously, no new major groups were introduced; the remaining trilobites were simply variations on themes established in the Ordovician. During Devonian times there was a gradual, if stepwise, reduction in the number of trilobite groups, culminating in the great mass extinction of the late Devonian (end Frasnian), the cause of which is still debated. The gradual reduction and loss of eyes through pedomorphosis, which occurred independently in different groups, may be attributed to the adoption of an endobenthic habit

by many groups, as shallow limestone-shelf seas were replaced by a mud blanket. By the Carboniferous, only one group, the Proetida, remained; small, standard trilobites with well-developed eyes and good enrolment facilities, but all rather similar to each other. They are found mainly in reefs and in dark shale's and limestones. The last trilobites died out during the catastrophic mass extinction at the end of the Permian some 245 million years ago. The stepwise extinction through time seems to have been more a matter of repeated environmental crises than of biological inadequacy or direct competition. See also **Paleontology**.

TRIM (Airplane). The trim of an airplane denotes the balance of aerodynamic and thrust forces around a lateral axis through the center of gravity. An airplane would be in trim if it had no tendency to change from its angle of attack with respect to the flight path in steady flight after it has been brought to that angle of attack by a specific angular deflection of the elevator.

TRIMMER CAPACITOR. A small capacitor used to adjust a tuned circuit to the desired resonance frequency. Essential in tracking superheterodyne receivers.

TRIPHYLITE. This mineral is a phosphate of lithium and ferrous iron, $LiFePO_4$. It crystallizes in the orthorhombic system but usually is characterized by large cleavable masses. The hardness is 4.5–5.0; specific gravity, 3.42–3.56, vitreous to resinous luster, translucent, and bluegray color. The mineral occurs as a rare primary mineral in granitic pegmatites and, when available in large quantities, is a source of lithium. Worldwide occurrences include Bavaria, Finland, Sweden, and in the United States, New Hampshire, Maine, and South Dakota.

TRIPLE BOND. A highly unsaturated linkage between the two carbon atoms of acetylenic compounds (alkynes), typified by acetylene (HC≡CH).

See also **Bond (Chemical)**; and **Chemical Elements**.

TRIPLE POINT. The temperature and pressure at which the solid, liquid, and vapor of a substance are in equilibrium with one another. Also applied to similar equilibrium between any three phases, i.e., two solids and a liquid, etc. The triple point of water is +0.072C at 4.6 mm Hg; it is of special importance because it is the fixed point for the absolute scale of temperature.

See also **Three-Phase Equilibrium**.

TRIPOLITE. A term frequently used synonymously with diatomaceous earth, but more particularly with reference to diatomaceous earth from Tripoli in North Africa. See also **Diatom**; and **Diatomite**.

TRISECTRIX OF MACLAURIN. A higher plane curve, a special case of the cissoid, which is represented in rectangular coordinates by the equation

$$2x(x^2 + y^2) = a(3x^2 - y^2)$$

and in polar coordinates by

$$r\cos\phi/3 = a/2$$

It is also related to the rose curves and thus is a member of the trochoidal type of cyclic curves.

Another trisectrix, that of Longchamps, has the polar equation $r\cos 3\phi = a$. Both can be used in the classical problem of angle trisection.

See also **Cissoid of Diocles**; and **Curve (Higher Plane).**

TRISMUS. See **Tetanus**.

TRISTIMULUS VALUES. Any sample of light can be matched by the mixture of three different standard stimuli. The magnitudes of the three stimuli needed to match a particular sample are called the tristimulus values of that sample. The standard stimuli must be specified. Those most commonly used are the CIE color mixture functions x, y, z, of which y is the luminosity function.

TRITIUM. The radioactive isotope of hydrogen, with a mass number 3, is termed tritium. It is one form of heavy hydrogen, the other form being deuterium. See also **Nuclear Power Technology**.

TRITIUM (Reactor). See **Nuclear Power Technology**.

TRIVIAL NAME. The name applied by early chemists to a number of simple organic compounds, usually based on their sources or properties, e.g., acetone and acetic acid, from Latin *acetum* (vinegar), urea from urine, glucose and glycerol from Greek *glyc*-(sweet). Such names remained in common use regardless of the systematic nomenclature later developed.

TROCHOID. The path described by a point on a line drawn through the center of a circle as it rolls along a straight line. It is a special case of the cyclic curve and its equation can be obtained from that case by the following limiting process:

Let $(R + r)\phi/r = \theta$, $Y = x - R\cos\phi$, $X = y$ and as $R \to \infty$, $R\sin\phi$ becomes $r\theta$ and $\cos\phi$ becomes unity. Finally, replace X and Y by x, y, respectively and r, a by a, b to get the usual form of the equation, $x = a\theta - b\sin\theta$, $y = a - b\cos\theta$.

The given line on which the circle rolls is the X-axis, the generating point is originally on the Y-axis, a is the radius of the circle, b is the distance of the point from the center of the circle, and q is the angle through which the circle has rolled. If $b = a$, the curve is called a cycloid; if $b < a$, the trochoid is curtate and if $b > a$, prolate. Nodes appear in the prolate case, they become cusps for the cycloid, and minima when the trochoid is curtate.

See also **Cycloid**.

TROGON *(Aves, Trogoniformes)*. A brilliantly colored and beautifully feathered bird of the Oriental region, tropical Africa, and Central and South America. A single species, the coppery-tailed trogon, *Trogon ambiguus*, enters southern Texas and Arizona. These birds have a moderately large beak, strong and curved. Crests and plumes are highly developed in some of the males. The males also have very long tails. The *quezal* of South America is one of the most widely known of the trogons, probably because it has been pictured numerous times on the postage stamps of Guatemala and partly because its brilliant colors persist in museum specimens. The male is brilliant green with blood-red under parts below the breast. It has a very long tail, drooping plumes over the wings, and the head bears a rounded crest. See also **Trogoniformes**.

TROGONIFORMES *(Aves)*. This order which is made up of the Trogons (family *Trogonidae*) are among the most colorful birds we know. They have long, staggered tails and short, powerful beaks which they use to make their brood holes in decaying tree trunks.

Their size ranges from that of a grosbeak to that of a magpie. The breast and the underside of the males are predominantly colored in brilliant shades ranging from red to yellow. They frequently have a magnificent green color above. The plumage of the females is usually not as rich in contrasting colors. The feet are notably weak and the arrangement of the toes is unique: not only the first but also the second toe is immovable and reversed, while only the third and fourth are directed forward (heterodactyly).

Trogons are usually seen singly or in pairs, but only rarely in small groups. They also occur in higher mountain regions and thus in cooler zones. In the luxuriant tropical forests they are not especially conspicuous despite their brilliant coloring, for they usually sit quietly on a branch or a liana in a strangely upright posture, with the tail pointed directly downward. From these lookout points they take off on short flights to hunt for an insect or to pick fruit in flight. They make their presence known by their loud calls, which are distinctive enough in the individual species to tell them apart.

Although this order, as hole-brooders, make their nesting chambers in decaying tree trunks or stumps, they also use abandoned woodpecker hollows. Some species use the nests of tree termites and even of wasps in which to build their brooding holes. Both sexes share in the building of the nest, but they do not bring nesting materials; the clutch is deposited on the bare floor of the brood chamber. The eggs are nearly globular in shape, white or pastel, but brownish and blue shades also occur. Incubation is shared by both parents.

There are 8 genera with 34 species in the tropics of Central and South America, Africa, and southern Asia. The best known of all trogons is the Quetzal (*Pharomachrus mocino*). This bird was much revered by the ancient civilizations of the Mayas and the Aztecs, and is still the heraldic emblem of Guatemala, whose monetary unit is also named for it. Red and green are beautifully contrasted in the plumage of the quetzal; added to this are the extraordinarily elongated upper tail coverts of the male, forming a magnificent train which can measure up to 1.05 meters ($3\frac{1}{2}$ feet). See also **Trogon**.

TROPHALLAXIS. An interchange of nourishment between the various members of colonies of insects, reciprocal feeding. The older idea that instinctive parental care is the basis of the concern manifested by ants and termites for the welfare of other individuals of the colony has been substituted by recognition of this interchange. The insects exude secretions at the surface of the body, which are licked off by others. This reward is apparently responsible for much of the solicitude. Even the insects of other species living within such colonies are welcome guests in some cases because of a similar contribution to their hosts. The relationship has complex ramifications which explain other aspects of colonial organization, such as cannibalism, that are difficult to reconcile with the older interpretations of mutual aid within the colony.

TROPHOSOME. One of several terms used to designate individuals that take in and digest food in colonies of primitive animals, or the stage of development of an individual during which it eats and grows. Trophosome is applied to the polyp stage of hydrozoa, also called gasterozooids. The term trophozooid is applied to an early stage in the development of the coral polyps of the family *Fungidae*, known as mushroom corals, and the term autozooid to individuals that take food in alcyonarian colonies. The root appears again in trophozoite, applied to the growing stage of some parasitic Protozoa (*Sporozoa*).

TROPICAL CYCLONE. See **Fronts and Storms**.

TROPICAL DISEASES. These are generally considered to be those ailments occurring mainly, but not necessarily, in the 47 degrees of latitude between the Tropic of Cancer (23.5°N) and the Tropic of Capricorn (23.5°S) of the equator. This area, which presents a large degree of uniformity of warm temperature and only mild seasonal variation in weather patterns, is eminently predisposed to the ecological cultivation of organisms and disease vectors inimical to human health. Of the 4.5×10^9 people populating the earth, some 55% inhabit tropical and subtropical zones and present annually with some 600 million cases of infectious and parasitic diseases, leading to as many as 20 million deaths per year from such diseases as diarrhea, malaria, schistosomiasis, and amebiasis. Malnutrition further exacerbates symptomology in affected individuals and can by itself lead to death.

The climatic conditions of the tropics are so aligned to the development of organisms causing disease in humans that the area has been said to present a boundary to the well-being of humans versus that of nonhumans. Because of these climatically induced dangers to human health, many tropical areas have remained relatively underdeveloped despite their enormous economic potential in lumber, oils, gums, fibers, and fruit, among other important items of commerce.

In tropical countries, diarrheal disease is the major infectious cause of death and this syndrome can be caused by many organisms — for example, *E. coli, V cholerae, Salmonella* sp., *Shigella* sp., and rotavirus. Diarrheas due to amebiasis, giardiasis and intestinal helminths must be considered separately. In developing countries, adults usually suffer from at least one attack of diarrhea annually; children under five years of age have an incidence of two to ten episodes annually. Thus, one can expect to encounter some 4.5 billion cases per year, with a case fatality rate which varies from 1% in the poorest, most malnourished children to less than 0.1% among adults. The effect of this infection rate upon the health of the work force is extensive and the economic effects are high.

Respiratory infections derive from viruses, adenovirus, and bacteria and cause half to two-thirds of the morbidity and mortality in the tropics. Acute tuberculosis is prevalent in approximately 6 to 8 million residents, and of these some 500,000 die annually. Adult men over the age of 25 years, in the economically productive years of life, sustain the highest incidence and death rates for the active disease, thus heavily burdening families dependent upon them for support.

Despite all attempts to control the vector mosquito and all chemotherapeutic measures, malaria still causes an enormous number of deaths. Schistosomiasis infects some 200 million people in the tropics and is spreading as agricultural irrigation projects progress. The extent of water contact largely controls the prevalence and intensity of this parasitic disease, but the majority of individuals remain asymptomatic regardless of the intensity of the infection. As in all tropical infectious diseases, the spread of contagion is facilitated by the usually low socioeconomic status, crowded and insanitary living conditions of many residents.

By the end of this century, 75% of all the people in the world to receive medical attention will be citizens of the tropical developing world. One third of those people now requiring care are in the low-income countries — those whose per capita gross national product amounts to $300 per year or less. Only about 6–10% of any country's GNP (gross national product) is spent on health care. For the poorest countries, this means a total of $6 to $10 per year per person, of which the government provides only about half. When it is realized that the provision of water and sewerage costs between $10 and $32 per capita, the paucity of medical facilities in the tropical field can be placed in perspective.

Over 2.5 million Americans live or travel abroad each year, many returning from regions where dangerous sanitation conditions exist. An estimated 8 to 9 million visitors from foreign countries add to the problems of public health in North America, because 20% of the visitors come from countries where diseases such as typhoid, cholera, yellow fever, or plague are endemic, or even epidemic. With increasing speeds of travel and the number of immigrants from the tropical countries, diseases normally indigenous to the area are appearing with increasing frequency in many of the temperate climate countries from which they were once excluded by virtue of higher standards of hygiene and medical attention. Quarantine is no longer of importance and is rarely used. Because of the speed of travel, epidemics can now span the world almost overnight. An infectious disease acquired, for example, in the tropical zone of Australia, can have its whole incubation period spent in transit over Asia and Europe, to become manifest hours later in North America.

The field of tropical medicine is too wide to be covered in one article in this encyclopedia and reference should be made to specific tropical diseases and their vectors as given in the alphabetical index.

Research on these tropical diseases, their prevention and cure, is being strongly pursued in North America, as for example by the National Institutes of Health in the United States, by the Schools of Tropical Medicine at Liverpool and London in Great Britain, and worldwide, by

the World Health Organization (WHO), centered in Switzerland. Most emphasis by these groups is placed on malaria, schistosomiasis, filariasis, and leprosy.

TROPICAL RAINFALL MEASURING MISSION (TRMM). The Tropical Rainfall Measuring Mission (TRMM) satellite is the first mission dedicated to measuring tropical and subtropical rainfall through microwave and visible infrared sensors, including the first spaceborne rain radar. The Precipitation Radar aboard TRMM is the first rain radar ever to be launched into space. It measures precipitation distributions over both land and sea. TRMM has exceeded expectations for accuracy and resolution and has given unprecedented insights into rainfall producing cloud systems over tropical land masses and oceans.

The TRMM satellite, a joint project between the United States (under the leadership of NASA's Goddard Space Flight Center, which hosts the main TRMM web site, http://trmm.gsfc.nasa.gov/) and Japan (under the leadership of the National Space Development Agency, http://www.eorc.nasda.go.jp/TRMM/index_e.htm), was successfully launched from Tanegashima, Japan, on November 27, 1997, at 13:27pm Los Angeles (California) time. See Figs. 1 and 2.

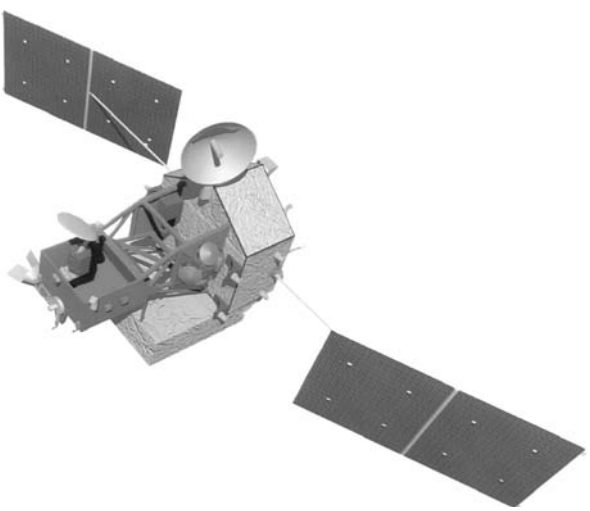

Fig. 1. Artist rendering of the TRMM Satellite.

Fig. 2. TRMM Satellite being assembled at Goddard Space Flight Center.

One of the great challenges facing mankind in the 21st century is the threat of global warming due to increased levels of carbon dioxide and other greenhouse gases in the atmosphere. Is the threat real? Computer models that predict the future climate still differ in some very substantial ways with some models predicting little or no warming while others predict temperature increases that would substantially alter humanity's way of life. Without more data and better understanding of the current climate system, there is little hope that one can understand the differences among our current models and both sides in the environmental debate will continue to press for their viewpoints.

TRMM is a research satellite designed to help our understanding of the water cycle in the current climate system. By covering the tropical and semitropical regions of the Earth, TRMM provides much needed data on rainfall and the heat release associated with rainfall. It will not single-handedly provide the solution to the climate change debate — it will, however, contribute to the understanding of how clouds affect climate and how much energy is transported in the global water cycle. In coordination with other satellites in NASA's Mission to Planet Earth, TRMM will begin the process of understanding the interactions between water vapor, clouds and precipitation that is central to regulating the climate system.

The energy balance of the global atmosphere shows that only about one fourth of the energy needed to drive the global atmospheric circulation comes from direct solar energy. The other three fourths of the energy is transferred to the atmosphere by evaporating water; mainly from the ocean. As the water vapor rises from the surface, it carries with it the energy it takes to turn liquid water into water vapor, the "latent heat of evaporation". Most of this latent heat is released into the atmosphere in huge equatorial cloud clusters when the vapor condenses to form cloud- and raindrops. The latent heat energy contained in the clouds cannot be seen or measured directly. Rainfall, however, is the product of the release of this energy, and rainfall can be measured. Responsible for three quarters of the energy that drives the global atmospheric circulation, tropical rainfall can be said to "drive the climate machine". Unfortunately, there are still uncertainties of as high as 50% in the amount of tropical rainfall. Unless we can better define the amount of rainfall and the energy released when rain occurs, we stand little chance of putting the climate models through the rigorous tests we need to gain confidence in their predictions.

TRMM Instruments

A total of five instruments will be flown aboard the Tropical Rainfall Measuring Mission (TRMM) observatory. Among the three primary instruments on TRMM, the most innovative is the Precipitation Radar. The other instruments are the TRMM Microwave Imager (TMI) and the Visible and Infrared Scanner (VIS) VIRS which have operated in space before, but to date there has not been any radar in space for the purpose of measuring rainfall.

Precipitation Radar (PR). The Precipitation Radar, built by the National Space Development Agency (NASDA) of Japan, was the first spaceborne instrument designed to provide three-dimensional maps of storm structure. These measurements yield invaluable information on the intensity and distribution of the rain, on the rain type, on the storm depth and on the height at which the snow melts into rain. The estimates of the heat released into the atmosphere at different heights based on these measurements can be used to improve models of the global atmospheric circulation.

The Precipitation Radar has a horizontal resolution at the ground of about 3.1 miles (five kilometers) and a swath width of 154 miles (247 kilometers). One of its most important features is its ability to provide vertical profiles of the rain and snow from the surface up to a height of about 12 miles (20 kilometers). The Precipitation Radar is able to detect fairly light rain rates down to about 0.027 inches (0.7 millimeters) per hour. At intense rain rates, where the attenuation effects can be strong, new methods of data processing have been developed that help correct for this effect. The Precipitation Radar is able to separate out rain echoes for vertical sample sizes of about 820 feet (250 meters) when looking straight down. It carries out all these measurements while using only 224 watts of electric power, the power of just a few household light bulbs.

TRMM Microwave Imager (TMI). The TRMM Microwave Imager (TMI) is a passive microwave sensor designed to provide quantitative rainfall information over a wide swath under the TRMM satellite. By carefully measuring the minute amounts of microwave energy emitted by the Earth and its atmosphere, TMI is able to quantify the water vapor, the cloud water, and the rainfall intensity in the atmosphere. It is a relatively small instrument that consumes little power. This combined with the wide swath and the good, quantitative information regarding rainfall make TMI the "workhorse" of the rain-measuring package on Tropical Rainfall Measuring Mission.

TMI is not a new instrument. It is based on the design of the highly successful Special Sensor Microwave/Imager (SSM/I) which has been flying continuously on Defense Meteorological Satellites since 1987. The TMI measures the intensity of radiation at five separate frequencies: 10.7, 19.4, 21.3, 37, 85.5 GHz. These frequencies are similar to those of the SSM/I, except that TMI has the additional 10.7 GHz channel designed to provide a more-linear response for the high rainfall rates common in tropical rainfall. The other main improvement that is expected from TMI is due to the improved ground resolution. This improvement, however, is not the result of any instrument improvements, but rather a function of the lower altitude of TRMM 250 miles (402 kilometers) compared to 537 miles (860 kilometers) of (SSM/I). TMI has a 547 mile (878-kilometer) wide swath on the surface. The higher resolution of TMI on TRMM, as well as the additional 10.7 GHz frequency, makes TMI a better instrument than its predecessors. The additional information supplied by the Precipitation Radar further helps to improve algorithms. The improved rainfall products over a wide swath will serve both TRMM as well as the continuing measurements being made by the SSM/I and radiometers flying on the NASA's EOS-PM and the Japanese ADEOS-II satellites.

Calculating rainfall rates from TMI requires some fairly complicated calculations. The basis of these calculations is in Planck's radiation law, which describes how much energy a body radiates given its temperature. Water surfaces such as oceans and lakes have an additional property which is very important. The surfaces emit only about one half the microwave energy specified by Planck's law and therefore appear to have only about half the real temperature of the surface. Water surfaces therefore look very "cold" to a passive microwave radiometer. Raindrops on the other hand, appear to have a temperature that equals their real temperature.

They appear warm to a passive microwave radiometer and therefore offer a contrast against "cold" water surfaces. The more raindrops, the warmer the whole scene appears, and research over the last three decades now make it possible to obtain fairly accurate rainfall rates based on the temperature of the microwave scene.

Land is very different from oceans in terms of the emitted microwave radiation, appearing to have about 90% of its real temperature. In this case, there is little contrast to observe the "warm" raindrops. Certain properties of rainfall, however, still can be inferred. The high frequency microwaves (85.5 GHz) measured by TMI are strongly scattered by ice present in many raining clouds. This reduces the microwave signal at the satellite and offers a contrast against the warm land background.

Visible and Infrared Scanner (VIRS). The VIRS serves as a very indirect indicator of rainfall. It also ties in TRMM measurements with other measurements that are made routinely using the meteorological Polar Orbiting Environmental Satellites (POES) and those that are made using the Geostationary Operational Environmental Satellites (GOES) operated by the United States. See also **Geostationary Operational Environmental Satellite (GOES)**; and **Polar-Orbiting Environmental Satellite (POES)**.

VIRS, as its name implies, senses radiation coming up from the Earth in five spectral regions, ranging from visible to infrared, or 0.63 to 12 micrometers. VIRS is included in the primary instrument package for two reasons. First is its ability to delineate rainfall. The second, and even more important reason, is to serve as a transfer standard to other measurements that are made routinely using POES and GOES satellites. The intensity of the radiation in the various spectral regions (or bands) can be used to determine the brightness (visible and near infrared) or temperature (infrared) of the source.

If the sky is clear, the temperature will correspond to that of the surface of the Earth, and if there are clouds, the temperature will tend to be that of the cloud tops. Colder temperatures will produce greater intensities in the shorter wavelength bands, and warmer temperatures will produce greater intensities in the longer wavelength bands. Since colder clouds occur at

higher altitudes the measured temperatures are useful as indicators of cloud heights, and the highest clouds can be associated with the presence of rain.

A variety of techniques use the infrared (IR) images to estimate precipitation. Higher cloud tops are positively correlated with precipitation for convective clouds (generally thunderstorms) which dominate tropical (and therefore global) precipitation accumulations. One notable exception to this rule of thumb are the high cirrus clouds that generally flow out of thunderstorms. These cirrus clouds are high and therefore "cold" in the infrared observations but they do not rain. To differentiate these cirrus clouds from water clouds (cumulonimbus), a technique which involves comparing the two infrared channels at 10.8 and 12.0 micrometers can be employed. Nonetheless, IR techniques usually have significant errors for instantaneous rainfall estimates. The strength of the IR observations lies in the ability to monitor the clouds continuously from geostationary altitude. By comparing the visible and infrared observations on the Tropical Rainfall Measuring Mission with the rainfall estimates of the TRMM Microwave Imager and Precipitation Radar, it is hoped that much more can be learned about the relationship of the cloud tops as seen from geostationary orbit.

VIRS uses a rotating mirror to scan across the track of the TRMM observatory, thus sweeping out a region 833 kilometers (518 miles) wide as the observatory proceeds along its orbit. Looking straight down (nadir), VIRS can pick out individual cloud features as small as 2.4 kilometers (1.5 miles).

The Clouds and the Earth's Radiant Energy System (CERES). The CERES instrument will be used to study the energy exchanged between the Sun; the Earth's atmosphere, surface and clouds; and space.

The CERES instrument is based on NASA Langley's highly successful Earth Radiation Budget Experiment which used three satellites to provide global energy budget measurements from 1984 to 1993.

CERES will measure the energy at the top of the atmosphere, as well as estimate energy levels within the atmosphere and at the Earth's surface. Using information from very high resolution cloud imaging instruments on the same spacecraft, CERES also will determine cloud properties, including cloud-amount, altitude, thickness, and the size of the cloud particles. All of these measurements are critical for advancing our understanding of the Earth's total climate system and further improving climate prediction models.

Five CERES instruments will be flown on multiple satellites starting with one CERES on TRMM, followed by a launch on the Earth Observing System Terra (EOS-AM-1) satellite with two CERES instruments in 1999 and the Aqua (EOS-PM-1) satellite with two CERES instruments onboard in 2002. Follow-up CERES satellite missions are planned to create a continuous 15-year history of highly accurate energy budget and cloud data for enhanced climate analyses. See also **Aqua (EOS PM-1)**; and **Terra Satellite (EOS AM-1)**.

School children worldwide will be involved in the CERES program, enabling them to be part of a scientific project. As a CERES instrument passes over, students will make local observations to determine the types of clouds over their school, the clouds altitudes and how much of the sky is covered by clouds. Via the Internet, the students will then place their data in the NASA Langley Distributed Active Archive Center where the data will be stored for further analysis by the CERES science team.

The Lightning Imaging Sensor (LIS). The Lightning Imaging Sensor is a small, highly sophisticated instrument that detects and locates lightning over the tropical region of the globe. Looking down from a vantage point aboard the Tropical Rainfall Measuring Mission (TRMM) observatory, 250 miles (402 kilometers) above the Earth, the sensor provides information that could lead to future advanced lightning sensors capable of significantly improving weather "nowcasting."

Using a vantage point in space, the Lightning Imaging Sensor promises to expand scientists' capabilities for surveying lightning and thunderstorm activity on a global scale. It will help pave the way for future geostationary lightning mappers. From their stationary position in orbit, these future lightning sensors would provide continuous coverage of the continental United States, nearby oceans and parts of Central America. Researchers hope that future sensors will deliver day and night lightning information to a forecaster's work-station within 30 seconds of occurrence, providing an invaluable tool for storm "nowcasting" as well as for issuing severe storm warnings.

The lightning detector is a compact combination of optical and electronic elements including a staring imager capable of locating and detecting lightning within individual storms. The imager's field of view allows the sensor to observe a point on the Earth or a cloud for 80 seconds, a sufficient time to estimate the flashing rate, which tells researchers whether a storm is growing or decaying.

The sensor was developed by the Global Hydrology Center at NASA's Marshall Space Flight Center in Huntsville, Ala., http://www.ghcc.msfc.nasa.gov/, in conjunction with Lockheed Martin, Palo Alto, Calif., and Kaiser Electro Optics, Carlsbad, Calif. The sensor provides information on cloud characteristics, storm dynamics, and seasonal as well as yearly variability of thunderstorms.

The Lightning Imaging Sensor will be three times more sensitive than a predecessor instrument known as the Optical Transient Detector, a lightning detector already orbiting the Earth. The sensor studies both day and night cloud-to-ground, cloud-to-cloud and intra-cloud lightning and its distribution around the globe.

The staring imager is made of an expanded optics lens system which provides a wide field of view and a narrow-band filter which minimizes background light. A highspeed, charge-coupled device detection array behaves similarly to the retina of the human eye by creating an image of the lightning event and the background scene. A real-time event processor then extracts the signal, thus determining when a lightning flash occurs.

The optics lens system allows lightning detection even in the presence of bright, sunlit clouds. Weak lightning signals that occur during the day are hard to detect because of background illumination. This system will remove the background signal, enabling the detection of 90% of all lightning strikes. Data recorded includes the time of a lightning event; its radiant energy; how bright the lightning flash is; and an estimate of the lightning location.

The Lightning Imaging Sensor is approximately eight inches (20 centimeters) in diameter and 14 inches (35.5 centimeters) high, while the supporting electronics package is about the size of a standard typewriter. Together, the two modules weigh approximately 46 pounds (21 kilograms) and use about 25 watts of power.

Conclusion

The TRMM satellite was decommissioned late in 2004. A highly successful scientific research mission, TRMM has provided data used worldwide in the monitoring and forecasting of hazardous weather on a demonstration basis. Originally intended to be a three-year mission when launched in 1997, the mission was extended for an additional four years. The extension of mission operations for four additional years was made possible through NASA's efficient management of available resources, technical innovations, and substantial additional funding.

"TRMM has been an outstanding example of scientific success and U.S.-Japanese collaboration in conducting Earth observations from space. The unique TRMM precipitation observations have led to new knowledge concerning the Earth's hydrological cycle and its variation," said NASA's Associate Administrator for Earth Science Dr. Ghassem Asrar. " We now look forward to continued cooperation with our Japanese partners on the Global Precipitation Measurement mission, that will build on the TRMM legacy," he added.

In 1998 TRMM observed Hurricane Bonnie and captured for the first time "sky scrapper" storm clouds towering some 59,000 feet (17,983 meters) above the ocean — an event scientists believe may have represented a precursor to storm intensification.

In August 2001, TRMM was boosted from an altitude of 350 kilometers (217.5 miles) to a higher 402 kilometer (250 mile) orbit to extend its life. This maneuver successfully reduced atmospheric drag on the spacecraft during a period of high solar activity and increased TRMM's life by two years while maintaining the high quality of its scientific observations. NASA also developed a technique to extend TRMM's life by using atmospheric drag, rather than fuel, to lower the spacecraft's altitude in the early stages of the controlled de-orbit process.

NASA and the Japanese Space Program (JAXA) will continue close collaboration by establishing a new advanced capability for the measurement of precipitation globally with the Global Precipitation Measurement

mission (GPM). The partnership will launch GPM's Core Satellite by the end of the decade.

This complex and pioneering international satellite constellation is a prototype for the comprehensive, coordinated, and sustained Earth observation system envisioned by the international Group on Earth Observations (GEO) framework. The GPM main satellite is planned to carry advanced, dual-frequency radar that will exceed the capabilities of TRMM's radar. This radar will be capable of making measurements of light rain and frozen precipitation present in higher latitudes in addition to the heavier rain present in the tropics.

In addition, GPM will comprise an international constellation of satellites to measure precipitation globally approximately every three hours; TRMM is limited to conducting less frequent observations at tropical latitudes. GPM will use an extensive ground validation network to further improve the accuracy of its measurements compared to those made by TRMM.

For more information about GPM see http://gpm.gsfc.nasa.gov/.

TROPICAL RAINY CLIMATE. See **Climate**.

TROPICAL SAVANNA CLIMATE. See **Climate**.

TROPICAL STORM. See **Fronts and Storms**.

TROPICAL WIND ENERGY CONVERSION AND REFERENCE LEVEL (TWERLE). See **Nimbus Satellite Program**.

TROPICAL YEAR. The period of one revolution of the Earth around the Sun, with respect to the vernal equinox. Because of precession of the equinoxes, the tropical year is not 360 degrees with respect to the stars, but 50 minutes 0.3 seconds less. A tropical year is about 20 minutes shorter than a sidereal year, averaging 365 days 5 hours 48 minutes 45.68 seconds in 1955 and is increasing at the rate of 0.005305 second annually. Also called *astronomical, equinoctial, natural*, or *solar year*.

TROPISM (Zoology). An unavoidable response of an animal to some environmental stimulus involving the orientation of the body in relation to the causative factor. In very simple animals this type of reaction is common. Protozoans, for example, may always move toward or away from light, and even animals with organized nervous systems may have some nerve paths associated in such a way that a given condition always evokes the same reaction. This type of response is also called a taxis, a term applied to the responses made without a nervous system and at the other extreme to simple reflexes, which may be nervously intricate although they are automatic.

TROPOPAUSE. The boundary between the troposphere and stratosphere, usually characterized by an abrupt change of lapse rate. The change is in the direction of increased atmospheric stability from regions below to regions above the tropopause. Its height varies from 15 to 20 kilometers (9 to 12 miles) in the Tropics to about 10 kilometers (6 miles) in polar regions. In polar regions in winter it is often difficult or impossible to determine just where the tropopause lies, since under some conditions there is no abrupt change in lapse rate at any height. It has become apparent that the tropopause consists of several discrete, overlapping "leaves," a multiple tropopause, rather than a single continuous surface. In general, the leaves descend, step-wise, from the equator to the poles. See also **Atmosphere (Earth)**.

TROPOSPHERE. That portion of the atmosphere from the earth's surface to the tropopause; that is, the lowest 10–20 kilometers (6–12 miles) of the atmosphere; the portion of the atmosphere where most weather occurs. The troposphere is characterized by decreasing temperature with height, appreciable vertical wind motion, appreciable water vapor, and weather. Dynamically, the troposphere can be divided into the following layers: surface boundary layer, Ekman layer, and free atmosphere. See also **Atmosphere (Earth)**.

TROPOSPHERIC OZONE. The troposphere (the region of the atmosphere <15 km (9 miles) contains organic and inorganic compounds that are introduced into the atmosphere via biogenic and anthropogenic sources. The troposphere also contains small amounts of ozone that is formed by photochemical oxidation of CO and hydrocarbons catalyzed by $HO_x(HO + HO_2)$ and $NO_x(NO + NO_2)$. Efforts are underway to determine how much stratospheric ozone drifts down to the upper troposphere [Marcy and co-workers, 2004 and Olsen, Schoeberl, and Douglas, 2004]. Although only ~10% of the atmospheric ozone is present in the troposphere, this small fraction plays a fundamental role in atmospheric chemistry because it is an initiator (via formation of hydroxyl radicals), a reactant, and a product in tropospheric oxidation chemistry. Generally, the concentration of pollutants is prevented from building-up to excessive levels due to their oxidation by the small concentration of hydroxyl radicals. However, in urban areas the concentrations of pollutants and ozone are appreciably higher than in remote areas due to contributions from fossil fuel burning and exhaust from internal combustion engines, which can result in so-called photochemical smog.

Photochemical Smog. Although the naturally occurring concentration of ozone at the earth's surface is very low, this distribution has been altered by the emission of anthropogenic pollutants which increase the production of ozone via the above mechanism. Photochemical smog, an aerosol irritant gas mixture, occurs in urban industrialized areas where heavy motor vehicle traffic is common, especially those areas where temperature inversions are common (e.g., Denver, Los Angeles, Washington, DC., and Mexico City). It forms at low altitudes by photolytic reactions involving nonmethane hydrocarbons, NO, and CO, resulting in low but potentially harmful concentrations of ozone and other irritating substances, such as aldehydes, ketones, acids, H_2O_2, organic peroxides, and peroxyacetyl nitrate.

Factors Affecting Background Ozone. The ambient ozone concentration depends on cloud cover, time of day and year, and geographical location. Although the background concentration of ozone in surface air is ~0.01–0.03 ppm, during severe smog days in the Los Angeles area, eg, it has often reached 0.5 ppm, and a maximum of 1 ppm in 1957. The main automobile exhaust pollutants (CO, NO, and hydrocarbons) peak at ~7 a.m. in Los Angeles, coinciding with the morning rush hour traffic [Heicklen, 1976]; the concentrations of nitrogen dioxide and ozone reach a maximum ~3 and 5 h later, respectively. While NO is largely oxidized in 4–5 h, NO_2 and O_3 persist over longer time spans. The initial buildup of CO and hydrocarbons is followed by a slow decline as they are oxidized. Maximum concentrations of organic oxidation products (eg, aldehydes, organo nitrates) tend to roughly coincide with the ozone maximum. The evening rush hour traffic does not produce much smog primarily because the inversion layer has undergone considerable thermal expansion and the sunlight intensity is weaker and soon disappears. By sundown, the concentration of ozone has fallen to very low levels. Nights are normally free of smog. In the early morning hours, NO is removed slowly by the oxygen atom chain, which is initiated by the photolysis of NO_2 and subsequently by the photolysis of ozone. Later in the day when the light intensity is higher, the hydroxyl chain causes the NO conversion to accelerate.

Oxidation Chemistry

Daytime. The primary source of hydroxyl radicals in the troposphere is reaction of electronically excited O atoms formed by photolysis of ozone with water vapor.

Nighttime. Despite the absence of sunlight, oxidation chemistry still occurs. Although oxidation of NO by O_2 is very slow, ozone rapidly

converts NO to NO_2, which is slowly oxidized to nitrate radicals by ozone: $NO_2 + O_3 \rightarrow NO_3 + O_2$

Halogen. Inorganic chlorine and bromine radicals and compounds similar to those in the stratosphere are present in the troposphere and are formed by oxidation of halocarbons (e.g., CH_3Cl and CH_3Br), however, their chemistry is relatively unimportant. By contrast, significant ozone depletions in high northern latitudes observed during the spring have been attributed to enhanced levels of chlorine and bromine formed in the gas phase in heterogeneous reactions involving seasalt aerosols.

TROUGH. In meteorology, an elongated area of relatively low atmospheric pressure; the opposite of a ridge. The axis of a trough is the trough line. This term is commonly used to distinguish the previous condition from the closed circulation of a low (or cyclone), but a large-scale trough may include one or more lows, an upper-air trough may be associated with a lower-level low, and a low may have one or more distinct troughs radiating from it. See also **Atmosphere (Earth)**; and **Fronts and Storms**.

TROUT *(Osteichthyes).* Of the order *Isospondyli*, family *Salmonidae*, the trout is well known as an excellent food as well as sporting fish. The salmon is also a member of the same family. Trout prefer cold and temperate waters, preferring a range from 50 to 65 °F (10 to 18 °C). They are found in freshwater lakes and streams, but a few species frequent salt water. Trout vary greatly in size and to a slight extent in game qualities. The scales are minute to small and the flesh is superior.

Trout are common in streams of the Northern Hemisphere and have been widely transported for stocking other than their native waters. The brook or speckled trout, *Salvelinus fontinalis*, is the most widely distributed species, ranging from Maine to the Dakotas and northward throughout the continent. Rainbow trout, *Salmo* (*Trutta*) *iridea*, from the West Coast, are now widely stocked in other waters, and, in places where trout fishing is important, imported species, including the European brown trout, *T. trutta*, and the Lochleven trout, are to be expected. The group includes almost two score of species in North America alone, many without common names other than trout while others are called red-fish, green-back, steel-head, blue-back, saibling, and yellow-fin. The lake trouts live in deep water and attain great weight. The mackinaw or common lake trout has been recorded up to 90 pounds (41 kilograms).

In North America the relative merits of the trout and bass as game fishes will probably always remain a matter of opinion. Trout fishing with the fly rod has long been regarded as the aristocrat of piscatorial sports, next to salmon fishing, which is less widely available, but the small-mouth bass has many devotees as a fish for the fly rod and its superiority to the trout is often loyally maintained.

The greenback is a species of trout (*Trutta smaragada*) reported from the headwaters of the Arkansas and South Platte rivers. The Tahoe trout (*Trutta henshawi*), also known as redfish, is found in streams and lakes on the eastern slope of the Sierra Nevada Mountains. The saibling is a fish related to the trout. The name has been applied to a species of charr found in mountain lakes of central Europe (*Salvelinus salvelinus*), and in North America to the introduced European trout (*S. alpinus*), a usage also found to some extent in Europe. A related species (*S. aureolis*), found in lakes of the northeastern states is called the American saibling. The name is also spelled saebling. The charr is a lake fish of the British Isles related to the trout. The trout-perch is a common fish of the Great Lakes and the rivers of the eastern half of the United States, but rare in the South. It attains a maximum length of about 10 inches (25 centimeters), with scales like the perches; otherwise similar to the trout.

The spawning habits of the trout are similar in many respects to those of the salmon. See also **Salmon (Osteichthyes)**. However, whereas the Pacific salmon dies shortly after spawning, many species of trout may spawn for a number of years.

TRUE MEAN TEMPERATURE. As adopted by the International Meteorological Organization, a monthly or annual mean of air temperature based upon hourly observations at a given place, or on some combination of less frequent observations designed to represent this mean as nearly as possible. See also **Mean Temperature**.

TRUE NORTH. The direction from any point on the earth's surface toward the geographic North Pole; the northerly direction along any projection of the earth's axis upon the earth's surface, for example, along a longitude line.

Except for much of navigational practice (which uses magnetic north), true north is the universal 0° (or 360°) mapping reference. True north differs from magnetic north by the magnetic declination at that geographic point.

The direction of true north is marked in the skies by the celestial north pole. For most practical purposes, this is the position of Polaris. However, due to the precession of the Earth's axis, true north rotates in an arc that takes approximately 25,000 years to complete. Currently, in 2002, Polaris is at its closest approach to the celestial north pole. 2,000 years ago, the closest star to the celestial north pole was Thuban.

On maps issued by the United States Geological Survey, and the U.S. military, true north is marked with a line terminating in a five-pointed star. Maps issued by the Ordnance Survey http://www.ordnancesurvey.co.uk/oswebsite/, contain a diagram showing the difference between true north, grid north and magnetic north at a point on the sheet. See also **North**.

TRUE WIND DIRECTION. See **Winds and Air Movement**.

TRUNCATION. The process of approximating the sum of an infinite series by the sum of a finite number of terms in that series. As applied to the dropping of digits in a number, truncation contrasts with rounding.

TRUNCATION ERROR. The error caused by dropping all but a finite number of terms from a possibly infinite series, but often applied to the error due to representing the limit of a sequence by one of its terms, or to representing a function by an interpolation polynomial.

TRUNCUS ARTERIOSUS. The great arterial vessel leading from the heart of vertebrates in the primitive unpaired condition and in the embryo. All blood leaving the heart passes through this vessel, which is differentiated to form the conus arteriosus and the ventral aorta in the fishes and persists as a short trunk in the amphibians. In the reptiles its subdivision to form the aorta and the pulmonary artery is begun and in the birds and mammals this splitting is complete. The truncus is divided by the growth of a pair of ridges in a spiral course along opposite walls. These ridges unite to form a partition.

TRUNK. 1. The body of a vertebrate, bearing the neck and head at one end and the tail at the other, with the two pairs of appendages attached laterally or ventrolaterally near the two ends. The trunk contains the body cavity in which the viscera lie, and is supported by the vertebral column and the ribs. It is divisible into an anterior thorax and a posterior abdomen.

2. The proboscis of the elephant.

TRUSS. A framed structure composed of a series of adjoining triangles which are formed by straight members, all lying in one plane. The members are connected at their points of intersection by pins or gusset plates or by welding. The point of intersection is called a panel point or joint. Since rigidity of the truss is secured by triangles which cannot deform without changing the length of the sides, it is generally assumed that loads applied at the panel points will produce direct stress only. This will be true if the gravity axes of the members meet at the panel points and if the members are considered connected by means of frictionless pins. Actually, since the joints are rigid, bending stresses due to the deflection of the panel points are also developed. These stresses are commonly called secondary stresses. If a load is applied to a member between the panel points it must distribute the load by beam action to the adjacent panel points. The top line of members of a truss is called the top chord and the lower line is known as the lower or bottom chord. The members connecting the top and bottom chords are called web members. The span of the truss is the horizontal distance center to center of end bearings. See Fig. 1.

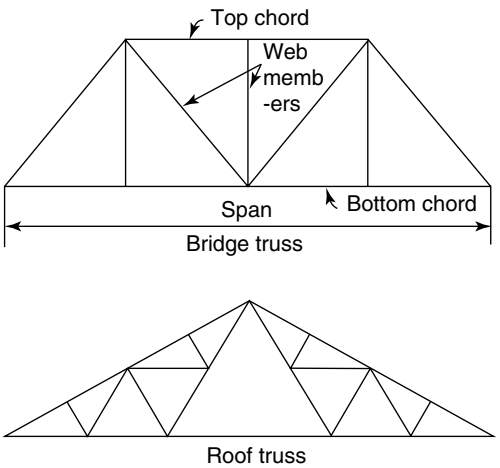

Fig. 1. Types of trusses.

Truss bridges consist of two or more parallel vertical trusses, which support the floor system. The lateral bracing in the plane of the top and bottom chords of bridges form the web members of horizontal trusses. A roof truss is one that supports the roof of a building. Trusses are also used over auditoriums to carry the loads from the floors above. The members of a truss are usually made of steel or wood, although concrete trusses are sometimes used. Steel has the advantage over wood in that it has far greater strength and is less subject to deterioration, but the latter is frequently used for temporary structures. See also **Bridge (Structural)**.

TRYPANOSOMIASIS. Trypanosomes are ubiquitous protozoan parasites of vertebrates transmitted by bloodsucking arthropod or leech vectors. The species *Trypanosoma brucei* and *T. cruzi* infect humans and cause the diseases known as sleeping sickness or African human trypanosomiasis and Chaga's disease, respectively. Sleeping sickness is restricted to sub Saharan Africa, while Chaga's disease occurs in the New World from Mexico to Argentina. Both diseases are zoonoses; that is, the infectious agent is naturally transmitted between animal reservoir hosts and humans. Insect vectors maintain the cycle of transmission between the human and reservoir hosts, tsetse flies in the case of sleeping sickness and triatomine bugs in the case of Chaga's disease (Table 1). Vector control by insecticides or other measures is thus an important line of public health defense. Sleeping sickness is fatal if untreated; current drugs are unsatisfactory due to high toxicity and a range of unpleasant side effects. Chaga's disease can be treated with variable success in the early, acute phase, but available drugs have high toxicity and unpleasant side effects. A proportion (∼30%) of those infected go on to develop chronic, inflammatory disease, perhaps many years after the original acute episode. This phase of the disease is characterized by myocarditis and "mega syndromes," gross dilation of the oesophagus or colon. Chronic invalidity ensues and the disease is incurable, relieved only by surgical intervention.

Occurrence, Epidemiology. Both the human trypanosomiasis are tropical diseases. Sleeping sickness occurs in 36 countries in sub Saharan Africa and an estimated 60 million people are at risk of the disease according to the World Health Organization (WHO). In 2001, WHO estimated that there were 300,000–500,000 cases of sleeping sickness per year, a figure 10 times greater than the number of cases actually reported (http://www.who.int/mediacentre/factsheets/fs259/en/). Sleeping sickness is essentially a rural rather than urban disease, and often goes unreported because of the lack of health infrastructure in more remote regions. Epidemics can flare up if routine medical surveillance and control measures break down. For example, ongoing epidemics in Angola, the Democratic Republic of Congo and Sudan have greatly increased the numbers of cases reported. Chaga's disease occurs in the Americas affecting 21 countries stretching from Mexico to Argentina (http://www.who.int/ctd/chagas/disease.htm). Traditionally a rural disease, urban dwellers also became increasingly affected through the use of unscreened blood for transfusion. WHO estimates that around 100 million people are at risk of the disease and 16–18 million people are infected (prevalence) (http://www.who.int/ctd/chagas/disease.htm).

The human trypanosomiasis are zoonoses. Both wild and domestic animals act as reservoir hosts of sleeping sickness. In the past, sporadic cases of sleeping sickness in those visiting areas of East and Southern Africa inhabited only by wild animals indicated that these animals acted as reservoir hosts, and the bushbuck was proved to harbor human-infective trypanosomes by experimental inoculation of volunteers in 1958. This pattern of infection still persists today, with occasional cases reported in overseas visitors to wildlife parks in East Africa). However, infected domestic animals, such as cattle, now appear to pose a greater risk of trypanosome transmission to humans, because of their abundance and proximity. In West Africa, since *T. brucei gambiense* infection is of

TABLE 1. SUMMARY OF THE DIFFERENCES BETWEEN THE HUMAN TRYPANOSOMIASIS

Diseasye	Distribution	Causative agent	Insect vector	Mode of transmission
Human African trypanosomiasis, sleeping, sickness,	Tropical Africa	*T. brucei*, *gambiense*, *T. b. rhodesiense*	Tsetse flies (genus *Glossina*)	Inoculation of infective forms via saliva
American trypanosomiasis, Chaga's disease	Central and South America	*T. cruzi*	Triatomine bugs	Contamination with infective forms in bug faeces

long duration, many believed that the reservoir of infection in humans was adequate to maintain disease transmission. However, biochemical characterization of trypanosome strains showed that pigs and other domestic and wild mammals harbored identical trypanosomes to those found in humans.

T. cruzi infects a wide range of mammals. Infected animals that sleep in the house, e.g. dogs, pose a particular threat, as they are bitten by the same bugs that bite humans. Opossums (*Didelphis* sp.) are considered to be important sylvatic reservoir hosts, as they tolerate infection and often build nests in or near houses. See also **African Trypanosomiasis**; and **Chaga's Disease (South American Trypanosomiasis)**.

T SECTION. A two-part network having two series arms and one shunt arm, as shown in Fig. 1. The symmetrical T section is one in which the series arms are similar. The T section two-part may be replaced by the equivalent Pi section two-part, shown in Fig. 2, by means of the following conversion formulas:

$$Y_1 = Z_1/\Delta_z$$
$$Y_2 = Z_2/\Delta_z$$
$$Y_3 = Z_3/\Delta_z$$

where $\Delta_z = Z_1Z_2 + Z_2Z_3 + Z_1Z_3$.

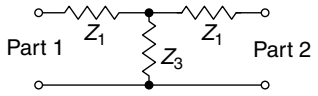

Fig. 1. T section.

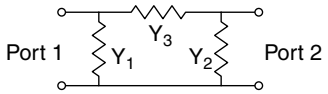

Fig. 2. Equivalent pi section.

TSETSE FLY *(Insecta, Diptera; Glossina)*. The unique viviparous genus Glossina contains some 30 species and subspecies, currently confined to tropical Africa between the latitudes of 15 °N and 30 °S. An isolated population was once known in southwestern Arabia and this, together with several fossil species, suggests that the distribution of the species was once considerably larger. Even so, the flies occupy roughly half the continent of Africa and are vectors of the trypanosome causing sleeping sickness in humans and various syndromes in other animals.

The tsetse fly is related to the house and stable flies of the North American continent. They are large, brown to grayish, narrow bodied, 6–15 mm long, with a stout proboscis projecting forward, well in front of the head. Except during the act of biting, the proboscis is adjoined laterally by labial palps, which enclose a space, the food canal, through which blood is sucked into the alimentary canal. Although plant juice has been imbibed by the tsetse fly, most of the species feed exclusively on the blood of vertebrates.

Three species groups are recognized — the *fusca*, the *palpalis*, and the *morsitans*. Characteristically, the fusca group is associated with dense, humid tropical forest or forest edges. Palpalis flies are dependent on more or less dense riverine or lacustrine vegetation, but their distribution extends into savanna zones well away from forested areas. The morsitans are the least hygrophilic and occupy bushland and thicket vegetation often far from lakes and rivers.

Tsetse flies have a method of viviparous reproduction, uncommon among higher insects, by which a single larva is produced at a time and is retained and nourished with the body of the female fly to the third instar state, at which time it is extruded by the mother into the ground, where it begins to pupariate. After a quiescent period, the fly, in its teneral state, seeks its first blood meal and then normally feeds at intervals of 3–4 days, dying of starvation if denied blood for longer than 12 days. The average life span of a female *Glossina* is 2 to 3 months and the males have a much shorter life span.

Although flies of the fusca group are vectors of trypanosomes pathogenic to livestock, they never have been associated with the transmission of trypanosomiasis to humans. Species of the palpalis and morsitans groups are active only during daylight hours, with flight and feeding activities decreasing markedly during dull and overcast weather. They hunt their prey mainly by sight, seeking moving, dark colors rather than light, with scent becoming increasingly important at close range.

In natural circumstances where there is no close contact with humans or domestic animals, flies of the palpalis group show preference for feeding on large reptiles, such as monitor lizards and crocodiles. Where humans and animals are available, they are attacked readily and become a major source of food. Sharp outbreaks of sleeping sickness are likely to occur where humans and cattle and small populations of flies tend to depend upon the same limited water supplies.

Infective metacyclic trypanosomes are found in the salivary glands of the tsetse fly. They undergo a complex migration in the fly, which takes about three weeks to complete. It follows that only flies more than three weeks old can be vectors of trypanosomes infective to humans.

The subject of tsetse fly control is a large one and beyond the scope of this article. References given pertain to this. Vaccines have not been effective in treating sleeping sickness because of the ability of the trypanosomes to vary their surface antigens.

University of South Florida, Tampa, FL

TSIOLKOVSKY, KONSTANTIN E. (1857–1935). Konstantin Eduardovich Tsiolkovsky was a Russian and Soviet rocket scientist and pioneer of cosmonautics. He was born at Izhevskoye (now in Spassky District, Ryazan Oblast), Russia in a middle-class Polish family. His formal education was terminated tragically at age ten when he suffered a near-total hearing loss from scarlet fever. Unwilling to accept defeat by his handicap, he began to educate himself at home. His extraordinary success at this venture was recognized by his family who then sent him to Moscow to complete his education. Because of his proficiency in mathematics and the sciences, he eventually won a teaching post at Kaluga.

Nearly deaf, he worked as a high school mathematics teacher until retiring in 1920. Tsiolkovsky theorized many aspects of space travel and rocket propulsion. He is considered the father of human space flight and the first man to conceive the space elevator, after visiting Paris in 1895 and becoming inspired by the newly-constructed Eiffel Tower. His most famous work was *(The Exploration of Cosmic Space by Means of Reaction Devices)*, which published in 1903 was arguably the first academic treatise on rocketry. Tsiolkovsky first calculated that the escape velocity from the Earth into orbit was 8 km/second and that to achieve this, a multi-stage rocket fueled by liquid oxygen and liquid hydrogen was required. During his lifetime he published over 500 works on space travel and related subjects, including science fiction novels. Among his works are designs for rockets with steering thrusters, multi-stage boosters, space stations, airlocks for exiting a spaceship into the vacuum of space, and closed cycle biological systems to provide food and oxygen for space colonies. Unfortunately his ideas never made it out of Russia, and the field lagged

until German and other scientists independently made the same calculations decades later.

His work influenced later rocketeers throughout Europe, and was also studied by the Americans in the 1950s and 1960s as they sought to understand the Soviet Union's early successes in space flight.

Konstantin Tsiolkovsky is generally considered the father of astronautics and rocket dynamics. Entering the world more than one hundred years before Sputnik became the first object rocketed into space, he prepared the way for it and all space exploration that followed. See also **Launch Vehicles: Russian**; and **Rocketry**.

TSUGA. See **Hemlock Trees**.

TSUNAMI. (also called Seismic Sea Wave, and popularly, Tidal Wave). An ocean wave produced by a submarine earthquake, landslide, or volcanic eruption. These waves may reach enormous dimensions and have sufficient energy to travel across entire oceans. From the area of the disturbance, the waves will travel outward in all directions, much like the ripples caused by throwing a rock into a pond. The time between wave crests may be from 5 to 90 minutes, and the wave speed in the open ocean will average 450 miles per hour.

Tsunamis reaching heights of more than 100 feet have been recorded. As the waves approach the shallow coastal waters, they appear normal and the speed decreases. Then as the tsunami nears the coastline, it may grow to great height and smash into the shore, causing much destruction.

1. Tsunamis are caused by an underwater disturbance — usually an undersea earthquake. Landslides, volcanic eruptions, and even meteorites can also generate a tsunami.
2. Tsunamis can originate hundreds or even thousands of miles away from coastal areas. Local geography may intensify the effect of a tsunami. Areas at greatest risk are less than 50 feet above sea level and within one mile of the shoreline.
3. People who are near the seashore during a strong earthquake should listen to a radio for a tsunami warning and be ready to evacuate at once to higher ground.
4. Rapid changes in the water level are an indication of an approaching tsunami.
5. Tsunamis arrive as a series of successive "crests" (high water levels) and "troughs" (low water levels). These successive crests and troughs can occur anywhere from 5 to 90 minutes apart. They usually occur 10 to 45 minutes apart.

The Tsunami Warning System, a cooperative international organization and operated by the United States Weather Service, has been in operation since the 1940s. The headquarters of the center is located in Hawaii. An associated Alaska Regional Tsunami Warning System is located in Alaska. Tsunami prediction essentially commences with earthquake monitoring and prediction information. Inputs from these systems (see also **Earth Tectonics and Earthquakes**) are linked with information from a series of tide monitoring installations. Locations of tide stations and of seismograph stations in the Tsunami Warning System are shown in Fig. 1.

When inputs indicate conditions are favorable for a tsunami, a watch is issued for the probable affected area. Warnings are issued when readings from various tidal stations appear to match the seismographic information. Because of the complexity of the factors involved and a large degree of uncertainty nearly always present, there is a tendency to issue watches and warnings as a safety precaution even though a tidal wave of significance may not later develop. Unfortunately, after awhile, persons in likely areas to be affected grow callous to watches and tend to ignore them. A tsunami that hit Hilo, Hawaii in 1960 killed 60 residents even though they had been warned of the coming event an ample 6 hours in advance of the strike.

In the late 1970s, scientists suggested an improved method for making tsunami predictions. For a number of years, specialists have suggested that better analysis and interpretation of seismic waves produced by earthquakes may improve the prediction of tsunamis. Seismic waves range from very short-period waves that result from the sharp snap of rocks under high stress to very long-period waves, due mainly to the slower movements of large sections of the ocean floor. Many researchers believe that tsunamis result mainly from the vertical movement of these large blocks, this leading to a tentative conclusion that the strength of seismic waves of very long

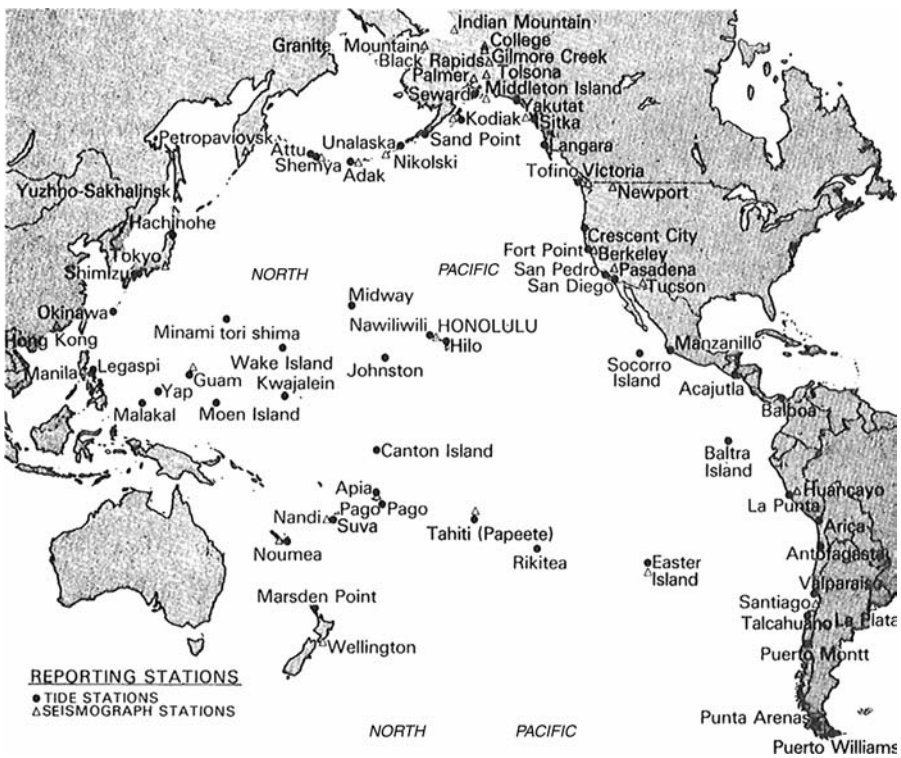

Fig. 1. Network of tide and seismograph stations that are part of the Tsunami Warning System, headquartered in Hawaii. (*National Oceanic and Atmospheric Administration*.)

period may be the best criterion for an earthquake's ability to generate a tsunami.

Part of the problem is that most seismographs installed in the system are not very sensitive to very long-period waves and thus a given earthquake cannot be analyzed effectively in terms of its potential for producing a tsunami. Equipment has been refined so that today, shorter period waves are used to locate an earthquake and 20-second waves are used to calculate the magnitude. However, some scientists feel that the true magnitude of some earthquakes can only be determined by measuring the characteristics of longer waves, such as 100-second waves. Brune and Kanamori (University of California at San Diego) have observed that the Chilean earthquake of 1960 had a magnitude of 8.3 when calculated on the basis of 20-second waves, but its magnitude was 9.5, or more than 10 times larger in wave amplitude and more than 60 times larger in energy released, when calculated by Kanamori's method, which attempts to include the energy release represented by very long-period seismic waves. Other scientists are coming to the viewpoint that many warnings could be omitted if predictions were based upon longer waves. Two of the first long-period seismographs incorporated in the Tsunami Warning System were installed in Hawaii and on the Russian island of Yuzhno-Sakhalinsk, which is northeast of Vladivostok. Later an installation was made at the Alaska Warning Center in Palmer. Whether or not the latest reasoning proves successful must await a number of years of experience with the earthquakes of the future and the resulting tsunamis.

Continuing Tsunami Research. During the 2000s, research pertaining to the fundamentals of tsunamis and the development of mathematical models of the phenomenon continues. Considerable attention is being directed to specific regions, including the west coasts of Mexico and Chile, the southwestern shelf of Kamchatka (Russia) and, in the United States, the generation of tsunamis in the Alaskan bight and in the Cascadia Subduction Zone off the west coasts of Washington (Puget Sound) and Oregon.

Research also is being directed toward the development of simple and more economic warning systems, particularly in the interest of the developing countries, the coasts of which border on the Pacific Ocean.

The Tsunami Warning System previously described requires millions of dollars for equipment, maintenance, and operation, well beyond the means of some countries. Also, some scientists believe that more localized equipment installations could possibly serve local shore communities better while costing less. These observations, however, do not challenge the need and validity for the larger tsunami network. The National Oceanic and Atmospheric Administration (NOAA) has developed a system costing in the range of $20,000 that can be installed and operated by non experts. The system has been undergoing trials at Valparaiso, Chile, a city that has been struck by nearly 20 tsunamis within the past two centuries. A sensor (accelerometer) is installed in bedrock under the city and can measure tectonic activity in excess of 7.0 on the Richter scale. These measurements are interlocked with level sensors.

Researchers B.F. Atwater and A.L. Moore (University of Washington), in their attempts to model earthquake and tsunami activity in the area over the last thousand years, have reported what they believe to have been a large earthquake on the Seattle fault some time between 1000 and 1100 years ago. The researchers report, "Water surged from Puget Sound, overrunning tidal marshes and mantling them with centimeters of sand. One overrun site is 10 km northwest of downtown Seattle; another is on Whidbey Island, some 30 km farther north. Neither site has been widely mantled with sand at any other time in the past 2000 years. Deposition of the sand coincided — to the year or less — with abrupt, probably tectonic subsidence at the Seattle site and with landsliding into nearby Lake Washington. These findings show that a tsunami was generated in Puget Sound, and they tend to confirm that a large shallow earthquake occurred in the Seattle area about 1000 years ago."

Simulations of tsunamis from great earthquakes on the Cascadia subduction zone have been carried out by M. Ng, P.H. Leblond, and T.S. Murty (University of British Columbia). A numerical model has been used to simulate and assess the hazards of a tsunami generated by a hypothetical earthquake of magnitude 8.5 associated with rupture of the northern sections of the subduction zone. The model indicates that wave amplitudes on the outer coast are closely related to the magnitude of sea-bottom displacement (5 meters). The researchers observe, "Some amplification, up to a factor of 3, may occur in some coastal embayments. Wave amplitudes in the protected waters of Puget Sound and the Straits of Georgia are predicted to be only about one-fifth of those estimated on the outer coast."

TUATARE *(*or *Tuatera)*. *Reptilia, Rhynchocephalia*. A primitive reptile, *Sphenodon punctatus*, of New Zealand, superficially like the lizards but different in several anatomical details. It is chiefly noteworthy for the high development of the pineal or median eye.

TUBA. See **Clouds and Cloud Formation**.

TUBERCULOSIS. An acute inflammation of the lungs, meninges, pericardium, kidneys, genitals, bones, or lymph system caused by invasion of one or more of these organs by *Mycobacterium tuberculosis*, a long, slender, rod-shaped bacterium. By far the organ most frequently affected is the lung.

Because *M. tuberculosis* is highly adapted to humans and has no reservoir in nature, people are the reservoir for human tuberculosis. Since the virtual elimination of bovine tuberculosis in the United States many years ago, the disease is contracted via person-to-person transmission. Patients with active pulmonary infection shed infected airborne droplets into the environment. Usually close, continued contact is required to spread the disease and hence it tends to occur among members of the same household, schoolmates, persons participating in car pools, and others in similar close conditions. Operators of nursing homes for the elderly must constantly be aware of the presence of *M. tuberculosis*.

With the exception of patients whose immune system is compromised, as in AIDS or infection with the human immunodeficiency virus (HIV), the prognosis of pulmonary tuberculosis is excellent where chemotherapy is commenced as soon as possible after the disease has been positively diagnosed. The principal antitubercular chemotherapeutic agent is *isoniazid*, although rifampin, streptomycin, and ethambutol also are used. Secondary drugs, including para -aminosalicylic acid, pyrazinamide, ethionamide, and cycloserine, are less frequently used. All of these are oral drugs. Also

available for parenteral administration are kanamycin, viomycin, and capreomycin.

If the disease is left untreated, very serious complications can occur. Sometimes patients are hospitalized during the initial stages of therapy. The administration of drugs for about two weeks usually markedly reduces the ability of the patient to infect others. Persons with nonpulmonary tuberculosis are considerably less infectious than those with the pulmonary form and thus sometimes can be managed entirely as outpatients.

About 10% of newly recognized cases of tuberculosis are *extrapulmonary*. About half of such patients will have entirely normal chest x-rays; the others will show evidence of inactive pulmonary disease.

The most definitive test for diagnosing tuberculosis is a culture. *M. tuberculosis* grows slowly, and the results of a culture test may require from 3 to 6 weeks. An early morning sputum collection is the best source for performing the test. A number of parallel tests should be made to differentiate *M. tuberculosis* from other mycobacterial species. The initial choice for diagnosis may be a skin test. The Mantoux test involves the careful intradermal administration of a purified protein derivative, which is stabilized by including a polysorbate detergent in the diluent. Palpable induration of over 10 millimeters occurring 48 hours after administration is considered a positive indication of tuberculosis infection, but not necessarily of *active* TB. Also, there are instances where a negative tuberculin test does not exclude a diagnosis of TB.

Unlike the majority of infectious diseases, there is a very long latent period between infection and clinical illness. Initially, the infection usually is found in the lower lung fields. In the alveoli, the bacilli proliferate slowly and, because they do not produce enzymes or toxins, there is little initial inflammatory response. The tuberculin skin test does not become positive for several weeks, at the end of which time cell-mediated immunity has become well established. When this occurs, the majority of bacteria are destroyed, and most persons so infected have a healing of the initial tuberculous lesions. X-rays of such cases may appear normal or indicate focal calcifications. On the other hand, in persons where immunity is incomplete, the bacilli spread the infection. Although the principal site of infection is in the lungs, the bacilli can invade the bloodstream and thus involve other organs, particularly those regions where there is a high blood flow. These include the renal cortex, the vertebral column, and the metaphyseal ends of long bones.

Although many persons with infections may be asymptomatic for a considerable period, the most common symptoms are low-grade fever and nonproductive cough. Notably among patients with reactivated tuberculosis, there is anorexia (loss of appetite), loss of weight, and night sweats. As the disease progresses, there will be low-grade fever, although more severe fever and chills are noted in some cases. Diagnosis can be difficult and requires the assistance of sputum tests and chest x-rays.

Chronology — The Rise, Decline, and Reemergence of TB

Historically, the incidence of tuberculosis has been closely associated with a society's general environment and living conditions. The disease was rampant in crowded city and town conditions of Europe during earlier centuries, where a large percentage of the population was forced to live in squalor and on poor diets. Tuberculosis, particularly the common pulmonary variety, is quite contagious and easily spread by aerosols from the oral and nasal tract. Slowly, during the late 1800s, people were educated by the commonly seen "No Spitting" signs encountered in public places. Because of crowded conditions, TB frequently was encountered in military establishments. The medical profession gradually became aware of how easily TB is spread and consequently public laws required isolation in the form of sanitoriums. Careful regimes for patients were established, and by the 1930s certain surgical procedures were suggested and found limited success. Meticulous care on the part of patients and providers proved successful in reducing the overall mortality of TB.

The first breakthrough occurred with the discovery of antibiotics, several of which were mentioned earlier in this article. These drugs initiated a remarkable decline in mortality, and, at one time, professionals in countries with advanced medical programs were commencing to think in terms of near-eradication of the disease. This optimism, however, did not extend to much of the third world because in many areas sordid living conditions continued, this coupled with inadequate awareness of how contagious TB can be.

The majority of professionals in the field accredited the newly discovered drugs for the success of reducing TB mortality during the 1940s through the 1980s. There is another school of thought that believes that the lower incidence of TB should be attributed more to the buildup of "natural" resistance to *M. tuberculosis* after centuries of exposure to the bacteria. This hypothesis, however, has many more disbelievers than supporters.

The rise of incidence of TB commencing in the mid-1980s generally is attributed to two causes, each of which has had a measurable effect:

1. An increased resistance shown by *M. tuberculosis* to the drugs administered. Current research is illustrating the veracity of this cause.
2. The appearance of the human immunodeficiency virus (HIV) and of AIDS, where the immune system is compromised. This is exacerbated because of the manner in which the presence of TB infection in an otherwise very ill person can be masked for a period of time without positive identification and hence early treatment.

Other possible causes for the increased risk of TB include greater numbers of elderly persons confined in crowded and otherwise unsatisfactory care facilities, the increasing numbers of homeless, or "street people," the immigration of persons from areas where TB is endemic, and the generally unhealthy habits of drug abusers.

TB, HIV, and AIDS. During the 1985–1992 time span, the number of TB cases in the United States rose by nearly 20%. Normally, only 5 to 10% of adults infected with *M. tuberculosis* (as indicated by a positive Mantoux skin test) develop active tuberculosis. Studies have shown, however, that TB, as manifested by a positive skin test, occurs at the rate of 7.9% per year if HIV infection also is present. As pointed out by R. Goodgame, "This is consistent with the observation that active TB is found in 60 percent of Haitians and in over 80 percent of Haitians who have positive skin tests for TB near the time of a diagnosis of AIDS."

Not only does infection with HIV increase the risk of tuberculosis, but there is a growing awareness that the effectiveness of antituberculosis treatment is decreased. Thus, the Centers for Disease Control (CDC) and the American Thoracic Society have recommended that antituberculosis chemotherapy be administered to HIV-infected patients for a minimum of 9 months after organisms have been cleared from the sputum. In a study conducted at the San Francisco General Hospital, it was concluded: "Tuberculosis causes substantial mortality in patients with advanced HIV infection. In patients who comply with the regimen, conventional therapy results in rapid sterilization of sputum, radiographic improvement, and low rates of relapse."

Tuberculosis has been found to be a common result of AIDS in Uganda. This is the result, of course, of the widespread prevalence of *M. tuberculosis* prior to the HIV epidemic. Reactive Mantoux skin tests are noted in from 50 to 60% of unvaccinated adult Ugandans. With over a million adults already HIV-seropositive in the early 1990s, it follows that 50,000 or more cases of HIV-induced active tuberculosis could arise each year, not including the 15,000 or more cases reported before the HIV epidemic. In other areas of the world, other diseases precipitated by HIV and AIDS may include *Pneumocystis carini* rather than TB.

Tuberculosis Meningitis. In 1992, a group of physicians and clinicians in Spain studied the cases of over 2200 patients with tuberculosis. Approximately 25% of the cases had *M. tuberculosis* isolated from the cerebrospinal fluid. The study showed that tuberculous meningitis is a frequent complication of patients with HIV infection in areas of endemic tuberculosis. The study concludes: "HIV-infected patients with tuberculosis are at increased risk for meningitis, but infection with HIV does not appear to change the clinical manifestations or the outcome of tuberculous meningitis."

TB Drug Resistance. In 1992, researchers at London's Hammer-smith Hospital and the Pasteur Institute in Paris described the identification of a mutation that causes *M. tuberculosis* to become resistant to *isoniazid*, the principal drug used to treat the disease. The mechanism described is the deletion of the gene that codes for an enzyme known as *catalase*.

The underlying theory is that isoniazid becomes toxic to *M. tuberculosis* only after it has been converted to another compound because of the presence of catalase. One goal then would be that of finding a way to bypass the catalase conversion step. This fundamental discovery has encouraged other bacterial geneticists to investigate the basis for resistance to other drugs by other bacteria. Since 1990, several clusters of multidrug-resistant tuberculosis have been identified among hospitalized patients with AIDS.

TUFF. Tuff or volcanic tuff is a sedimentary rock, resulting from the partial or complete consolidation of the products of explosive volcanic eruptions. Tuffs may be well sorted and stratified, due to the action of wind or water, or may have an unsorted, heterogeneous character. As particles making up a tuff become coarser the rock grades into an agglomerate.

TUKON HARDNESS TEST. See **Hardness**.

TULAREMIA. An infectious, communicable disease caused by the gram-negative bacillus, *Francisella tularensis*. The agent is harbored by rabbits, squirrels, skunks, mink, rats, foxes, mice, coyotes, as well as some fowl, snakes, and fish. Dogs and cats, although themselves immune to the disease, may harbor the organism and transmit it to humans by bites and scratches. Vectors include mosquitoes, fleas, and ticks. Blood-sucking insects, usually ticks, are the most commonly identified vectors, but exposure to infected animals is also common. Persons who handle rabbit meat and hides assume a risk of becoming infected.

The disease has been reported in many countries in the Northern hemisphere, with about 300 cases reported in the United States each year. These present a bimodal incidence curve attributed to tick bites in the summer and the hunting of rabbits in winter.

The incubation period is 3 days. The disease takes three forms, depending upon site of infection. (1) In *ulceroglandular tularemia*, an ulcerative papule develops within 3–4 days with regional lymph tissue involvement. The lesion may suppurate (discharge pus). Fever may reach 104–105.8 °F (40–41 °C). Headache may be an accompanying feature. Diseases with somewhat similar symptoms include plague, cat-scratch disease, and infectious mononucleosis. (2) *Pulmonary tularemia*, which can precipitate tracheitis, bronchitis, pneumonia, and plural effusions, is characterized by cough and dyspnea. (3) *Enteric infection* usually causes pharyngitis, sometimes with the formation of a gray membrane. Less commonly, there will be abdominal pain, nausea, vomiting, and diarrhea. When the entry site of infection is not apparent, this may indicate that the infection was waterborne.

The usual drug of treatment is streptomycin administered intramuscularly. Tetracycline and chloramphenicol have also been used successfully. Full recovery depends upon the course followed by the disease and, in some cases, can require several weeks. In treated cases, the mortality is low. In untreated cases, fatality is perhaps 5%, although in the pneumonic and septicemic forms it may reach 30%.

The incidence of tularemia in the United States steadily declined from 1950 (approximately 60 cases/year) to a plateau (about 10 cases/year) in 1970 and since. Recent small outbreaks have been associated with ticks.

TULIP TREE. See **Magnolia Trees**.

TUMBLE-BUG *(Insecta, Coleoptera)*. A beetle of the family *Scarabaeidae*, which forms and buries balls of dung. Numerous species of scavengers in this family have the same habit. They are said to use the dung as a supply of food during periods when they remain underground, and also to bury a ball with an egg attached, to provide food for the developing larva. The balls of dung are often much larger than the beetles themselves, and their clumsy maneuvers in rolling their booty to the place where it is to be buried are responsible for the name tumble-bug.

TUMORIGENICITY ASSAYS. Tumorigenicity is defined as the ability of cultured cells to give rise to either benign or malignant progressively growing tumors showing viable and mitotically active cells in immunologically nonresponsive animals over a limited observation period [WHO, 1987].

Tumorigenicity assays are important in very different areas of medicine and biology. For example, when using live cells in the production of vaccines it is important to secure that the cells are nontumorigenic, while in cancer research the ability of a cell line to form tumors is essential for the study of tumor formation and progression.

It is important to keep in mind that the ability of a given cell line to give rise to tumor in an animal is not an absolute property of a cell line but is highly dependent on and defined by the assay in which it is tested. In addition, the potential for false negative results due to immunological or

physiological determinants is certainly possible, while false positive results are not likely to appear.

Outline of Methods

There is a large variety of animal systems suitable for *in vivo* tumorigenesis studies. Animal cell studies are the most easily performed in the corresponding syngeneic strains. Although the use of syngeneic strains of animals is obvious when performing murine tumorigenicity assays, conventional rodents cannot be used to determine the tumorigenicity of human cells. Instead, immunodeficient animals can be used. Several types of animals with either genetic or acquired immunodeficiency exist:

1. Athymic nude mice, which are characterized by lack of functional T lymphocytes [Rygaard]. Almost all transformed human cells will form tumors in these mice.
2. SCID (severe combined immunodeficient) mice with a lack of functional T and B lymphocytes [Bosma, et al.:]: some reports suggest that SCID mice are more susceptible to metastasis formation than are conventional nude mice [Xie, et al.;].
3. Newborn mice, rats or hamsters treated with antithymocyte serum or globulin have a lack of functional T lymphocytes [Furesz, et al.:].
4. Thymectomized and irradiated mice that have been reconstituted with bone marrow from healthy mice (lack of functional T lymphocytes) [Steel, et al.:].
5. *RAG2* mice, which are deficient in the recombinase activating 2 gene, resulting in the failure to generate mature T or B lymphocytes [Shinkai, et al.:].
6. Beige mice carry a mutation that results in cytotoxic T cell and macrophage defects as well as selective impairment of NK cell functions [Talmadge, et al.:].

In addition to the *in vivo* tumorigenicity of a given cell line, information can be obtained about other characteristics associated with the tumorigenic phenotype. For example, cells can be studied under *in vitro* conditions, where the ability of the cells to grow in semisolid media such as soft agar is studied [Levenbrook, et al.:], or where the invasiveness of the cells is studied using inoculation of the cells onto organ cultures. These methods are, in our opinion, certainly helpful in describing additional characteristics of a certain cell line but not adequate when it comes to judging whether a cell line is tumorigenic or not.

When it comes to determining whether a new cell line is tumorigenic, a positive (tumorigenic) cell line has to be included in the experiment, e.g. HeLa, Hep 2 or FL cells, while the inclusion of a negative control cell line should not be necessary but could be helpful in interpreting the results [WHO, 1998]. According to the WHO standards, a new cell line must give rise to a tumour in at least 9 out of 10 mice if the cell line is to be designated as tumorigenic.

Variables to be Considered When Testing Cells for Tumorigenicity

- Types of media for propagating the cells.
- Cells should be in logarithmic growth phase (subconfluent) at the time of the harvest.
- Method of harvesting the cells.
- Site of inoculation and number of cells to be inoculated into the animal. According to WHO a fixed number of cells are to be inoculated [WHO, 1998] whereas other authors use a more differentiated approach, inoculating various number of cells and characterizing the cell lines as high, moderate or low in tumorigenicity, or nontumorigenic [Gurtsevitch and Lenoir].
- Animals should be kept under standardized conditions and handled according to appropriate national animal care and handling guidelines. See also **Animals, Ethics and Treatment in Research**.

Applications

Tumorigenesis assays are important in the testing of continuous cell lines used as substrates in the production of biologicals, such as Vero cells in the preparation of live and inactivated viral vaccines, or the use of CHO cells in the production of recombinant proteins, where it is mandatory that the cells used for production are nontumorigenic. See also **Vaccination**.

Besides being used in describing the characteristics of continuous cell lines (infinite lifespan), the assays are also used in characterization of diploid cell lines (finite lifespan) used for the production of biologicals, such as the human lung cell lines WI-38 and MRC-5 derived from embryos and used in the production of numerous live virus vaccines (oral poliomyelitis, measles, etc.).

In cancer research, tumorigenicity assays can be used to determine the carcinogenic effect of a chemical compound, for example by *in vitro* exposure of the cells in question followed by *in vivo* tumorigenicity testing. In addition, tumorigenicity assays can be used in experiments aiming at elucidating genetic and cellular mechanisms involved in carcinogenesis, including the testing of preventive medicines.

Future Developments

It is now well established that the stromal compartment of a tumor, e.g. fibroblasts, macrophages, endothelial cells, contribute to the malignant phenotype. Thus, the tumorigenicity of a given cell line may also be dependent on the genotype and phenotype of the host animal in which the tumorigenicity assay is performed. To dissect out the involvement of stromal factors, the tumorigenicity assay can be performed in transgenic mice either overexpressing or lacking a certain protein. This can be achieved through the use of the technique of homologous recombination and gene targeting. This has mostly been used in models involving syngeneic animals, but would be important in work with transgenic immunodeficient animals such as the nude mice in order to separate out the importance of the host versus cancer cells in human cell tumorigenicity models.

Summary

Tumorigenesis assays are used in different areas of medicine and biology, including the production of vaccines as well as numerous areas of cancer research. Assays are most easily performed in syngeneic strains of animals, but immunodeficient animals are needed for testing the tumorigenicity of human cells.

In vivo tumorigenesis models will continue to be of importance in the future, although there will probably be a growing requirement for changing animal-based assays to assays that can be performed *in vitro*.

TUNAS *(Osteichthyes).* *Thunnus* and other genera are part of the mackerel family (see also **Mackerels**), but differ so much in their skeletal structure and circulatory system that they were once classified in their own order. The body of the tuna is similar to that of a typical mackerel. Only the pectoral fins and the part of the body posterior to them are covered with small scales. A corselet extends from the back to beneath the rear end of the dorsal fin, and on the belly to behind the pelvic fins. The tail shaft has a median keel. The back is blue-black, the sides are silver-gray, and the belly is white. The front fins are smoky black, and the rear ones are lighter. The finlets behind the second dorsal fin and anal fin are light yellow, with a dark edge. The eyes are enclosed in bony capsules. There is a pair of deep depressions in front of the bones of the rear aspect of the head. A well-developed subcutaneous circulatory system is connected to the vessels of the lateral musculature. Parts of the lateral muscles located on both sides of the vertebral column have a dark red coloration. Another unusual vessel system is located on the inside of the liver and in the tail. This system is responsible for the "warm bloodedness" of tuna. When excited, tuna can have a body temperature of 10.8–21.6 °F (6–12 °C) higher than that of their surroundings.

The most important species of tuna from a commercial standpoint are the *yellow-fin tuna* (*Thunnus albacares*), which accounts for from 25–36% of the total annual catch, varying from one year to the next; the *skipjack tuna* (*Katsuwanus pelanus*), 20–32% of the total catch; the *albacore* (*T. alalunga*), 20–24% of the catch; the *bigeye tuna* (*T. obesus*), 10–16% of the catch; and the *bluefin tuna* (*T. thynnus*), accounting for 11–15% of the total annual catch worldwide.

The great tuna migrations have long been of interest and the subject of numerous marking experiments. A few tuna caught in the Mediterranean have been found to have hooks in their mouths from the Azores; many caught off the coast of Spain have come from Norway. In Norway, tuna are sometimes caught with harpoons, and these harpoons have been found in Mediterranean specimens. Two tuna marked in 1954 at Martha's Vineyard, Massachusetts were recovered in the Bay of Biscay 5 years later, establishing the fact that at least some American tuna swim across the Atlantic to the shores of Europe.

Bluefin Tuna. This is the largest species of tuna, with lengths ranging up to 16.5 feet (5 meters) and weights up to 1800 pounds (820 kilograms). It is distributed in all warm and temperate seas, including the Mediterranean and the Black Seas, and along Europe's Atlantic coast northward to Tromsö, Norway. It is regularly encountered in the North Sea, and occasionally in the Baltic Sea to Stralsund. On the American East Coast, bluefin tuna occur as far north as Newfoundland. The diet of the bluefin consists of herring, mackerels, and gar, which are usually pursued in small schools for great distances near the surface of the water. Tuna also feed on schooling deep sea fishes. The killer whale is the tuna's chief enemy. During the spawning period in June, tuna migrate by the thousands to the Mediterranean coasts; then they retire again to their feeding grounds. Their small (1–1.2-millimeter) eggs develop quickly. The young (about 4 millimeters in length) hatch after 2 days, and they grow quite rapidly. In the fall of the same year, a great many of these juveniles migrate away from the coastal regions and begin feeding in the open sea. Since the main catch period corresponds with the tuna spawning period (when they are near the coast in greatest numbers), there has been a danger of overfishing them.

Albacore. This fish can easily be recognized by the long, sword-shaped pectoral fin, which extends to underneath the second dorsal fin. The albacore achieves a length up to 43 inches (110 centimeters) and weighs up to 66 pounds (30 kilograms). This species has a distribution somewhat similar to that of the bluefin tuna, but penetrates far to the north with the warm currents and, in winter, moves south again. It is most prevalent in the Pacific Ocean, where it undertakes extensive migrations.

Yellowfin Tuna. This fish is found only in the warmer parts of the ocean. It achieves a length up to 8 feet (2.5 meters) or more and weighs up to 500 pounds (225 kilograms). This species is characterized by a narrow, elongated second dorsal fin, and a similar anal fin. Both fins, plus the gill cover and front of the belly, are brilliant yellow. In one year, a single yellowfin tuna can gain up to nearly 60 pounds (27 kilograms).

Bigeye Tuna. This fish is very similar species to the yellowfin, but it has shorter pectoral fins and larger eyes. Furthermore, it typically inhabits deeper water levels.

Skipjack Tuna. This fish achieves a length of about 3 feet (1 meter) and a weight of 48 pounds (22 kilograms). It is an important commercial species which belongs to a tuna group having stripes instead of spots. It grows very rapidly, but does not live longer than 4 years. The skipjack is especially prevalent in the Pacific, accounting for a high percentage of the total catch in some years. During the summer, skipjack may be found in the North and Baltic Seas. It is recognized by the 4 to 7 dark longitudinal bands on the sides of the body. Skipjack tuna lack a swim bladder. See Fig. 1. Another member of this group, the bonito (*Sarda sarda*) has 8 or 9 longitudinal and dark stripes on its back, extending from the middle of the body upward. Bonitos are widely distributed in the Atlantic. A very similar species, *S. orientalis*, occurs in the Indo-Pacific, while in the northeastern and southeastern Pacific, *S. chillensis* is caught in California and Chile. They are all valued for their firm, tasty meat, and all have local economic importance.

Fig. 1. Skipjack tuna.

The spanish mackerel, closely related to the other tunas, is described briefly in the entry on **Mackerels**.

Major Changes in Tuna Fisheries. Until about 1961, the majority of the tuna fleet consisted of independent vessels from 300 to 500 gross tons (270 to 450 metric tons). After that time, due to the rapid decline in tuna abundance in other oceans, and also because of the increasing number of overseas bases for operation in the Atlantic (these were acquired by agreement with strategically located countries), a number of smaller vessels were attracted into the area so that the average size of vessel was reduced. The conventional mothership-type of operation, which had proved effective in the earlier years of the central and western Pacific fishery, was not permitted by the Japanese government to operate in the Atlantic, but the modified version of it, the deckboat-carrying mothership, which had first been tested experimentally about 1955 and found good, was permitted to operate there. The first operation of this kind entered the Atlantic in 1961. It was found so effective that by 1963 there were 28 such units fishing in many parts of the Atlantic. Because of its remoteness from the home islands, the Japanese Atlantic tuna fishery developed characteristics that increased efficiency and lowered costs. One such distinction was the development of new and closer markets for their catches in Europe and America. Introduction of Japanese-caught tuna to these countries started in a small way, but ultimately became a large-volume operation. The progressive and intensive development of tuna fishing in the Atlantic continued and dictated changes in the species of tuna caught, and in the seasons and areas the various species could be caught (Kask, 1969).

The seasonal pattern of the Atlantic tuna fishery is quite erratic. Fishing grounds and fishing seasons for each species seem to vary even more in the Atlantic than in other known tuna fishing areas. Yellowfin catches occur in two peaks, one in February–March and the second in August. This

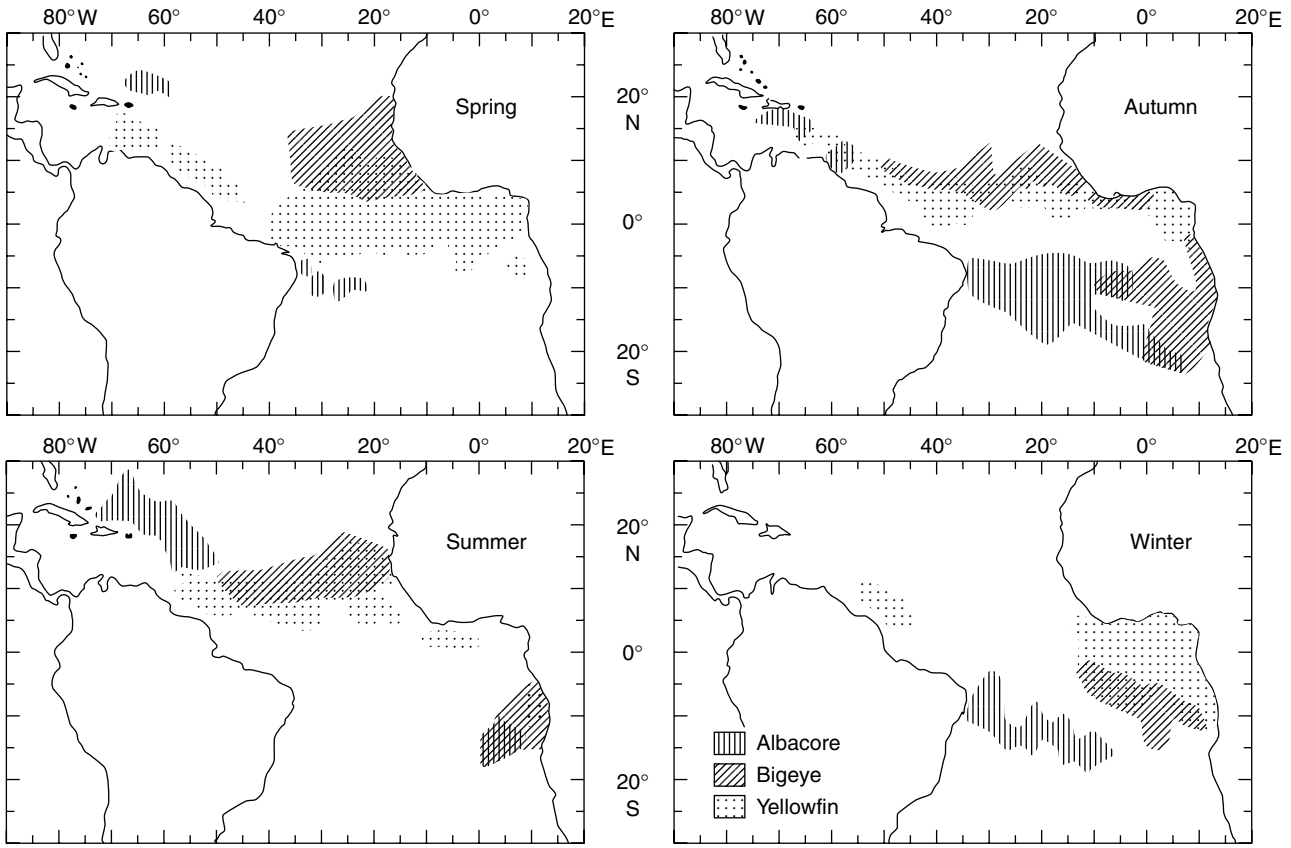

Fig. 2. Seasonal variations in distribution of longline fishing grounds in the Atlantic Ocean.

catch is mostly made in equatorial waters and is relatively stable, but the rate has fallen in recent years. Albacore catches are made in December in the Southern hemisphere and in July in the Northern hemisphere. In general, albacore are more abundant in the western half of the Atlantic and bigeye in the eastern half. Bigeye catches also show two seasonal peaks, one in summer months in the Northern hemisphere, and the other in the fall months between 5° and 20° south latitude. Bluefin are most abundant in March and April and again in September to November in the waters off Brazil. The development of the Japanese tuna fishery in the Atlantic has been dramatic, ingenious, and arduous. In recent years, of course, considerable competition for the catch by other countries has taken place. Seasonal variations in the distribution of longline fishing grounds in the Atlantic Ocean are shown in Fig. 2.

TUNDRA. Treeless plains that lie poleward of the tree line (i.e., the poleward limit of tree growth). The plants thereon are sedges, mosses, and lichens and a few small shrubs. It is mostly underlain by permafrost, so that drainage is bad and the soil may be saturated for long periods. Nearly all of the world's tundra is found in the Northern Hemisphere, where it covers vast expanses of northern North America and Eurasia. In the Southern Hemisphere, only the northern extremities of Antarctica (i.e., Palmer Peninsula) and some surrounding islands contain tundra. See also **Biome**.

TUNG *(Aleurites fordii; Euphorbiaceae)*. A tree, native to China and Japan, which is raised for the tung oil of its seeds. It has been introduced to the United States and large acreages are raised along the Gulf Coast. The plant is a tree bearing fruits about 2 inches (5 centimeters) in diameter, each containing 4–5 seeds. The seeds consist of about 65% oil.

Tung oil has been produced for centuries in China, where the oil is extracted by extremely crude methods. In this country, mechanical processing has increased the yield and improved the quality of oil. The fruits are dried, and the seeds are removed. The separated ground seeds are passed through a continuous screw press, which removes the oil. The oil is used in making quick-drying, waterproof varnish, or may be mixed with other oils and resins, to which it imparts desirable properties.

TUNG OIL. See **Cashew and Sumac Trees**.

TUNGSTEN. [CAS: 7440-33-7]. Chemical element, symbol W, at. no. 74, at. wt. 183.85, periodic table group 6, mp 3,390–3,420 °C (6,134-6,180 °F), bp 5,660 °C (10,220 °F), density 19.3 g/cm^3, and there are 31 isotopes ranging from 160 to 190. Two forms of metallic tungsten are known: α-tungsten, which has a body-centered cubic crystal structure, and β-tungsten, which has a face-centered cubic crystal structure. The metal exhibits the phenomenon of passivity so that it is quite resistant to chemical action even though it has a strong reducing action when a fresh surface is exposed, or in potentiometric titrations. Tungsten is a silver-white to steel-gray, brittle, hard metal; not oxidized by air at ordinary temperature, but burns at high temperature, best dissolved by a mixture of

hydrofluoric and HNO_3 acids. Tungsten has five naturally occurring isotopes ^{180}W, ^{182}W through ^{184}W and ^{186}W. See Table 1. ^{180}W is radioactive with a half-life of approximately 3×10^{14} years. Six other radioactive isotopes have been identified ^{176}W through ^{178}W, ^{181}W, ^{185}W, ^{187}W, and ^{188}W. All have half-lives considerably less than 4 months in length. Tungsten does not occur in the free state and is a relatively scarce element, making up an estimated 7×10^{-3}% of the Earth's crust. The tungsten content of seawater is estimated at about 950 pounds per cubic mile. Although the tungsten mineral *wolframite* (iron manganese tungstate) was described as early as 1574, it was then mistaken as a mineral of tin. With exception of the United States, the element generally is referred to as *wolfram*. First ionization potential of tungsten is 7.98 eV. Electronic configuration $1s^2 2s^2 2p^6 3s^2\ 3p^6 3d^{10} 4s^2 4p^6 4d^{10} 4f^{14} 5s^2 5p^6 5d^4 6s^2$. Ionic radius W^{+4}0.68Å, W^{+6}0.65Å. Metallic radius 1.3704_5Å. Other important physical properties of tungsten are given under **Chemical Elements**.

TABLE 1. ISOTOPES OF STABLE TUNGSTEN

Isotope	CAS Registry no.	Abundance, %
^{180}W	[14265-79-3]	0.13
^{182}W	[14265-80-6]	26.30
^{183}W	[14265-81-7]	14.30
^{184}W	[14265-82-8]	30.67
^{186}W	[14265-83-9]	28.60

The term *tungsten*, meaning heavy (tung) stone (sten) in Swedish, was first applied to a tungsten-containing mineral in 1755. The mineral was subsequently identified by K.W. Scheele in 1781 as containing lime and a then-unknown acid that he called *tungstic acid*. The mineral was then referred to as *scheelite*. Metallic tungsten was first produced by the carbon reduction of tungstic acid in 1783 in Spain and termed *wolfram*. This designation became common usage in German. In 1957, the IUPAC (International Union of Pure and Applied Chemistry) chose the English term *tungsten* and the French term *tungstene* with *wolfram* as an alternative. However, W is still used as the chemical symbol.

During the nineteenth century, tungsten remained a laboratory material. The latter half of the century saw the development of high-speed tool steels containing tungsten, which became the prime use for the metal in the first half of the twentieth century. The pure metal itself was first used as a filament for electric lamps at the beginning of the twentieth century. After some limited success with paste-extruded tungsten powder, the Coolidge process was developed in 1908, by which a pressed and sintered tungsten ingot could be worked at high temperatures by swaging and drawing to form a fine-wire filament. This was a landmark in the development of the incandescent-lamp industry and, later, in the use of tungsten as a welding electrode. In the 1920s, the search for an alternative to expensive diamond dies required for the drawing of the tungsten wire led first to cast tungsten carbides and then to the manufacture of cemented carbides, now accounting for over half of the tungsten consumption in the world. Divers authorities accredit Scheele or the d'Elhuyar brothers with the discovery of the element.

Tungsten is the eighteenth most abundant metal, having an estimated concentration in the earth's crust of 1–1.3 ppm. Of the more than 20 tungsten-bearing minerals known, Table 2 lists the most significant ones, but only four are of commercial importance: ferberite (iron tungstate), huebnerite (manganese tungstate), wolframite (iron–manganese tungstate containing ~20–80% of each of the pure components), and scheelite (calcium tungstate). Typical concentration in ores is ~0.5% and only rarely exceeds 2%.

The WO_3 content of wolframite minerals varies from 76.3% in $FeWO_4$ to 76.6% in $MnWO_4$. These minerals, are commonly called *black ores*, as their colors range from black to brown. They occur as well-defined crystals to irregular masses of bladed crystals. They have a Mohs hardness of 5.0–5.5 and a specific gravity of 7.0–7.5 and tend to be very brittle. They are also weakly magnetic. Scheelite contains 80.6% WO_3, is white to brown, and is strongly fluorescent in short-wave ultraviolet radiation. Scheelite occurs as massive crystals and as small grains. It has a Mohs hardness of 4.5–5.0 and a specific gravity 5.6–6.1 and is very brittle.

Usually tungsten minerals are found in pegmatites, sills, and batholiths. Minerals often accompanying tungsten minerals are cassiterite, quartz, feldspar, sulfides, arsenites, apatite, calcite, molybdenite, and bismuthinite. Several of these minerals are described under separate alphabetical entries. In order of decreasing magnitude, tungsten deposits occur in the People's Republic of China, the United States, Korea, Bolivia, Portugal, Burma, and Australia. Deposits also are found in at least ten other areas. In the United States, the most significant deposits are found in California, Nevada, South Carolina, Idaho, and Colorado. Tungsten concentration in the ores found in the United States run from 0.5% to 3% WO_3 (20 pounds 9 kilograms of WO_3 contains about 15.9 pounds 7.2 kilograms of W). High-purity tungsten metal is prepared by extracting the tungsten from the ore by use of a strong alkali hydroxide solution at the boiling point. The alkali-metal carbonate or hydroxide thus obtained then is fused to form the water-soluble, alkali-metal tungstate. Where NH_4OH is used, the product is ammonium tungstate (NaOH yields sodium tungstate). The compound is reduced to metal powder. Conversion of the powder to massive metal is done by pressing, sintering, and mechanical working at high temperatures. In another process, the ore is fused with sodium carbonate and nitrate to yield sodium tungstate. Reduction of the oxide is accomplished by heating with carbon or hydrogen, whereupon tungsten metal is yielded.

Uses. Approximately one-half of the tungsten produced is in the form of sintered tungsten carbides. These compounds are used for cutting tools and wear-resistant parts. About 15% of production is consumed for making wire used in lamps and also for various shapes used in aerospace and defense products. Another 15% of production is used for high-temperature alloys and powder metallurgy. Approximately 10% goes into high-speed tools. The remaining production goes into a wide variety of applications.

Tungsten carbide, WC, is extremely hard (9.5 on the Mohs scale; diamond = 10) and has a melting point of 2,870 °C (5,198 °F). This combination of hardness and high-temperature stability makes it an excellent material for cutting tools. Additionally, the wear-resistant properties are excellent, accounting for the use of tungsten carbide for dies for hot and cold working of wire, rod and tubing, mining tools, snow-tire studs, and ball-point pens. For hard carbide tools and dies, tungsten carbide in the form of fine powder (1–10 micrometer particle size) is bonded with cobalt.

Special carbide tools also will often contain various percentages of titanium, tantalum, niobium (columbium), and hafnium carbides, along with the tungsten carbide. Chromium and vanadium carbides are also added to produce special, fine-grain-size grades of cemented tungsten carbide-cobalt materials. See Fig. 1.

For hard-facing applications, fused tungsten carbide is used. Tungsten also forms the ditungsten carbide W_2C, which has a melting point of

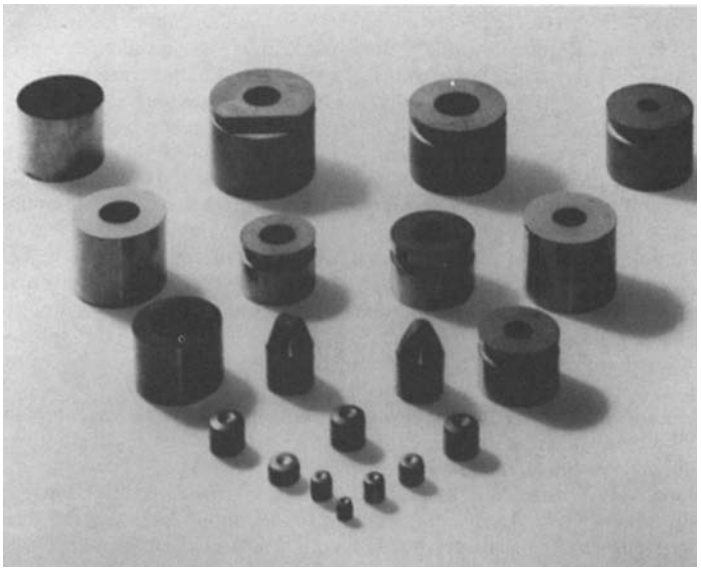

Fig. 1. Cemented tungsten carbide compacts and mud nozzles for oil well drilling. (*Fansteel.*)

2,860 °C (5,180 °F). However, the term *tungsten carbide* usually refers to the mono compound. WC generally is made by combining tungsten metal powder with finely divided lampblack. The mixture then is heated to about 1,500 °C (2,732 °F). A variety of tungsten powders are made which then are subjected to various powder metallurgy techniques to form numerous shapes with a wide range of characteristics. Tungsten carbide can also be manufactured by a so-called menstrum process, which employs calcium carbide and aluminum metal to reduce scheelite via a thermite reaction, with the tungsten carbide recovered by acid washing.

Tungsten wire, including pure (unalloyed), doped nonsag; (potassium silicate and aluminum chloride or nitrate doped), and thoriated and zirconiated types are used extensively in applications such as filaments for incandescent lamps, thermocouples, arc-lamp electrodes, electrochemical electrodes, and instrument springs. See Fig. 2. Tungsten disks are used for electrical contacts; tungsten is used in glass-to-metal seals, where the coefficient of thermal expansion of tungsten is close to that of hard borosilicate glass; and tungsten pads are used in connection with silicon semiconductors because of the high thermal conductivity of tungsten and good match of the coefficient of thermal expansion of tungsten with that of silicon.

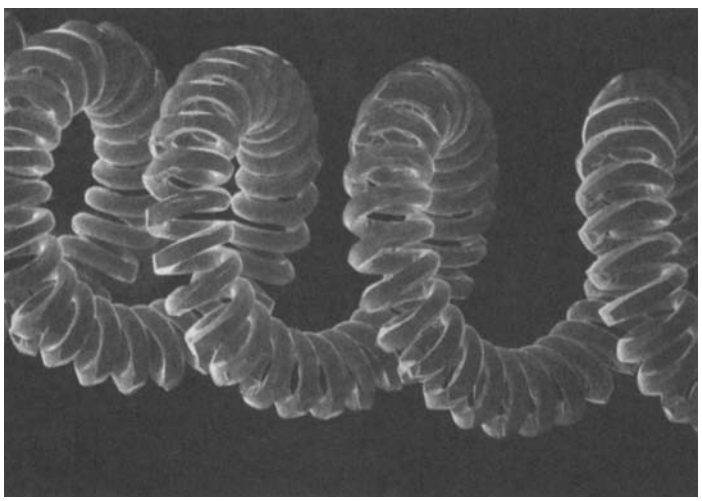

Fig. 2. Scanning electron photomicrograph of a nonsagging tungsten filament taken after several hundred hours of operation at 2500 °C in a 60-watt light bulb. (*After Wittenaur, Nieh, and Wadsworth.*)

Compositions of silver and tungsten and of copper and tungsten find application as electrical contacts where they are subject to severe arcing. As a shield or as containers for radioactive materials, heavy-metal alloys of tungsten alloyed with about 7% nickel and 4% copper are effective. The same alloys also find other uses where high density is required, as in gyroscope rotors, counterweights in aircraft, and self-winding watch parts. Alloys of cobalt, chromium, and tungsten also find use in cutting tools, dies, and wear-resistant parts. The function of tungsten in steel is that of forming stable carbides, strengthening ferrite, and refining the grain size for retaining high hardness at elevated temperatures — a requirement of highspeed steels.

Tungsten chemicals find limited use in inks, paints, enamels, dyes, and glass manufacture. Some tungsten compounds and their derivative phosphors find use in x-ray screens, television picture tubes, and luminescent light sources.

Chemistry and Compounds. In keeping with its $5d^4 6s^2$ electron configuration, tungsten forms many compounds in which its oxidation state is 6+, just as molybdenum does. It forms divalent and tetravalent compounds to about the same extent as molybdenum but its trivalent and pentavalent compounds are somewhat fewer. Its anion chemistry is closely akin to that of molybdenum.

Among the divalent compounds of tungsten, the diiodide, WI_2, dibromide, WBr_2, and the dichloride, WCl_2, are among the most clearly characterized; they all hydrolyze, although the iodide reacts only with warm water. Like molybdenum, tungsten(II) has a complex chloroion, $[W_6Cl_8]^{4+}$ which, however, is much more easily oxidized than its molybdenum analog.

Trivalent tungsten occurs rarely in simple compounds, other than certain high-temperature products such as one of the borides, WB, one of the phosphides, WP, and the complexes. Among the latter is the ion $[W_2Cl_9]^{3-}$ in which the two tungsten atoms participate in a ClWClWCl bridging structure, as they do in a W_2Cl_6 structure.

In addition to the tungsten(II) boride mentioned above, the element forms at least two other borides, W_2B and WB_2; it forms a similar series of phosphides, W_2P, WP, and WP_2 as well as WO_2 (brown oxide), W_4O_{11} (blue oxide), and WO_3 (yellow oxide), and two sulfides, WS_2 and WS_3. The tungsten(IV) oxide and sulfide are representative of the simple tetravalent compounds, which also include a tetrabromide, WBr_4, and tetraiodide, WI_4. Like the dihalides, these tetrahalides undergo hydrolysis quite readily.

Among the best known simple pentavalent tungsten compounds are the pentachloride, WCl_5, and the pentabromide, WBr_5. As is true of tungsten(IV), tungsten(V) forms complexes.

By far the greatest number of tungsten compounds are those in which the element is hexavalent. These include all common halides except the iodide, i.e., WF_6, WCl_6, as well as a number of oxyhalides, WOF_4, $WOCl_4$, WO_2Cl_2, $WOBr_4$, and WO_2Br_2, the trioxide, trisulfide, diboride, and diphosphide already mentioned, various complexes and organometallic compounds, and the anions.

Tungsten trioxide dissolves in hot alkali metal hydroxide solutions to yield in more or less hydrated form, the tungstate ion, WO_4^{2-}. However, the ionic species that exist in solution are more complex than mere hydration of the WO_4^{2-} would indicate, and this is especially true of the compounds obtained from such solutions. There are, however, two simple forms of the orthotungstic acid: H_2WO_4, which is precipitated upon addition of HCl to a hot tungstate solution, and $H_2WO_4 \cdot H_2O$, which is similarly obtained from a cold solution. Neutralization of a tungstate solution under most conditions yields, upon crystallization, much more complex salts. The acidic groups condense, with elimination of water, to form complexes, that can be crystallized as salts, which can be regarded as derived from "poly" acids. When such salts have only one kind of metal atom (e.g., W) in their anions, they are called *isopoly acids*; when they have more than one kind, they are called *heteropoly acids*. The latter group comprises an entire field of tungsten chemistry (as well as that of molybdenum and other elements.); the tungstophosphates are important in analysis and other applications. Other examples are the heteropoly acid salts formed by tungsten with oxyanions of boron, silicon, germanium, tin, arsenic, titanium, zirconium, and hafnium. In particular, the 6-series

and the 12-series, containing, respectively, 6 and 12 tungsten atoms per molecule, have been extensively investigated.

Other interesting compounds are the "tungsten blues," complex oxides of colloidal nature, obtained by reduction of tungstates in alkaline solution. At higher temperatures, reduction of tungstates (of main group 1 and 2 elements) by alkali metal, hydrogen, zinc, tungsten, or electrolysis yields the semimetallic "tungsten bronzes," formulated as M_nWO_3, where M is the alkali metal and n is less than 1. They have cubical structures with W-O-W groups forming the sides, and the alkali or alkaline earth atom randomly located in the center of some of the cubes. The resulting extra electrons are considered to distribute over the entire structure, giving it metallic properties.

Tungsten forms many other complexes. Of particular interest are the octacyano complexes, containing eight cyanide, CN^- ions coordinated to a single tetravalent or pentavalent tungsten ion, $W(CN)_8{}^{4-}$ or $W(CN)_8{}^{3-}$, the latter being exceptionally stable, and forming octacyanotungstic(V) acid, $H_3[W(CN)_8] \cdot 6H_2O$, which is known in salts. Similar complexes are known for molybdenum, rhenium and osmium. The fluorocomplex of tungsten(VI) has the structure $[WF_8]^{2-}$ and forms salts with the higher alkali metals, potassium, rubidium and cesium.

Like molybdenum and chromium, tungsten forms a number of cyclo pentadienyl compounds which are also carbonyls, e.g., $C_5H_5W(CO)_3H$, $C_5H_5W(CO)_3CH_3$, $C_5H_5W(CO)_3C_5H_5$, $C_5H_5(CO)$ $WW(CO)C_5H_5$, and $C_5H_5(CO)_3WW(CO)_3C_5H_5$. Tungsten(VI) also forms several other orga nometallic compounds, e.g., $W(OC_6H_5)_6$ and $W(OC_6H_4CH_3)_6$, as well as a simple carbonyl, $W(CO)_6$.

An excellent and comprehensive review of tungsten and its alloys is given in the Wittenauer reference listed.

TUNING FORK. An oscillator that has been described as one piece of metal with two moving parts. It is termed a fork because of its obvious forklike shape. The device was invented by John Shore, an English musician, in 1711. Manually operated low-frequency forks still are used to tune musical instruments. Precision tuning forks, electromagnetically driven, are used as frequency standards in wristwatches and clocks; as oscillators in electronic systems for functions similar to those of quartz crystals; and as modulators of laser and other light and energy beams in electro-optical systems. Frequencies range from 10 Hz to more than 25 kHz. Frequency is determined by time (prong) dimensions and varies slightly with amplitude. For high precision, the drive power, transmitted by a magnetic transducer, is held constant by a zener diode, negative feedback, or automatic gain control.

Other fork drives include electrostatic magnetostrictive, pneumatic, piezoelectric and, most efficient of all, electrodynamic. With the latter method, the coils are stationary and the magnet system moves. In the 360 Hz tuning fork watch movement, for example, this drive reduces power requirements to six microwatts.

Normally, a fork is driven to vibrate in a fundamental mode, but highest frequencies are produced by driving it in an overtone mode—which can result in frequencies some six times those for the fundamental mode. In effect, the fork becomes a piece of metal with four moving parts. A 25 kHz fork in this mode is less than an inch (2.5 cm) long.

TUNNEL ENGINEERING. Broadly defined, a tunnel is a subsurface (underground or underwater) passageway. A natural tunnel may exist in some caves, but tunnels of engineering interest are manually-created structures that generally fall within the province of civil engineering.

Tunnels are commonly identified by the purpose for which they serve. Thus, there are railway, highway, and pedestrian tunnels that are located beneath crowded municipalities, that penetrate through mountains, or that rest on the bottom of rivers, lakes, bays, or channels. A tunnel may be as short and as shallow as an underground passage between two buildings or as long as several miles (kilometers), with a large cross section to accommodate several lanes of traffic. It is not uncommon for two tunnels to parallel each other in order to accommodate more traffic. Also, there are tunnels for conveying large quantities of water and sewage. See Table 1.

Tunnels date back to the ancient Egyptians, Assyrians, and Indians who constructed tunnels in connection with tombs and temples. It has been determined that a tunnel about 12 feet (3.7 meters) and 15 feet (4.6 meters) long was constructed by the Assyrians to divert water from the Euphrates River. The Romans built a tunnel about 3000 feet (914 meters) long on a roadway between Naples and Pozzuoli. The ends of the tunnel were constructed in the form of conical frustums to permit light to penetrate to the center of the tunnel. Practically all early tunnels were hand-hewn out of rock. Gunpowder for use in tunnel construction was first used circa 1680 in France. The need for tunnels expanded in France and England because of the increasing use of canals. Tunnel construction in sand and wet ground was not undertaken until the early 1800s. A 24-foot (7.3 meters) tunnel was built for the Saint Quentin Canal (France) in 1803. The type of construction required large support timbers and base planking. Such tunnels also required masonry lining to avoid water penetration from above.

Probably the greatest impetus for tunnel building was the introduction of the railway. Two tunnels were constructed on the line of the Liverpool and Manchester Railway in England, and, in the United States, the first railway tunnel was built near Auburn, Pennsylvania, in about 1820. The tunnel measured several hundred feet (meters) in length, was approximately 22 feet (6.7 meters) high and 15 feet (4.6 meters) wide. Numerous tunnels were constructed in the Appalachian mountains and later, as the railways moved west, in the Rocky, Sierra Nevada, and Cascade mountain ranges.

Large highway tunnels were pioneered in Europe (Alps) to shorten the distances between towns as well as to reduce the costs and dangers of winding roads that depended upon natural mountain passes.

Tunnel engineering must consider numerous factors, several of which extend beyond physically creating a passageway:

- A thorough preliminary geological and topological survey of the proposed tunnel location.
- An environmental impact study.
- Design of required drilling and excavating equipment.
- Ample provision for continual earth, rock, and debris removal and selection of an appropriate "dumping" area.
- Selection of acceptable upgrade and downgrade for the types of vehicles that will be using the tunnel.
- Selection of acceptable curves in the tunnel when required.
- Provisions for adequate ventilation.
- Provisions for adequate lighting.
- Creation of a thorough safety program—from the start to the end of construction—and a revised safety program when the tunnel is in operation. All possible contingencies must be considered.
- Provisions for adequate communication—between various stations within the tunnel and to stations on the surface. Communication, of course, plays a large role in the safety program.

- Provisions for expeditious but safe access to and egress from the tunnel. This is particularly important with highway tunnels, which most often require reducing the number of lanes of traffic.

The remainder of this entry is devoted to the *Channel Tunnel*, one of the greatest technological and engineering feats of the 20th century.

The Eurotunnel — Folkestone, England–Calais, France

The first attempt to bore a tunnel under the English Channel was made in 1880, using a machine designed by Colonel Beaumont. The tunnel, which was almost 8 feet (2.4 meters) in diameter, started from an access shaft and was approximately 1.2 miles (2000 meters) long when the project was halted in 1882. A similar tunnel also was started in France from a shaft sunk near Sangatte.

In 1922, a trial bore was made at Folkestone, using a Whitaker machine, which cut a tunnel about 9.8 feet (3 meters) in diameter. Part of this machine has been recovered and restored and is now displayed at the *Eurotunnel* Exhibition Centre in Folkestone.

In 1974, work began on a much larger tunnel system, similar in size and configuration to the *Eurotunnel* scheduled for dedication in 1994. In the United Kingdom, an access tunnel (or adit) was made between the upper and lower sites at Shakespeare Cliff near Dover, and a rail access adit was bored from the lower site down to the level of the future rail tunnels. A 1321-foot (400 meters) length of service tunnel was bored before work was abandoned at the start of 1975. During these works, the 1880 Beaumont tunnel and shaft were found to be in good condition. In France, an adit was constructed at Sangatte, but progress was slower because of bad ground conditions. However, a tunnel-boring machine (TBM) had been built and delivered to the site.

The present *Eurotunnel* project was started in the early 1980s, when the British and French governments jointly decided that a fixed link should be built across the Channel. Both governments stipulated, however, that the work would have to be privately financed. In April 1985, bids were invited for the financing, construction, and operation of a fixed link. The *Eurotunnel* proposal was selected in January 1986. The company was awarded the concession for building the Channel Tunnel system and operating it for a period of 55 years beginning in 1987.

On June 15, 1987, the legislative approval for the *Eurotunnel* project was signed by President Mitterrand and received Royal Assent by the British government on July 23, 1987. Actual tunnel construction work commenced on December 1, 1987. The historic first contact between British and French undersea workers occurred on October 30, 1990. On February 10, 1992, *Eurotunnel* directors announced a delay of the tunnel opening date from June 15, 1993, to the summer of 1993. Later, another postponement was announced. Commercial operation began in 1994. The cost of the tunnel at the time of completion was approximately $5.4 billion (£9.0 billion).

The *Eurotunnel* transport company operates every day of the week around the clock to facilitate the movement of people, products, and vehicles across the English Channel through the railway system. The *Channel Tunnel* system consists of three tunnels, each 31.35 miles (50.45 kilometers) long of which 24 miles (38 kilometers) is under the sea. The three tunnels are approximately 100 feet (30 meters) apart and are located under the Channel at an average depth of 148 feet (45 meters) below the seabed. The two larger tunnels are 25 feet (7.6 meters) in diameter and contain a single-track railway line. The smaller tunnel is 16 feet (4.8 meters) in diameter and contains the wire guidance system for custom-designed tunnel service vehicles. The railway system runs shuttle trains between terminals at Folkestone, in the county of Kent in Southeast England and Coquelles in the Nord-Pas-de-Calais region of France. High-speed through-trains connect with the national rail networks of France and Great Britain. The names *Eurotunnel* and *Channel Tunnel* are used interchangeably.

TABLE 1. OUTSTANDING TUNNELS — WORLDWIDE

Name	Location	Type	Length		Completed
			Mi	Km	
Seikan	Tsugara Strait, Japan	RWY	33.1	53.3	1983
Eurotunnel	Folkestone, England–Calais, France	COM	32	50	1994

Since the beginning of commercial operation in 1994, the two types of shuttle trains, which transport tourist vehicles or freight trucks, have carried more than 3.5 million cars and coaches and nearly 1 million lorries. The *Eurostar* trains, which carry passengers between London, Paris, and Brussels, have transported nearly 8 million travelers, while the freight trains have moved nearly 3.9 million short tons (4 million tonnes) of material through the tunnel system.

Geography of Eurotunnel. Contrary to common conceptions, the Eurotunnel is not a tube lying on the sea bed, exposed to the hazards

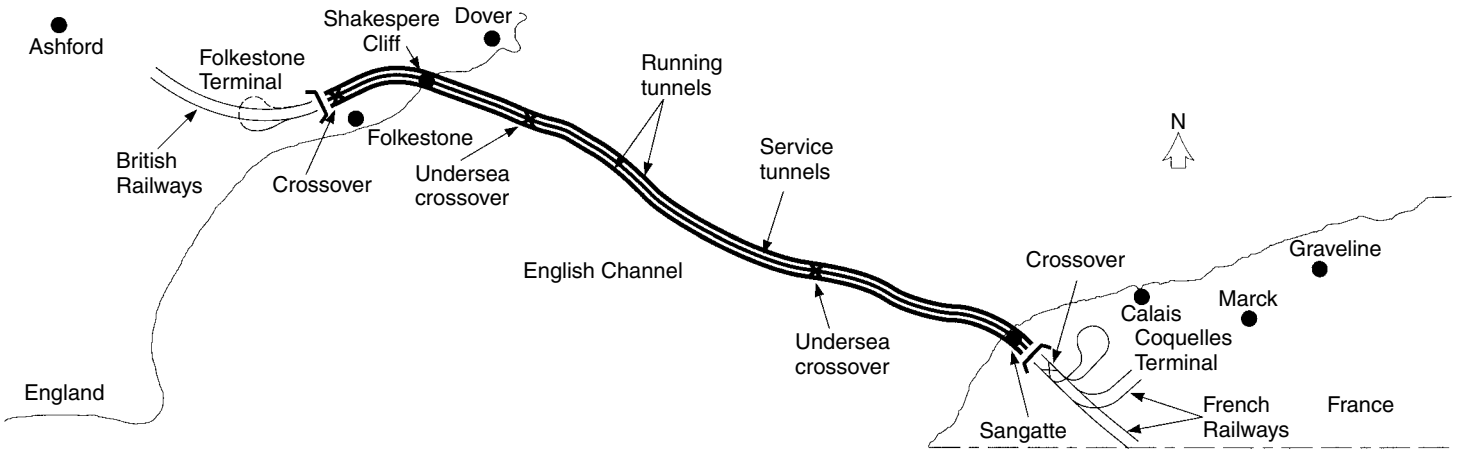

Fig. 1. Route of *Eurotunnel* as "viewed" from above. (*The Channel Tunnel Group*.)

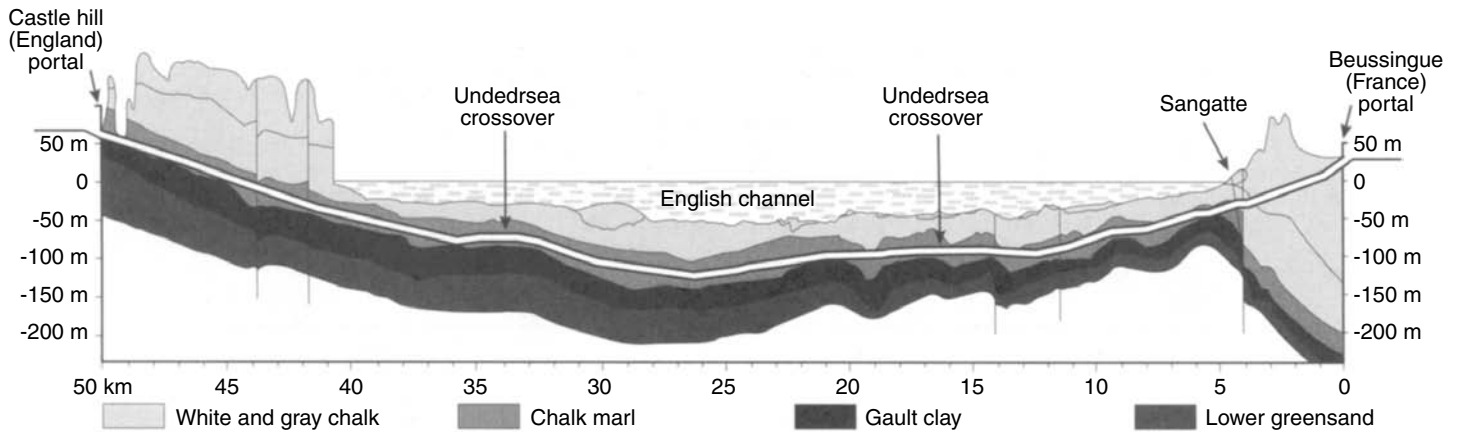

Fig. 2. Geological cross section of *Eurotunnel* pathway. (*The Channel Tunnel Group*.)

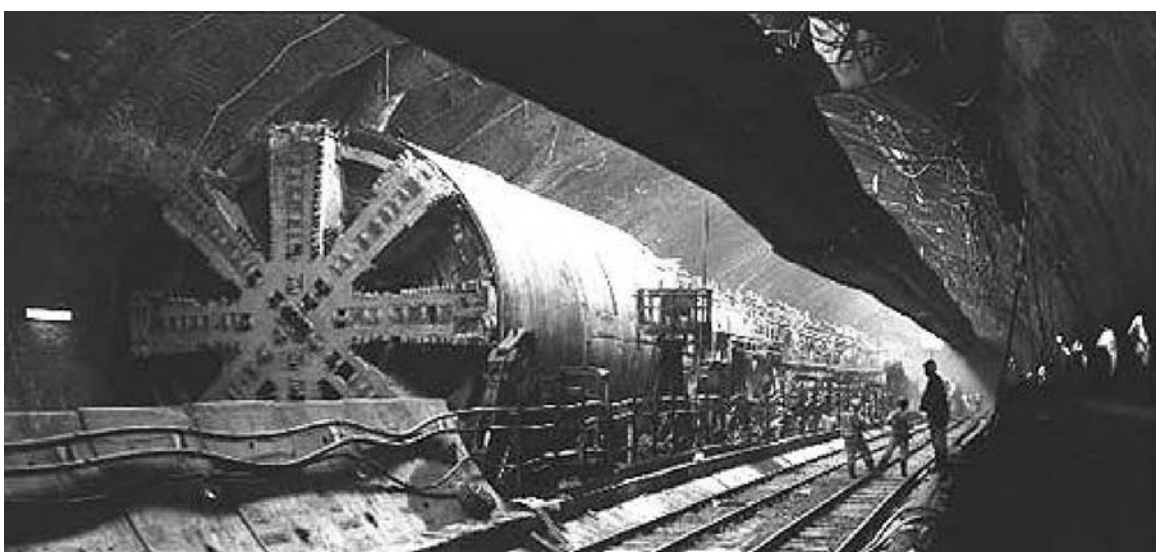

Fig. 3. The custom designed tunnel boring machines (TBM's) were used to excavate the chalk mari rock which lay beneath the seabed along the tunnel route. Tunneling commenced on December 1, 1987. The rate of advance on the best day was 185 feet (56 meters), in the best week was 966 feet (292.6 meters), and in the best month was 3,649 feet (1,105.7 meters). In all, 287,714,286 cubic feet (8 million cubic meters) of soil was removed during construction at a rate of 2,646 short tons (2,400 tonnes) per hour. (*The Channel Tunnel Group*.)

of the sea. Tunnels were bored generally between 82 feet (25 meters) and 148 feet (45 meters) below the sea bed. From Folkestone past Dover and under the Channel for a total distance of about 30 miles (45 kilometers), the tunnels are bored through chalk marl, generally considered to be one of the most consistent and safe tunnelling mediums. As the tunnels approach the Folkestone terminal, they pass through gault clay and other strata and, for the first 3.1 miles (5 kilometers) from the Coquelles (France) terminal, the tunnels pass through more faulted zones and sands and gravels. These materials were the most difficult to bore.

Chalk marl is a soft rock, generally impermeable to water, and is homogeneous. This allows excavation to be carried out at a relatively high rate. The chalk marl is overlain by grey chalk, which generally is a harder and a more fractured material. It is underlain by gault clay, which essentially is impermeable. The vertical and horizontal alignment of the tunnels, therefore, was chosen so that the maximum possible length of the tunnels would be in the chalk marl, taking into account the acceptable gradients (not exceeding 1.1%) and the power consumption criteria applicable to a high-speed railway system, as well as drainage and pumping requirements.

The risk of earthquakes was not overlooked, including very detailed studies of the history of the region. Such studies are on a continuing basis.

In summary, the detailed location of the tunnels was determined not only in terms of a short distance between the European continent and the United Kingdom, but also by favorable geologic conditions. See Figures 1 and 2.

Structure of the Tunnels. The tunnels were bored by very special tunnel- boring machines (TBMs) to permit the installation of reinforced concrete linings or, in certain areas, linings of cast iron. See Fig. 3. The running tunnels have a diameter outside the concrete lining of up to 28.8 feet (8.78 meters) and an inside diameter of 24.9 feet (7.6 meters). The large size can be appreciated by comparing *Eurotunnel* with typical underground tunnels. See Fig. 4.

In addition to boring, the TBMs also erected the tunnel linings. Cement grout is injected behind the linings to fill the voids between them and the chalk marl and to create a solid bond between them. This bond gives the structure extra strength.

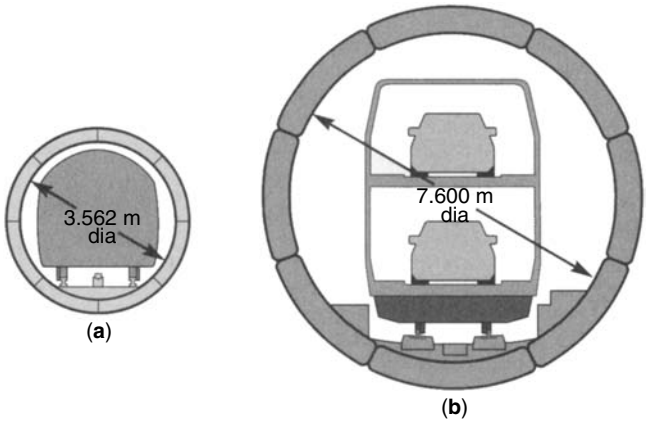

Fig. 4. Comparison of (**a**) Piccadilly Line (London Underground) subway tunnel with (**b**) one of Eurotunnel's running tunnels. (*The Channel Tunnel Group Limited*.)

Cross passages join the running tunnels and the service tunnel about every 1230 feet (375 meters). Piston relief ducts to permit the equalization of air pressures connect the two running tunnels about every 820 feet (250 meters).

Two rail crossovers between the running tunnels are located under the sea bed approximately one-third of the distance from each portal. Two further sets of crossovers are located close to the portals. In each tunnel crossover, there are doors between the tunnels. Pumping stations along the tunnels handle any water spilled in or entering the tunnels.

Fixed equipment is installed in the service tunnel. See Fig. 5. A three-dimension sectional view of the three tunnels is shown in Fig. 6, and a sectional view of a running tunnel is shown in Fig. 7.

Each running tunnel has a single rail track, overhead line equipment (catenary), and two walkways, one for maintenance and the principal one

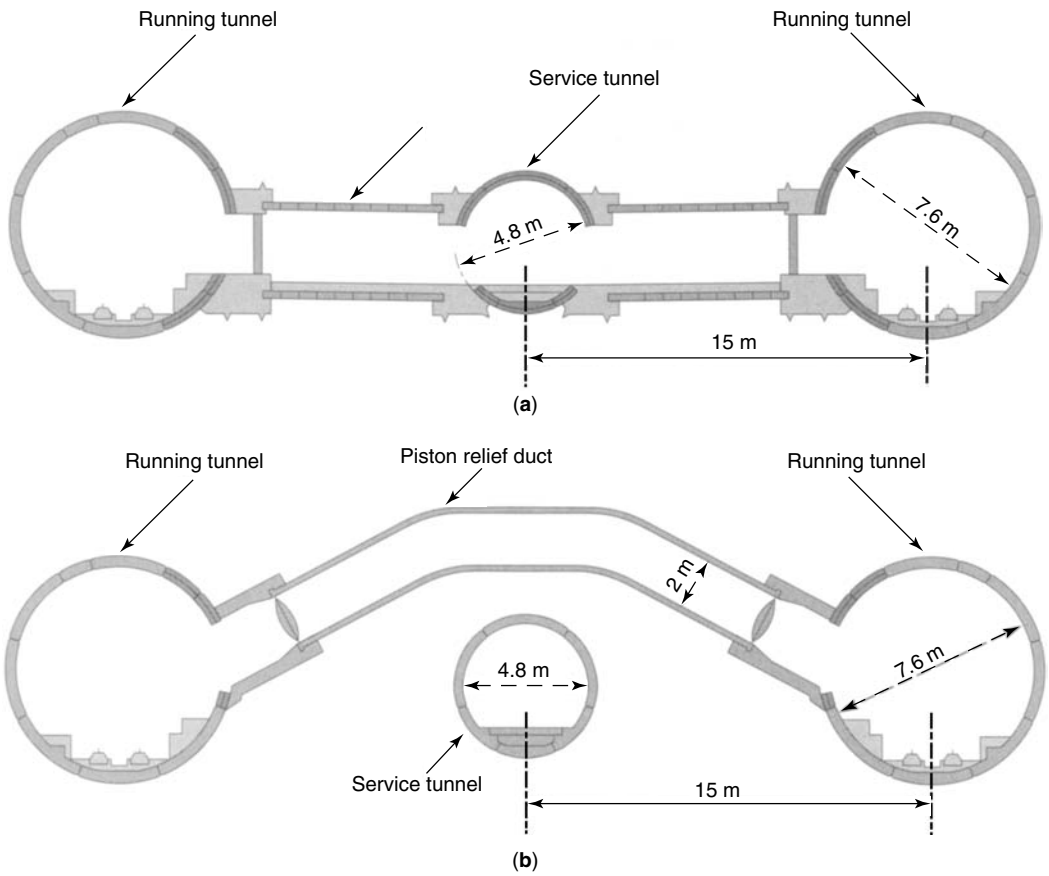

Fig. 5. Typical section through tunnels showing (**a**) cross-passage structure and (**b**) piston relief duct structure. (*The Channel Tunnel Group Limited*.)

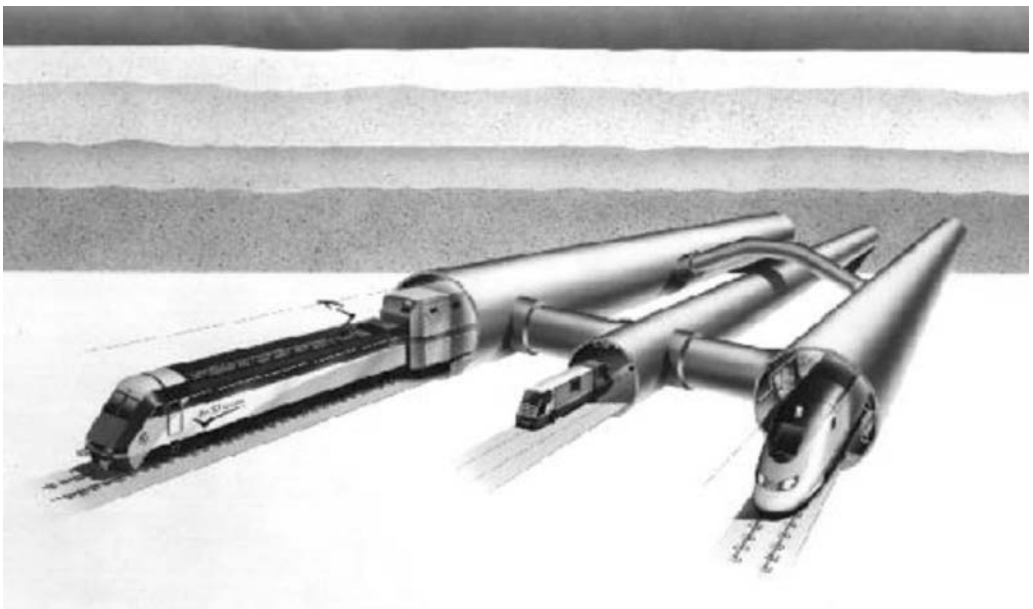

Fig. 6. Three-dimensional sectional view of the three tunnels. The outer tunnels each contain a single railway track, and the central tunnel, which passengers can reach from the rail tunnels, if necessary, is for support services. In normal operation, *Eurotunnel* shuttles and through-trains travel from the UK to France through the southern rail tunnel. Trains from both countries "drive" on the left.

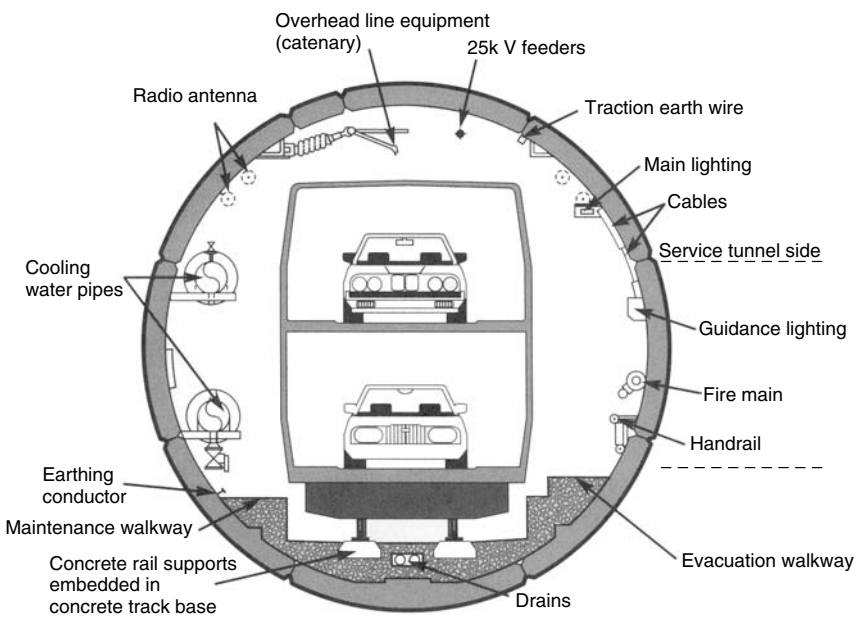

Fig. 7. Section through a running tunnel showing numerous features, including locomotive overhead power line, cooling water pipes, track and track supports, maintenance walkway, lighting, fire main, and drains. (*The Channel Tunnel Group Limited.*)

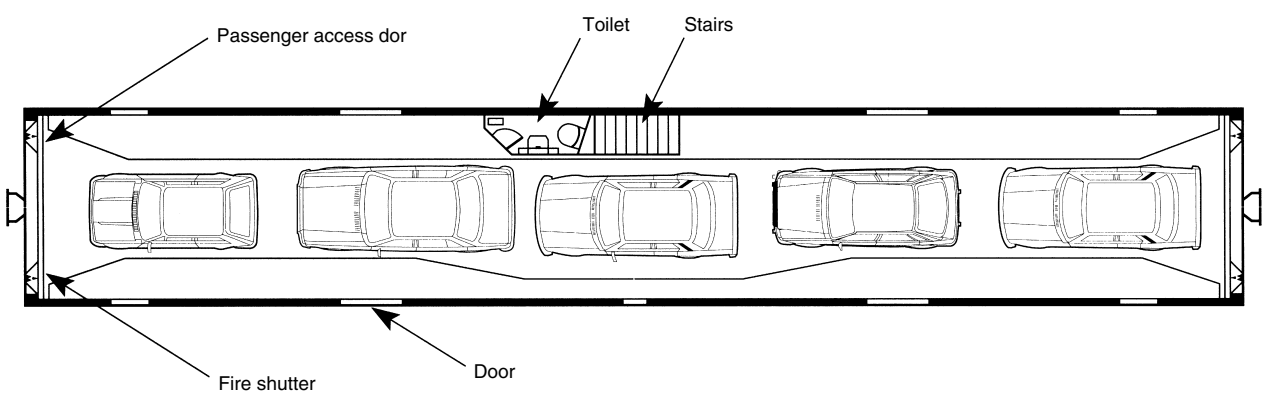

Fig. 8. Top view of shuttle wagon showing arrangement of five passenger vehicles. Passengers remain with their vehicles. Each wagon features restroom facilities. (*The Channel Tunnel Group Limited.*)

on the side nearest the service tunnel for any emergency evacuation. The walkways are designed to maintain a shuttle upright and traveling in a straight line in the event of a derailment.

The single rail track through each running tunnel has continuously welded rail on precast concrete rail supports embedded in a concrete track base. Fixed to the sides of the tunnels are cooling pipes, fire mains, signalling equipment, and cables.

The catenary supplies traction power to the shuttles and through-trains in the running tunnels. The line is divided into sections so that only one train is likely to be immobilized at any one time in the event of a fault. *Eurotunnel* has its own standby auxiliary power for emergency situations.

All tunnels and connecting passages have sufficient lighting for operational, maintenance, and emergency purposes. Wherever practical, materials and equipment, including cables, are fire-resistant. All tunnels and connecting passages have sufficient lighting.

A shuttle vehicle for carrying automobiles and passengers riding in the cars is shown in Fig. 8. Cars and vehicles that do not exceed 6 feet (1.85 meters) in height (including top loading racks) are placed on five-vehicle, single-deck shuttles.

In contrast to passenger vehicles, trucks (lorries) and their occupants are separated during the journey. The drivers and passengers, if any, are taken to an air-conditioned rail coach at the front of the shuttle.

The tunnel journey requires approximately 35 minutes. Procedures at the entrances and exits of the tunnel facility essentially will double that time, making a total trip is about 1 hour and 20 minutes.

Passenger trains pass through the tunnel much as in passing through any other tunnel. The terminus in England is Waterloo Station, London; in France, it is Gare du Nord or Brussels Midi. An impressive view of one of the running tunnels toward the end of construction in 1991 is shown in Fig. 9.

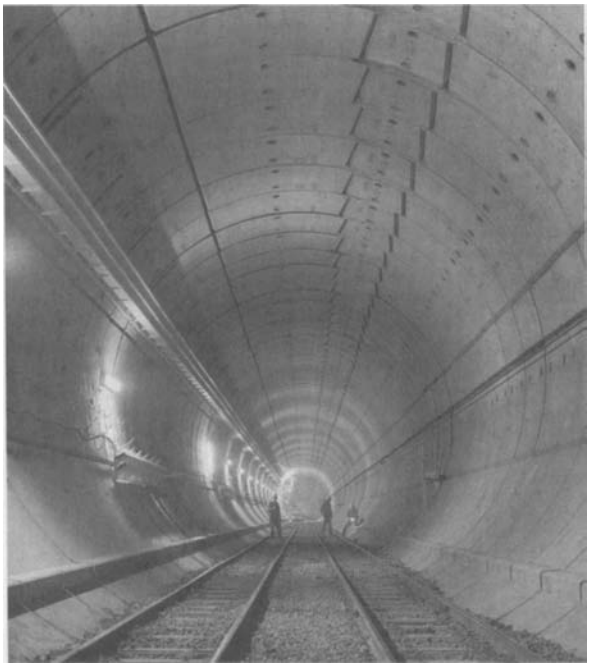

Fig. 9. Cross section of a railway tunnel nearing completion in 1991. (*The Channel Tunnel Group Limited*.)

TUPELO TREES. Members of the family *Davidiaceae* (family *Davidia*), tupelos are broadleaf trees found in North America and eastern Asia. Generally, they thrive well in or near swamps. They have alternate leaves and small, regular, greenish flowers in clusters. The drupe is essentially oval and contains a compressed stone. The *Nyssa sylvatica* is known as the sour gum or pepperidge and ranges farther north and farther away from the water than other tupelos. The bark is rough and gray; the wood is light-colored and has a twisted grain, making it difficult to work. It is a desirable wood for some applications, however, because of practically no tendency to split. The wood has been used for the hulls of ships because of its excellent strength when immersed in water and because of its resistance to salt. Record tupelo trees in the United States are listed in Table 1.

TABLE 1. RECORD TUPELO TREES IN THE UNITED STATES[1]

	Circumference[2]		Height		Spread		
Specimen	Inches	Centimeters	Feet	Meters	Feet	Meters	Location

TURACOS *(Aves, Cuculiformes, Musophagidae).* This family of birds is confined exclusively to Africa. They range in size from that of a magpie to that of a raven; the length is 40–70 centimeters ($15\frac{1}{2}$–$27\frac{1}{2}$ inches) and the weight is 250–1000 grams ($8\frac{1}{2}$–35 ounces). The lateral foretoe can be turned laterally (reversible toe). Turacos are perching birds of the jungle, the edges of woods, or of the savannas, and their diet is chiefly vegetarian. Usually they live in pairs, occasionally in small flights (4 or 5 birds), but rarely in larger groups. Their calls are characteristic and loud. The nests are shallow, built of twigs in densely foliated trees, and remind one of pigeons' nests. The clutch varies from 1 to 3 white or pastel-shaded unmarked eggs. The young wear a dense down coat at first, and the contour feathers are tardy; the nestling period is about 4 weeks.

The turacos are divided into 4 genera: 1. the Crested Turacos (*Tauraco*); 2. the Violet Plaintain-Eaters (*Musophaga*); 3. the Great Blue Turacos (*Corythaeola*); 4. the Go-Away Birds (*Crinifer*). Altogether they comprise 18 species.

The green color of the plumage of many turaco species does not result, as it does in most other green-plumed birds, from the physical structure of the feathers, but from a green pigment peculiar to turacos called turacoverdin. Turacin, which is a pigment containing copper, is also peculiar to turacos and lends an attractive red to the wing feathers of most of them. See also **Cuculiformes**.

TURBELLARIA. The free-living flatworms, a class of the phylum *Platyhelminthes*. Unlike the parasitic members of this phylum, these worms have a cellular ectodermal covering bearing cilia, with the exception of a few parasitic members which resemble the flukes and tapeworms in the absence of cilia. The free-living members of the class also have sense organs located at the anterior end of the body, including a pair of eyes and tentacles. The mouth opens on the ventral surface, either near the head or near the end of the body, and the alimentary tract (see also **Digestive System (Other Life Forms)**) is branched in many forms to extend widely through the body. The terminal portion of the tract forms a protrusible proboscis. The turbellarians are hermaphrodite with very few exceptions.

Flatworms of this group are often common in small streams and ponds, and some are marine. They glide over surfaces by the action of the cilia of the lower surface, aided by the secretion of a trail of mucus, or move by undulations produced by muscular action. Their food consists of small animals, living or dead.

TURBIDIMETRY. The cloudiness in a liquid caused by the presence of finely divided, suspended material is termed *turbidity*. A turbidimeter measures this quality by determining the reduction in transmission of light that is caused by interposing a turbid solution between a light source and a detector, such as the eye or photocell. By using a known volume of solution in comparison with a standard, the instrument makes it possible to determine the mass effect, attributable to the number and size of the particles in the solution, and thus the quantitative amount of material present. Turbidimetric methods are similar to colorimetric procedures in that both involve measurement of the intensity of light transmitted through a medium. They differ in that the light intensity is attenuated by scattering in turbidimetry and by absorption in colorimetry. Both determinations may use similar instrumentation. Several designs of combined nephelometers, turbidimeters, and colorimeters are available.

Turbidimetry is applicable to the determination of suspended material in liquids encountered in nature and in manufacturing processes. Numerous uses are found in water treatment plants, sewage works, power and stream generating plants, beverage bottling plants, and petroleum refineries. The turbidity may be due to a single chemical substance, or it may be due to a combination of several components. For example, silica may be determined in the approximate concentrations of 0.1 to 150 parts per million, expressed as SiO_2. Sometimes, composite turbidities are expressed as equivalent to silica. Higher concentrations may be determined by dilution. Numerous applications are possible in which a turbidity is developed from the test sample under controlled conditions. A widely used determination is that of sulfate, after the addition of barium chloride to an unknown sample to form a suspension of barium sulfate. The procedure is particularly applicable within the concentration range of 0.2 to 100 parts per million sulfate. Routine procedures have been developed for the determination of sulfur in coal, oil, and other organic materials in which the sample first is fused in a sodium peroxide bomb prior to precipitation of the sulfur as barium sulfate.

The *Parr turbidimeter* is an extinction type instrument, which consists of a cylinder to contain the turbid suspension, a lamp filament of fixed intensity at the base, and an adjustable plunger through which visual observation is made. Measurement is made of the depth of turbid medium necessary to extinguish the image of the lamp filament. Standard suspensions are used to prepare a calibration curve, which is a plot of depth *vs.* concentration.

The *Hellige turbidimeter* is also a variable depth type of instrument using visual detection. A combination of vertical and horizontal illumination of the sample and a split ocular permit the eye to function merely to compare the intensities of two images simultaneously appearing in the ocular. This is a special form of double-beam operation, and the intensity emitted by the light source need not be extremely constant from one sample to another. Adjustment is made of a slit in the path of the direct, or vertical, illumination of the sample, and the calibration curve consists of a plot of this slit opening *vs.* concentration.

See also **Analysis (Chemical)**; **Nephelometry**; and **Photometers**.

TURBIDITY. The effect of (primarily) aerosols, through their total optical depth, in reducing the transmission of direct solar radiation to the surface below that through a purely molecular atmosphere. Measures of turbidity refer to the total aerosol optical depth, either directly at a specified wavelength (e.g., the Volz turbidity factor or the Ängström turbidity coefficient, which is referenced to a wavelength of 1 μm), or indirectly by the ratio of aerosol to Rayleigh optical depth (e.g., the Linke turbidity factor).

TURBIDITY CURRENT. See **Ocean**.

TURBINE ENGINE. An engine incorporating a turbine as a principal component; especially, a gas-turbine engine.

TURBINE (Hydraulic). See **Hydroelectric Power**.

TURBINE (Hydroelectric). See **Hydroelectric Power**.

TURBINE (Steam). When steam is expanded adiabatically through a stationary nozzle, it does not retain all the heat it originally had. The heat released during expansion, of course, does not disappear. According to the first law of thermodynamics, it must reappear as work energy in equivalent amounts (778 foot-pounds (108 kilogram-meters) for each Btu). In the case of steam expanding through a stationary nozzle, the moving steam must gain this mechanical energy, with the result that its speed is considerably increased. An ordinary expansion involving a heat drop of about 100 Btus (25 Calories) of steam has the capacity to increase its speed to the large magnitude of 30 miles (48 kilometers)/ minute. This gives some clue as to the reason why so light a fluid medium as steam is capable of producing so much power in a machine of moderate dimensions.

There are two principles of action employed in steam turbines: (1) impulse; and (2) reaction. The impulse principle involves stationary nozzles and moving blades, which absorb the mechanical energy from the steam as it flows over the blades. In the reaction turbine, the nozzles are themselves attached to the shaft. In one case, the motivating force is one of impulse of a stream against a blade; the other, one of a reaction force created by the acceleration of the steam in the moving nozzles. Very high rotative speeds are necessary if the entire adiabatic heat drop for the turbine is released in one set of nozzles. For example, an impulse turbine with a conservative expansion would create a steam speed which, if absorbed on one row of blades revolving in an 18-inch (46-centimeter) circle, would require a rotative speed at the shaft of better than 10,000 revolutions per minute. This gives a clue to the desirability of staging a turbine by subdividing the heat drops, the energy being absorbed after each incremental heat liberation. Thus, in a 5-stage impulse turbine, each stage may be called on to absorb only one-fifth of the total heat drop. The subdivision is

even greater in the case of reaction turbines, where the Btus liberated per stage rarely exceed 10. In consequence, the number of stages found in the reaction-type turbine is greater than in the impulse-type turbine. Except for areas of nozzles, size of blades, and blade angles, the stages resemble one another.

Large steam turbines fall into three classes: (1) the straight reaction; (2) the straight impulse; and (3) the impulse-reaction turbine. The straight reaction turbine may have numerous stages; the straight impulse turbine rarely more than 20 stages (half that number may be more common). One or two impulse stages preceding a straight reaction section enable reduction of the number of reaction stages to about twenty.

An impulse turbine is pressure staged, i.e., the pressure drop is subdivided among a number of stages, any one stage of which may be, in addition, velocity staged. By this is meant that, following one set of nozzles there may be two rows of moving blades which, together, effect the reduction of velocity and the absorption of energy created in those nozzles. The two rows of moving blades are separated by a row of fixed reversing blades, which receives the steam from the first row and directs it at the proper angle for the second row. A velocity stage within a pressure stage is known as a Curtis stage. A simple pressure stage is a Rateau stage, and the reaction stage often is called Parson's staging. As steam expands through a multistage turbine it increases in volume after each stage, making it necessary either, that the diameter of the circle in which the blades travel be increased, or that the height of the blades be increased to provide sufficient area for the increased volume of flow. Usually both of these expedients are adopted, so that the turbine exhibits, roughly, a somewhat conical shape, being smallest at the high pressure end, and largest at the exhaust.

Essential to the operation of a turbine are a number of auxiliary devices. The impulse turbine rotor receives a moderate end thrust, due to fluid friction on the blades. The reaction turbine has a large end thrust, arising from the drop of steam pressure, across the moving blades, acting on the blading annulus. While the end thrust of an impulse turbine can be accommodated by special thrust bearings, the large forces set up in a reaction turbine necessitate the use of a special device known as a dummy piston. The dummy piston is a circular plate mounted concentric with the axis of the turbine, and having, on one side, high, and on the other, low steam pressure. The pressures are so chosen that the direction of the resultant force on the plate is counter to the end thrust on the blades. A separate piston is used to balance each different diameter of the drum, so that although steam pressure and end thrusts may vary with different loads, the equalizing pressures also similarly vary. A thrust bearing is provided to absorb the small amount of unbalance that may still exist.

The moving parts of the turbine are few. Principally, there are two bearings, one at each end of the turbine, which support the rotor. These are rather heavily loaded so that plain babbitted bearings are usual. Oil is pumped to these bearings and wasted from them to a sump, from which it is withdrawn, filtered, and cooled before being again supplied to the bearings. An auxiliary pump maintains oil pressure during the starting and stopping cycle of the main unit. Where the shaft of the turbine projects through the casing, means are provided for packing against leakage of the steam outward at the high-pressure end, and infiltration of air at the low-pressure end. Packed stuffing boxes are used only on small turbines. This service is performed on large turbines by sealing glands which are built into the turbine, and which seal the shaft with steam or water. The outward leakage from the glands is minimized by labyrinths.

Governing of steam turbines is accomplished by three methods, viz.: (1) throttling at inlet, (2) varying number of inlet nozzles in action, (3) varying duration of full pressure puffs (blasts), of which there are several per second. In addition, some turbines are provided with hand-operated by-pass valves which, by admitting high-pressure steam to low-pressure stages, enable the turbine to carry more overload though, of course, at reduced economy. Of these methods, the first is widely used on small turbines. In the large turbine field, the second is applied to the Curtis type, and the third to the Parsons type.

The losses in a steam turbine, as is the case with the engine, are topped in magnitude by the heat in the exhaust. Unfortunately, this is difficult to reduce because of the troubles attending the use of steam of quality lower than about 85% in the turbine. Wet steam erodes turbine blades, due to the high velocity with which the particles of moisture strike them. The other losses that occur in steam turbines are:

1. Thermodynamic losses:
   a. Leakage. Past shaft gland packings, dummy pistons, diaphragms and blade tips:
   b. Blade and disk friction.
   c. Throttling at the control valves.
   d. Nonstream line flow at other than design conditions.
   e. Leaving loss, and pressure losses in exhaust nozzle.
2. Mechanical losses:
   a. Bearing and stuffing box friction.
   b. Windage action of idle blades.
   c. Gland water-seal power.
   d. Oil pump and governor power.

All the thermodynamic losses of one stage are returned to the steam as it enters the next lower stage, so that one definite advantage of multi-staging is to make available to the next stage the thermal losses of the preceding one. This is one factor in the superior performance of multi-stage turbines. To illustrate the point, consider the case of friction on the nozzles. If the turbine casing is well insulated, the heat that is generated by friction of the steam against the nozzles simply elevates the nozzle temperature until it returns, by conduction to the steam, as much heat as is generated by friction. The greater part of the stage loss is returned to the steam at the low pressure, and in turbine design it is considered that all of the reheat occurs at the low pressure of the stage. Figure 1 shows how an adiabatic heat drop, as in nozzles, followed by a reheat, in which the stage losses are added at the low pressure, results in a steadily increasing entropy in a multistage turbine. This explains the typical expansion line of the steam turbine, which, as pressure is reduced, increases in entropy, whereas an ideal turbine would expand the steam at constant entropy. The increase of entropy corresponds to a decrease of energy availability, and that turbine which has the minimum entropy increase shows the best performance.

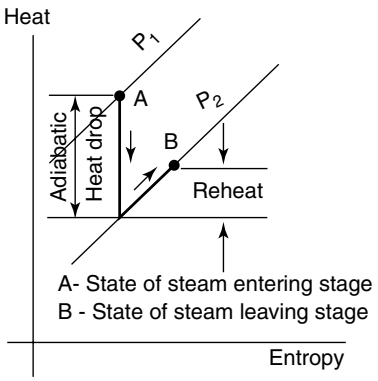

Fig. 1. Steam conditions in one stage of a turbine.

It is obvious from the foregoing analysis that all the heat taken out of the steam during its passage from the throttle to the exhaust must have been put onto the rotating shaft as mechanical energy. This is true because of the negligible radiation loss from the casing. Friction and power required to drive the governor and oil pump take their toll of this energy, but they rarely amount to as much as 5% of the heat drop, so that practically all of the heat drop appears at the turbine shaft coupling as useful work.

Trends in Steam Turbine Design. For fossil applications in the 500 to 600 megawatt range, a turbine consisting of a combined high pressure-intermediate pressure turbine element and two double flow low-pressure turbine elements is usually provided. The low-pressure turbine elements may have 25-, $28\frac{1}{2}$, or 31-inch (63.5-, 72.4-, or 78.7-centimeter) long last row blades, depending on the economic optimization with available cooling water, fuel costs and other cycle parameters. The world's first 500 megawatt tandem-compound steam turbine was a unit of this type, placed into service late in 1965. Combined elements, with the high and intermediate pressure blading in a single casing, offer significant

advantages. The installed length of such a unit is 18 feet (5.4 meters) less than that required when the high pressure and intermediate pressure elements are contained in separate turbine casings. With one less turbine element, the savings in capital, erection, and maintenance costs are appreciable. A similar arrangement is provided for units in the 150 or 400 megawatt size class, consisting of a combined high pressure-intermediate pressure turbine coupled in tandem with one double flow low-pressure turbine element. The last row blades of the low-pressure turbine element may be 23, 25, $28\frac{1}{2}$, or 31 inches (58.4, 63.5, 72.4, or 78.7 centimeters) long, depending upon the unit rating, cycle, fuel costs, and expected load factor. Many of the improvements developed for the higher-rated units are also available in units rated less than 150 megawatts. An example of this is the single-case, single-exhaust-flow unit for nonreheat applications, such as the 100 megawatt steam turbines designed for some combined-cycle plants.

For larger fossil applications, above 650 megawatts, the complete unit may consist of a separate double-flow high pressure turbine element and a separate double flow intermediate pressure turbine element coupled in tandem with either two or three double-flow low pressure turbine elements. This type unit may utilize either $28\frac{1}{2}$- or 31-inch (72.4- or 78.7-centimeter) long last row blades. Units of both the four casing four flow type and five casing six flow type are in service. Maximum turbine-generator capabilities of units in service are slightly over 800 megawatts and several flow types are projected in the 1,200 megawatt size range.

Prior to the great increases in cost of raw fuel, the story of how the economy of scale in turbine generator unit sizes drove down the cost of electrical power generation is well known. Larger units provide better thermal performance, lower capital costs, and fewer parts to maintain than multiple sets of smaller ratings for the same total capacity. The sharply accelerating trend to even larger unit sizes, which began in the 1950s, continues.

Some recent technological advances that have contributed to improved steam turbines include:

1. Development of an anchored throttle valve-steam chest system, which eliminates the concern for possible turbine casing distortion from main steam inlet pipe reactions. The steam chest, anchored to the foundation, isolates the reactions to the main steam station piping so they are not imposed on the turbine casing.

2. Improvements in the design of internal stationary parts have consisted of innovations to minimize the effects of thermal gradients and thermal cycling. Fossil units in particular are designed with the expectation that they will be called upon to support intermediate peaking or cyclic duty operation. Separate nozzle chambers are used to eliminate locked-in thermal stresses when only a portion of the admission arc is active while operating at reduced load. Inner casings are mounted in the outer casings so they are free to expand radially and axially. The alignment of the inner casing is maintained by supports at the horizontal joint and keys on the vertical center line. All blade rings, dummy rings, and gland rings are separately mounted in the inner or outer casing with their alignment maintained by supports on the horizontal joint and dowel pins at the vertical center line. Each component is free to expand independently, without being restricted or restrained by surrounding parts. Thermal distortion due to temperature gradients and load cycling is practically eliminated. Thermal cracking of casings and nozzle chambers, once a major industry problem, is solved where these features are applied.

3. The first stage in a high-pressure turbine, the control stage, is subjected to the shock load associated with partial arc admission and the flow excitation produced by the nozzle vane wakes. Research has been carried out regarding the operating characteristics of control-stage blading. Troublesome modes of vibration have been identified and their frequencies established. Nozzle vane sections have been developed to provide lower levels of excitation and better control of exciting frequencies.

4. In fossil turbine units, steam temperatures are high enough to affect materially the useful creep life of a turbine rotor at the operating stress level. Considerable design effort has concentrated on reducing the exposed rotor temperature at the two inlet zones of the unit by blanketing these rotor areas with cooling steam. Steam, which has been cooled by expansion through the control stage, blankets the zone between the nozzle chambers and the rotor. For 538 °C inlet temperature, the maximum rotor temperature is limited to about 496 °C. At this reduced temperature, the creep life of the rotor is nearly doubled.

5. Many innovations have been applied to rotating parts to improve thermal performance and reliability. Improved mechanical design in the form of a side-entry blade root has simplified rotor design. This route allows the use of a full row of blades, thereby eliminating the loss in performance and the additional blade loading which exists due to the flow disturbance created when the closing blade of the row must be omitted. This type of blade root was invented by Westinghouse nearly 50 years ago.

6. One of the most significant innovations during the last few years has been the application of sophisticated control techniques made possible by the development of solid-state technology. A particularly valuable feature of digital electrohydraulic control is the ability to switch control between single valve and sequential valve operation. This valve management gives the operator the flexibility to match more favorably temperatures in the first-stage zone of the high-pressure turbine. This minimizes starting and loading periods required for intermediate or cyclic duty application. Automatic startup programs also have been developed.

TURBOEXPANDER. See **Gas and Expansion Turbines**.

TURBOFAN. A turbojet engine in which additional propulsive thrust is gained by extending a portion of the compressor or turbine blades outside the inner engine case. The extended blades propel bypass air flows along the engine axis but between the inner and outer engine casing. This air is not combusted but does provide additional thrust caused by the propulsive effect imparted to it by the extended compressor blading.

TURBOPAUSE. The surface that separates the homosphere, in which the constituents of the atmosphere are well mixed by turbulence, from the heterosphere, in which constituents adopt their individual distributions with height as the result of molecular diffusion. The turbopause is not very clearly marked, but usually lies at a height of about 100 kilometers (62 miles), near the base of the thermosphere. See also **Atmosphere (Earth)**.

TURBOT. See **Flatfishes**.

TURBULENCE. 1. Irregular fluctuations occurring in fluid motions. It is characteristic of turbulence that the fluctuations occur in all three velocity components and are unpredictable in detail; however, statistically distinct properties of the turbulence can be identified and profitably analyzed. Turbulence exhibits a broad range of spatial and temporal scales resulting in efficient mixing of fluid properties. Analysis reveals that the kinetic energy of turbulence flows from the larger spatial scales to smaller and smaller scales and ultimately is transformed by molecular (viscous) dissipation to thermal energy. Therefore, to maintain turbulence, kinetic energy must be supplied at the larger scales.

2. Random and continuously changing air motions that are superposed on the mean motion of the air.

TURBULENCE (Atmospheric). See **Atmospheric Turbulence**.

TURBULENCE LENGTH SCALES. Measures of the eddy scale sizes in turbulent flow. The separation between the largest and smallest sizes is determined by the Reynolds number. The largest length scales are usually imposed by the flow geometry, for example, the boundary layer depth. Because turbulence kinetic energy is extracted from the mean flow at the largest scales, they are often referred to as the "energy-containing" range. The smallest scales are set by the viscosity and the rate at which energy is supplied by the largest-scale eddies. Intermediate between these scales are the inertial subrange scales for which turbulence kinetic energy is neither generated nor destroyed but is transferred from larger to smaller scales. Smaller-scale eddies are generated from the larger eddies through the nonlinear process of vortex stretching. Typically, energy is transferred from the largest eddies to the smallest ones on a timescale of about one large- eddy turnover. There are standard turbulence length scales for each of the eddy scale sizes; integral length scales for the energy-containing eddies, Taylor microscale for the inertial subrange eddies, and Kolmogorov microscale for the dissipation range eddies.

See also **Integral Length Scales**; **Kolmogorov Microscale**; and **Taylor Microscale**.

AMS

TURBULENT FLOW. A condition of fluid flow in a closed conduit that is above a critical velocity. In this condition, there is a random, irregular motion of the fluid particles in directions transverse to the axis of the main flow. This is converse to the condition of laminar or streamline flow. See also **Laminar Flow**.

At velocities greater than the critical, the fluid velocity profile in the conduit is uniform across the conduit diameter except for a thin layer of fluid at the conduit wall. This *boundary layer* continues to move in laminar flow. In connection with flow measurement, most flowmeters have constant coefficients under turbulent flow conditions. Some flowmeters have the advantage of constant coefficients over Reynolds Number ranges encompassing both turbulent and laminar flows. See also **Fluid Flow (Boundary Layer)**; **Free Turbulent Flow**; and **Reynolds Number**.

TURBULENT FLOW (Air). See **Aerodynamics and Aerostatics**.

TURBULENT FLUX. Transport of a quantity by quasi-random eddies or swirls; the covariance between a velocity component and any variable. For example, time series of potential temperature θ and vertical velocity w can be used to find the turbulent vertical kinematic heat flux, F_H:

$$F_H = \frac{1}{N}\sum_{i=1}^{N}(w_i - \overline{w})(\theta_i - \overline{\theta}) = \frac{1}{N}\sum_{i=1}^{N} w_i'\theta_i' = \overline{w'\theta'},$$

where there are N data points in each time series, i is the time-series data index, primes denote deviations from the mean (i.e., the turbulent gusts), and the overbar denotes an average over the whole time series.

TURING, ALAN (1912–1954). Turning was a British mathematician and computing pioneer. His theories were important in the development of the digital computer. He studied at Cambridge University and then came to Princeton University in the U.S. for graduate studies. At Princeton, he explored the concept of the modern digital computer. In 1936, Turing produced his first, and best known work, "On Computable Numbers" in which he laid out processes that would be performed by a "universal" computer for solving math problems. The *Turing machine* would judge the "computability" of any problem, solving all mathematical problems provided it was given the proper algorithms. His idea was revolutionary and defined the modern computer.

During WWII, Turing went home to England and worked at Bletchley Park on the ULTRA project. He played a critical role in the development of a machine that helped to decipher German military codes by testing key codes until it found the correct combinations. He constructed relay-driven decoders that shortened the code-breaking time down to hours instead of weeks. Later, in 1945, he went to Great Britain's National Physical Laboratory and worked to help build the Automatic Computing Engine, which was the first British electronic digital computer. Later, at Manchester University he helped develop the Manchester automatic digital machine. And in 1950, he published a notable paper, which offered what has become know as the *Turing Test* to determine whether machines possessed intelligence and could think.

Turing died June 7, 1954 of an apparent suicide when he ate a cyanide-laced apple. His death was a major loss for the computer science world.

See also **Digital Computer Systems**; and **Turing Machine**.

J. M. I.

TURING MACHINE. A mathematical abstraction of a device that operates to read from, write on, and move an indefinite tape, thereby providing a model for computerlike procedures. The behavior of a Turing machine is specified by listing an alphabet (i.e., collection of symbols read and written), a set of internal states, and a mapping of an alphabet and internal states which determines what the symbol written and tape motion will be, and also what internal state will follow when the machine is in a given internal state and reads a given symbol. The Turing machine, proposed in 1936 by Alan M. Turing, is the theoretical prototype of real general purpose computers and has had profound impact in many areas of computer science. An excellent description of a Turing machine and its implications is found in "Mathematical Foundations of Programming" by F.S. Beckman, Addison-Wesley, Reading, Massachusetts (1980).

TURKEY *(Aves, Galliformes; Meleagris).* A large game bird of North and Central America. Wild turkeys are now abundant in some of the protected areas of the eastern states, and in the Southwest they may be found in wild areas. In comparison with their former abundance, however, they are now rare. The eastern species is easily distinguished from the western by the absence of white tips on the feathers of the tail and rump. A third species occurs in Central America. See also **Galliformes**; and **Poultry**.

TURKEY BUZZARD. See **Vulture**.

TURMERIC (CURCUMA). See **Spices**.

TURMERIC *(Curcuma longa; Zingiberaceae).* A name given to both the plant, *Curcuma longa*, and to its derivatives, a dye and a drug, which are obtained from the swollen rhizomes of the plant.

Curcuma, a native of southern Asia, is widely grown in India and other tropical Asian and East Indian lands, where it is used as a drug as well as a condiment and dyestuff. The plant has long smooth pointed leaves, and dull yellow flowers. To prepare it for use, the yellow-brown aromatic rhizome is cleaned and cut into pieces 1–2 inches (2.5–5 centimeters) long. The cut surfaces show the bright yellow color of the substance of the rhizome. These cut pieces are dried in an oven and then ground. In western countries turmeric is sometimes used as a dye; as an ingredient to curry powder; to color and flavor pickles, mustard, and other foods; and in chemistry, where it is a pH indicator. See also **Flavorings**.

TURN-AND-BANK INDICATOR. An instrument for installation in an aircraft. Also termed a turn-and-slip indicator, the instrument contains a

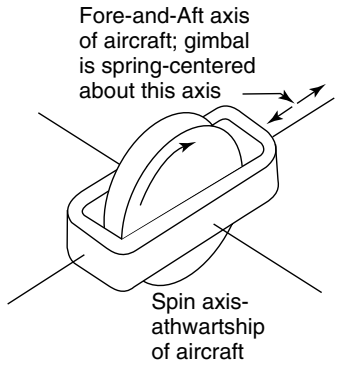

Fig. 1. Arrangement of a turn gyro as used in turn-and-bank indicator.

rate gyro mounted with its spin axis athwartship and its spring-restrained gimbal axis aligned fore and aft as shown in Fig. 1. Deflection of this axis from its neutral position is translated to motion of a pointer, calibrated in rate of turn. Below the pointer is a ball bank indicator, which acts as a damped pendulum, showing the dynamic vertical component lying in the plane perpendicular to the fore-and-aft axis. If both pointer and ball are centered, the pilot knows the aircraft is flying straight and that the wings are horizontal. The turn-and-bank indicator is also used in making desired rates of turn with proper bank. Both air-drive and electric gyros are used. In a properly designed turn-and-bank indicator, the direction of rotation, moment of inertia, and speed of the gyro wheel are so matched to the centering spring that the gyro spin axis remains nearly horizontal as the plane makes a turn with proper bank at its normal cruising speed. Instead of a rotating gyro wheel, other sensing elements, such as a vibrating reed or a stream of liquid, have been used.

Gyros of the type described are often called *rate gyros* and, when their speed is accurately controlled, they can serve as accurate measures of rate of turn. They find many uses, as in gunsights, bombsights, autopilots, and navigation devices. Instead of driving a pointer, they may mechanically perform some function in a computer or may drive a potentiometer, synchro, switch, or similar device to provide an electrical function of rate of turn.

TURNER ANGLE. A parameter used to define the local stability of an inviscid water column to double- diffusive convection.

Defined as

$$\mathrm{Tu} = \tan^{-1}(\alpha\partial_z T - \beta\partial_z S, \alpha\partial_z T + \beta\partial_z S)$$

where $\tan^{-1}$ is the four-quadrant arctangent, α is the coefficient of thermal expansion, β is the coefficient of saline contraction, T is temperature, and S is salinity. If $-45^\circ < \mathrm{Tu} < 45^\circ$, the column is statically stable. If $-90^\circ > \mathrm{Tu}$ or $\mathrm{Tu} > 90^\circ$, the column is statically unstable to Rayleigh–Taylor instability. If $-90^\circ < \mathrm{Tu} < -45^\circ$, the column is unstable to diffusive convection. If $45^\circ < \mathrm{Tu} < 90^\circ$, the column is unstable to salt fingering. See also **Salt Fingering**.

AMS

TURNER'S SYNDROME. A set of symptoms that develops in a person who has only one X-chromosome and no Y-chromosome. The person will be female, but will not mature sexually. She will also be stunted physically and may show certain other characteristics, such as a webbing of the skin at the side of the neck and wide spaced nipples on the chest. Some degree of feminine normality can sometimes be induced through the use of female hormone therapy.

TURNIP. See **Brassica**.

TURNSTILE ANTENNA. An antenna composed of two dipole antennas, normal to each other, with their axes intersecting at their midpoints. Usually, the currents are equal and in phase quadrature.

TURNSTONE. See **Waders, Shorebirds, and Gulls**.

TURPENTINE. See **Resins (Natural)**.

TURQUOISE. The mineral turquoise is a hydrated phosphate of aluminum and copper. Its exact composition is doubtful, the formula may be expressed $CuAl_6(PO_4)_4(OH)_8 \cdot 5H_2O$; iron is often present. This mineral is found in minute triclinic crystals, but chiefly massive as seams and crusts. The fracture is conchoidal; hardness, 5–6; specific gravity, 2.6–2.8; luster, soft waxy; color, may be various shades of blue, bluish-green and green; essentially opaque. It takes a good polish and the sky-blue varieties have long been used as a gem material. Unfortunately, many beautiful blue stones in time change their color to some greenish hue, usually not attractive, rendering them practically valueless.

For hundreds of years turquoise has been mined in Iran, where it is found with limonite filling crevices in a brecciated trachyteporphyry, and because it found its way into Europe through Turkey, it became known as turquoise, from the French word *turque*, Turkish. Other mines were worked by the Egyptians in ancient times on the Sinai Peninsula. Turquoise is also found in Siberia, Turkestan, Saxony and France; and in the United States in Arizona, California and New Mexico. A blue stone that has passed for turquoise is in reality odontolite, from the Greek meaning tooth, usually fossil teeth or bones colored with iron phosphate. Odontolite is softer than true turquoise, has a somewhat higher specific gravity, 3.0–3.5, and may be distinguished by chemical tests, or by a microscopical examination which will reveal its organic structure.

TURTLES. Of the class *Reptilia* (reptiles), subclass *Anapsida*, order *Testudines* (turtles). Two suborders of turtles are of principal interest: *Cryptodira* (modern turtles), and *Pleurodira* (side-neck turtles). The organization of the turtles is shown in Table 1.

The characteristic shell sets the turtles so distinctly apart as a separate order that one would find it difficult to confuse them with other animals. Moreover, they are probably the only reptiles that most humans view without prejudice. In fact, the number of people who positively like turtles is surprisingly large. Both terrestrial and aquatic turtles (some of which are called tortoises or terrapins) are often kept as pets in gardens, terrariums, and aquariums.

Turtles are compactly built reptiles with a bony shell, which is a part of the skeleton, protecting both the back and the underside. The animals can more or less completely pull the head and neck, legs, and tail in under the shell. The massive skull is of the anapsid type, having no temporal openings, but rather indentations on the posterior or lower edge. In the species alive today, the jawbones are covered not with teeth but with sharp horny edges. The shell encloses the body so completely that only head, limbs, and tail protrude; it consists of an inner bony capsule and usually an outer covering of large horny plates (sometimes with a thick leathery skin instead).

The basic shell structure is often considerably modified. For example, in the soft-shelled turtles (*Trionychidae*), the pitted-shell turtle, and the leatherneck turtle, in the place of horny scutes there is a thick, leatherlike skin which covers the shell. The marginal bony plates are usually lacking in the soft-shell turtles. The usual bony elements of the shell have almost disappeared in the leatherback turtle, and in their place is a new, tessellated shell, composed of small bony plates, that apparently has nothing to do with the true bony carapace of other turtles. In other species that spend most of their time in the water, there are reductions of parts of the bony shell. Frequently quite large openings (fontanelles) have appeared between the costal plates, so that in certain groups — for example, in the *Cheloniidae* — the ends of the ribs are visible.

Many aquatic and some terrestrial species have evolved single or double traverse hinges in the plastron, places where elastic cartilaginous tissue is interposed between two adjacent plate pairs. In this way, the plastron, ordinarily quite rigid, is divided into movable anterior and posterior

TABLE 1. CLASSIFICATION OF TURTLES
CLASS . . . . . REPTILIA (Reptiles)
ORDER . . . . . TESTUDINES (Turtles)

Family (Subfamily)	Examples
Suborder: MODERN TURTLES (*Cryptodira*)	
Dermatemydidae	Mexican river turtle (*Dermatemys maivii*)
Chelydridae **Snapping Turtles**	Snapping turtle (*Chelydra serpentina*); Alligator snapping turtle (*Macroclemys temminckii*)
Kinosternidae **Musk Turtles**	Common musk turtle (*Sternotherus odoratus*); Keel-backed musk turtle (*S. carinatus*); Loggerhead musk turtle (*S. minor*); Mud turtle (*Kinosternon subrubrum*); Striped mud turtle (*K. baurii*); Scorpion mud turtle (*K. scorpioides*); Narrow-bridged mud turtle (*Claudius angustatus*); Giant musk turtle (*Staurotypus triporcatus*)
Platysternidae	Big-headed turtle (*Platysternon megacephalum*)
Emydidae	European pond turtle (*Emys orbicularis*); Blanding's turtle (*Emygoidea blandingii*); Chicken turtle (*Deirochelys reticularia*); Painted turtle (*Chrysemys picta*); Pond slider (*C. scripta*); Red-eared turtle (*C. s. elegans*); Cooter or terrapin (*C. floridana*); River cooter (*C. concinna*); Red-bellied turtle (*C. rubriventris*); Ornate slider (*C. ornata*); Brazilian slider (*C. dorbigni*); Jamaican slider (*C. terrapen*); Map turtle (*Graptemys geographica*); False map turtle (*G. pseudogeographica*); Diamondback terrapin (*Malaclemys terrapin*); Box turtle (*Terrapene carolina*); Western box turtle (*T. ornata*); Spotted turtle (*Clemmys guttata*); Wood turtle (*C. insculpta*); Bog turtle (*C. muhlenbergii*); Western or Pacific pond turtle (*C. marmorata*); Caspian terrapin (*C. caspica*); Chinese terrapin (*Clemmys mauremys nigricans*); Japanese terrapin (*C. m. japonica*); Annam turtle (*Annamemys annamensis*); Black pond turtle (*Geoclemys hamiltonii*); Reeve's turtle (*Chinemys reevesii*); Amboina box turtle (*Cuora amboinensis*); Three-lined box turtle (*C. trifasciata*); Annandal's turtle (*Hieremys annandalii*); Diadem turtle (*Hardella thurjii*); Indian roof turtle (*Kachuga tecta*); Painted batugur (*Callagur borneoensis*); Bornean pond turtle (*Orlitia borneensis*)
Testudinidae **Ture Tortoises**	West African hinge-backed tortois (*Kinixys erosa*); Bell's Eastern hinged tortoise (*K. belliana*); Home's hinged tortoise (*K. homeana*); Parrot-beak tortoise (*Homopus areolatus*); Spider tortoise (*Pyxis arachnoides*); Pancake or Tornier's tortoise (*Malacochersus tornieri*); Spur-tailed Mediterranean land tortoise (*Testudo hermanni*) Star tortoise (*Testudo geochelone elegans*); Leopard tortoise (*T. g. pardalis*); African spurred tortoise (*T. g. sulcata*); Geometric tortoise (*Testudo psammobates geometrica*); Tent tortois (*T. p. tentoria*); Bowsprit tortoise (*Testudo chersina angulata*); Radiated tortoise (*Testudo asterochelys radiata*); Aldabra tortoise (*Testudo aldabrachelys gigantea*); Horsfield's tortoise (*Testudo agrionemys horsfieldii*); Red-footed tortoise (*Testudo chelonoidis carbonaria*); Argentine tortoise (*Testudo chilensis*); Yellow-footed tortoise (*T. c. denticulata*); Giant Galápagos tortoise (*T. c. elephantopus*); Gopher tortoise (*Gopherus polyphemus*)
Cheloniidae **Marine Turtles**	Green turtle (*Chelonia mydas*); Hawksbill (*Eretmochelys imbricata*); Loggerhead (*Caretta caretta*); Ridley (*Lepidochelys olivacea*)
Dermochelyidae	Leatherback turtle (*Dermochelys coriacea*)
Carretochelyidae	Pitted-shell turtle (*Carettochelys insculpta*)
Trionychidae (*Cyclanorbinae*) **Soft-shelled Turtles**	Soft terrapin (*Lissemys punctata*); Nubian softshell (*Cyclanorbis elegans*); Senegal softshell (*C. senegalensis*); Aubry's softshell turtle (*Cycloderma aubryi*); Bridled softshell turtle (*C. frenatum*)
(*Trionychinae*) **Soft-Shelled Turtles**	River softshell (*Chitra indica*); Florida softshell (*Trionyx ferox*); Eastern spiny softshell (*T. spiniferus*); Smooth softshell (*T. muticus*)
Suborder: SIDE-NECK TURTLES (*Pleurodira*)	
Pelomedusidae	Helmeted turtle (*Pelomedusa subrufa*); Adanson's mud turtle (*Pelusios adansonii*)
Chelidae **Snake-Necked Turtles**	Matamata (*Chelus fimbriatus*); Otter turtle (*Hydromedusa rectifera*); Murray's river turtle (*Emydura macquarii*)

Note: Some of the better known as well as other species selected at random are included in the various examples given. The examples represent only some of the species of turtles.

sections which the animal can fold upward to close the apertures between the top and bottom of the shell.

The skull of the turtle, in comparison with that of other reptiles, seems short, massive, and strongly arched. There are never true temporal openings, but instead there are characteristic indentations in the temporal region. Not uncommonly the upper jaw terminates anteriorly in a point, curved downward like a hook (as for example in the alligator snapping turtle and the big-headed turtle); the result reminds one of the beak of a bird of prey.

The skin may be either smooth or rough, with scales only on the limbs or the tail; on the upper side of the tail there are sometimes, as in the snapping turtles, scales forming rows of pronounced ridges. On the legs of the *Testudinidae*, too, there are often sturdy lumps, some even ossified at the base. Certain species have special epidermal appendages, the numbers of which can be important in classification. Among these are the barbels on the chin of musk turtles (*Kinosternidae*) and some pleurodires; the warts of the snapping turtles (*Chelydridae*); and the lobes on the head and neck of the matamata. Skin glands are restricted in distribution.

Since turtles can cause the air to flow from one part of the lung to another, the aquatic forms are able to displace their center of gravity at will, so that their lungs act functionally like the swim bladders of fish. But this ability is impaired when the lungs are diseased; for this reason, aquatic turtles with respiratory insufficiencies float at an angle in the water and do not dive. In particularly deep-diving species, the lungs are embedded in bony chambers formed by projections of the inner wall of the shell. It is assumed that this arrangement acts against the effects of high water pressure.

Among the aquatic turtles, there is considerable gas exchange in other parts of the body as well. For example, the soft-shelled turtles are said to take up as much as 70% of their oxygen through the skin that covers the bony shell. Moreover, the mouth cavities of all turtles are richly provided with capillaries. In the marine turtles and soft-shelled turtles, there are also fingerlike villi of skin in the throat through which the blood circulates freely and which serve to remove oxygen from the water. The same function is probably served by the paired vesicles (the anal sacs) attached to the gut near the cloaca; they, too, presumably operate as "physiological gills," taking up a certain amount of oxygen by way of the copious flow of blood through their walls. Thus, the aquatic turtles can actually pass the winter under a completely closed roof of ice. During this period of dormancy, the metabolic rate and thus the oxygen requirement is considerably reduced.

The vertebral column consists of 8 cervical vertebrae, 10 trunk vertebrae, and 18 to 33 tail vertebrae. The form of the cervical vertebrae is extremely variable; it permits the animals to withdraw the head under the shell by bending the neck into an S, either in the vertical (suborder *Cryptodira*) or the horizontal (suborder *Pleurodira*) plane. The limbs usually end in

5 toes, although in one tortoise (*Testudo horsfieldii*), there are only four. The toes are also reduced in the hind limbs of one subspecies of the American box turtles (*Terrapene carolina triunguis*). Freshwater turtles ordinarily have rowing legs somewhat flattened laterally, whose toes are joined by more or less well developed membranes. In contrast, the toes on the columnar (i.e., round in cross-section) legs of the terrestrial forms are not free, but rather form part of a stumpy foot with only the claws sticking out. The legs of cheloniid turtles, soft-shelled turtles, and the pitted-shell turtle have become powerful swimming paddles, very greatly flattened laterally. These animals, too, have no free toes and may have either no claws or as many as three extending from the anterior edge of the paddle. See Fig. 1.

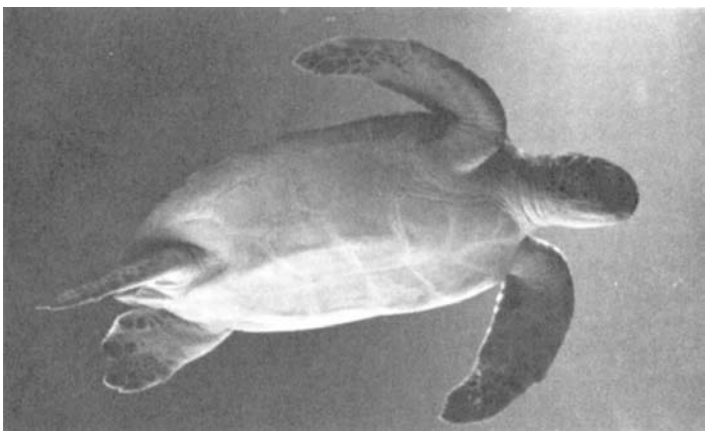

Fig. 1. Young specimen of a green turtle. When fully grown, it may reach a weight of 272 to 363 kg (600 to 800 pounds). (*New York Zoological Society*.)

With their horny jaws, turtles cut off pieces of food and swallow them whole. As a rule, these blades of horn are exposed, but in the soft-shelled turtles, they are covered with fleshy lips. Although the mouth is well provided with salivary glands, the actual process of digestion probably first takes place in the stomach, which curves to lie crossways in the body cavity. Often it contains stones, picked up voluntarily by both aquatic and terrestrial turtles, presumably as aids to grinding food more thoroughly. The small intestine of the aquatic turtles, predominantly carnivores, is relatively short, but, in the vegetarian land turtles, it can be several times longer than the body. Thirty percent of the cellulose consumed can be digested. The liver is unusually large.

The kidneys excrete a relatively large quantity of urine, which is stored in fluid form in the urinary bladder, present in all turtles. Often turtles squirt a sharp stream of water from the anus when one picks them up. This does not come from the urinary bladder, but rather from the anal sacs.

The turtle brain is small but nevertheless rather highly developed, especially with respect to its centers for the senses of vision, smell, and equilibrium. Thick, movable lids protect the eyes, which have excellent resolution. Marine turtles and the diamond-backed terrapin have tear glands. Turtles can discriminate distinctly not only forms, but colors as well. Their range of visible wave lengths is shifted considerably toward the red part of the spectrum. Some infrared light waves can be detected. In general, turtles are thought to be deaf, although their hearing organs, however simply constructed, are well developed. Turtles are fundamentally mute, apart from the hoarse cheeping or groaning noises made by testudinids at the peak of excitement during copulation. The sense of smell is well developed. The animals sniff all food extensively, and they can be attracted in masses from some distance by the smell of ripe fruit. In terms of mental capacity, turtles display impressive feats of orientation, learning, and memory. In captivity, they develop a surprising sense for certain regular feeding times.

Turtles live in all parts of the earth and the oceans with a temperate to warm climate, and are particularly numerous in the tropics and subtropics. The aquatic forms are found in swamps, ponds, pools thick with vegetation, large lakes, brooks, rivers, and broad streams. The diamond-backed terrapin is confined to brackish water near the coast. The *Cheloniidae* live exclusively in the open ocean. The *Testudinidae* dwell in warm, dry regions — in steppes and semideserts, on rocky slopes, and in the bush and the savanna. Two South American testudinid species, called *jabutis* by local Indians, inhabit humid tropical forests; the North American gopher tortoises are found in sun-drenched deserts. Some of the *Testudinidae* are semi-aquatic — for example, the hinged tortoises and some of the aquatic turtles, such as the box turtles, at least occasionally spend time on land. Certain aquatic turtles leave the water only to lay eggs or to sun themselves.

In recent years, it has been found that all marine turtles are not carnivorous. The marine green turtle, as an adult, consumes only marine plants, probably accounting for the fact that its flesh does not have an oily taste like other marine turtles. But the alligator snapping turtle, the matamata, the big-headed turtle, and the soft-shelled turtles are pure carnivores. Nor do all terrestrial turtles abstain from animal foods. They show a preference to strong-smelling substances, such as old cheese and sometimes excrement. The Malayan freshwater turtle (*Malayemys subtrijuga*) feeds almost exclusively on mollusks.

All turtles reproduce by way of eggs. There are usually between 2 and 20 eggs in a batch, although the large marine turtles can deposit as many as 100 eggs in one laying. The number of eggs laid usually increases with the age of the female. The enormous masses of eggs laid by the arrau on the sandbanks in the Amazon basin are well known. The eggs are always laid on land, even by marine turtles, and always in about the same manner. Using her hindlegs, the female digs a hole in loose ground; the freshwater turtles can soften the earth as they dig with the fluid they eject from their anal sacs. Observations indicate that female freshwater turtles return to the water several times during the digging process in order to refill these sacs. The nests of marine turtles are built in two stages. First the female prepares a broad trench, throwing the sand out in all directions with all four legs. This large pit functions only to hide the animal during egg-laying. Once the female is thus protected, she begins to dig the real nest chamber at the bottom of the pit.

When the female turtle has completed her preparations, she holds her tail in the entrance to the egg chamber and then lays the eggs, one by one. She catches the eggs first with one hindleg and then with the other, and carefully lets them slide to the floor of the nest. After the eggs are laid, she shoves the excavated earth back into the nest, smooths the surface with her plastron, and even piles leaves or other ground litter over it until the nest site is indistinguishable from its surroundings. The extensive migrations made by marine turtles to their traditional nesting beaches are quite astonishing. After laying the eggs, the female has no further concern over them. Incubation is dependent entirely upon the warmth of the soil. When development within the egg is complete, the young hatch by breaking through the protective coverings with the egg caruncle, a sharp, horny thickening at the tip of the upper jaw, which later falls off.

The life of the turtle follows an annual rhythm, both in the tropics and in temperature latitudes. This yearly cycle, usually determined by temperature, is most evident among species living in cooler regions. When the average daytime and nighttime temperatures fall below a certain value, the animals withdraw to protected places and there spend the inhospitable season in a state of dormancy from which they awaken only when more favorable conditions prevail. European and North American species hibernate in winter. Aquatic turtles in general probably awaken much earlier from hibernation than do land turtles. The period after emergence from hibernation is often the most dangerous for turtles — they cannot withstand sudden cold snaps after emerging. Females lay their eggs shortly after hibernation is over. The dormant period in the tropical regions occurs with most species during summer.

Growth proceeds very slowly in turtles. Turtle size is expressed as the straight-line distance from the anterior to the posterior edge of the shell. One of the smallest species is the bog turtle (*Clemmys muhlenbergi*), which has a length of about 11 centimeters (4.3 inches), whereas the marine leatherback turtle, the giant of the order, reaches a shell length of up to 2 meters (6.6 feet) and a weight of up to 800 kilograms (1764 pounds). Some freshwater turtles, like the arrau and the giant soft-shelled turtle, can attain a length of nearly 1 meter (3.3 feet). The huge land turtles live on two quite isolated and widely separated groups of islands: the Galápagos Islands off western South America; and the Seychelles, north of Madagascar. See Fig. 2. Some of the giant tortoises of the Galápagos have

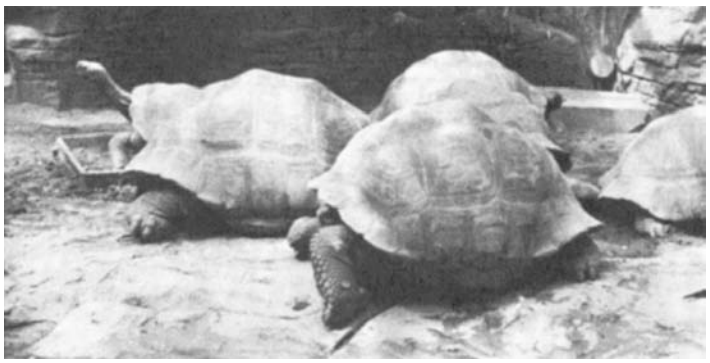

Fig. 2. Galapagos tortoises. (*A.M. Winchester.*)

shells up to about 110 centimeters (43.3 inches); those of the subspecies of the Seychelles giant tortoise may measure up to 125 centimeters (49.2 inches).

In recent years, there has been considerable concern over the endangerment of certain turtle species, notably sea turtles. An international conference on this topic was held in November 1979 by the U.S. State Department. Participants from 40 nations discussed a conservation strategy for seven species of sea turtle, six of which have been adjudged endangered. In some areas, sea turtle meat is an important food for indigenous populations. The conflict posed here is similar to that which has occurred over the bowhead whale in Alaska. Turtles yield a variety of products of economic value — eggs, skin, meat, calipee (cartilage used for soup), shells, oil, and as trophies. It was pointed out at the conference that the habitats of the sea turtle are being threatened, their eggs are being poached, and adults are being lost in large numbers to shrimp fishing operations, where they are caught in shrimping nets and drowned. The species pointed out at the conference for attention include the hawksbill (supplier of tortoiseshell), the leatherback, the olive (Pacific) ridley, the Kemp's (Atlantic) ridley, and the flatback. It was pointed out that as recently as 1947, some 40,000 Atlantic ridleys were observed nesting on a beach in Mexico. As of the early 1980s, these turtles are at the top of the endangered species list. Some authorities have estimated that there may be no more than 500 to 1000 nesting females left. A committee was appointed to monitor conservation progress well into the 1980s.

TUSSOCK MOTH *(Insecta, Lepidoptera)*. This moth (*Hemerocanoa keycistugna*) is injurious to apple. The moth is yellow and black, with a red head. It attains a length of about 1 inch (2.5 centimeters). The moth prefers feeding on leaves, but on occasion will eat into the fruit. The frothy egg-masses should be collected in fall and winter and destroyed and the trees should be banded to prevent a reinfestation by migrating caterpillars. Other treatment is similar to that for the codling moth, see also **Codling Moth**.

TWILIGHT. The intervals of incomplete darkness following sunset and preceding sunrise. Twilight is produced primarily by reflection of the light of the sun from the upper atmosphere of the Earth, but effects of scattering of light and refraction also enter into the period of duration of twilight. Morning twilight begins and evening twilight ends when the sun is about 18° below the horizon, although this value varies somewhat with the purity of the atmosphere. The times are determined by arbitrary convection; and several kinds of twilight have been defined and used. Civil twilight, nautical twilight, and astronomical twilight are in common usage, the limiting solar depression angle being, respectively, 6°, 12°, and 18° for those three.

For each of the three kinds of commonly used twilight limits, the duration of the twilight period varies considerably with latitude and calendar date due to the fact that the sun's diurnal path across the observer's celestial sphere meets his horizon at quite different angles and declinations at different latitudes and times of year. When the sun approaches the horizon obliquely, and is at high declination, a longer time (Earth rotation) is required to bring the sun into the limiting depression angle. At very high north or south latitudes, any of the three types of twilight may last as long as 24 hours or may not occur at all.

The so-called *bright segment*, or *twilight arch*, may be observed above the eastern horizon on a clear evening as the sun sets in the west. This is a blue segment bounded by a faintly reddish arc, and is, in reality, the shadow of the Earth cast on the upper atmosphere. It is only a few degrees in vertical angular extent, but discernible over 20 to 30 degrees of horizon. The final disappearance of the bright segment after sunset marks the end of astronomical twilight and represents the beginning of full darkness.

The *anti-twilight arch* is the pink or purplish band of about 3 degrees vertical angular width that lies just above the antisolar point at twilight; it rises with the antisolar point at sunset and sets with the antisolar point at sunrise. See also **Atmospheric Optical Phenomena**; and **Purple Light**.

TWINNING (Crystal). A process in which a region in a crystal assumes an orientation which is symmetrically related to the basic orientation of the crystal. Usually, layers of atoms within this region are translated with respect to a basic plane (the twinning plane). Each atomic plane is displaced by a distance which is proportional to its distance from the twinning plane. Bands of metal (twin bands) thus assume a lattice structure which is the mirror image of the unchanged portion of the lattice. See also **Mineralogy**.

TWINS. Two individuals, born at the same birth. The incidence of twins is about 1 to 2% of births. Heredity is a factor in the etiology of multiple pregnancies. Identical twins are twins developing from the cleavage of one fertilized ovum. They are always of the same sex and similar in appearance. Fraternal twins are twins developing from two fertilized ova. These may be of either sex, and may or may not be of similar appearance. See also **Gonads**.

TWITCHELL PROCESS. One of the very early methods for the hydrolysis of fats and oils on an industrial scale. The key to the process is *Twitchell's reagent*, which is prepared by interacting oleic acid (CAS: 112-80-1], benzene [CAS: 71043-2], and sulfuric acid, H_2SO_4 [CAS: 7664-93-9]. The product sometimes is termed *sulfobenzenestearic acid*. The agent accelerates hydrolysis. Naphthalene [CAS: 91-20-3] may be used in place of benzene in the reagent with the assigned $C_{18}H_{35}O_2 \cdot C_{10}H_6SO_3H$.

TWO-BODY PROBLEM (Astronomy). The two-body problem may briefly be stated as follows: given the relative position of two objects at any instant, together with their motions and masses at that instant, predict the positions and motion of those two objects at any other instant. The solution of the motion of bodies in space is the foundation of celestial mechanics. In the simplest case, where only two bodies exist, it is necessary to assume or determine the force law between the two bodies. Kepler's celebrated three laws of planetary motion solved this problem empirically, making the solution necessarily an approximation, as any other solution for the planetary system must be. Newton was the first to attack the two-body

problem analytically, and he had to develop his own mathematics to solve it. He was able to derive Kepler's laws and thus explain the motions of Jupiter's satellites, the motion of the moon about the Earth and of the Earth about the sun. However, each of these problems is much more complex than the simple two-body problem. The Earth-moon system is really part of a three-body problem that involves the sun.

The solution to the two-body problem is presented here in a nonhistorical way. Let T be the kinetic energy and V the potential energy. The equations of Lagrange are then written:

$$\frac{d}{dt}\left(\frac{\partial L}{\partial \dot{q}_i} - \frac{\partial L}{\partial q_i}\right) = 0$$

where the qi are the coordinates, L is the Lagrangian function, and the dot over a letter denotes the first derivative with respect to time. The kinetic energy in polar coordinates is

$$T = \frac{m}{2}(\dot{r}^2 + r^2\dot{\theta}^2 r^2 \sin^2\theta \cdot \dot{\phi}^2)$$

If the force field is central, then the potential energy is a function of r only. The Lagrangian is then written:

$$L = T - V = \frac{m}{2}(\dot{r}^2 + r^2\dot{\theta}^2 r^2 \sin^2\theta \cdot \dot{\phi}^2) - V(\dot{r})$$

The Lagrangian is now

$$q_1 = r, \quad q_2 = \theta, \quad q_3 = \phi$$

And from this the equations of motion are obtained:

$$\frac{d}{dt}(m\dot{r}) + \frac{dV}{dr} - mr\dot{\theta}^2 = 0$$

$$\frac{d}{dt}(mr^2\theta) = 0$$

Integrating the last equation gives the law of areas, and substituting this into the first equation leads to the equation of the path.

TWO WIDE-ANGLE IMAGING NEUTRAL-ATOM SPECTROMETERS (TWINS). See **Explorers Program**; and **Space Science Missions: Sun**.

TYMPANIC MEMBRANE. See **Hearing and the Ear**.

TYNDALL EFFECT. A phenomenon first noticed by Faraday (1857). When a powerful beam of light is sent through a colloidal solution of high dispersity, the sol appears fluorescent and the light is polarized, the amount of polarization depending upon the size of the particles of the colloid. The polarization is complete, if the particles are much smaller than the wavelength of the radiation. See also **Nephelometry**.

TYNDALL, JOHN (1820–1893). John Tyndall was a man of science: draftsman, surveyor, physics professor, mathematician, geologist, atmospheric scientist, public lecturer, and mountaineer. Throughout the course of his Irish and later, English life, he was able to express his thoughts in a manner none had seen or heard before. His ability to paint mental pictures for his audience enabled him to disseminate a popular knowledge of physical science that had not previously existed. Tyndall's original research on the radiative properties of gases as well as his work with other top scientists of his era opened up new fields of science and laid the groundwork for future scientific enterprises.

In January 1859, Tyndall began studying the radiative properties of various gases. Part of his experimentation included the construction of the first ratio spectrophotometer, which he used to measure the absorptive powers of gases such as water vapor, "carbonic acid" (now known as carbon dioxide), ozone, and hydrocarbons. Among his most important discoveries were the vast differences in the abilities of "perfectly colorless and invisible gases and vapors" to absorb and transmit radiant heat. He noted that oxygen, nitrogen, and hydrogen are almost transparent to radiant heat while other gases are quite opaque.

Tyndall's experiments also showed that molecules of water vapor, carbon dioxide, and ozone are the best absorbers of heat radiation, and that even in small quantities, these gases absorb much more strongly than the atmosphere itself. He concluded that among the constituents of the atmosphere, water vapor is the strongest absorber of radiant heat and is therefore the most important gas controlling Earth's surface temperature. He said, without water vapor, the Earth's surface would be "held fast in the iron grip of frost." He later speculated on how fluctuations in water vapor and carbon dioxide could be related to climate change.

Tyndall related his radiation studies to minimum nighttime temperatures and the formation of dew, correctly noting that dew and frost are caused by a loss of heat through radiative processes. He even considered London as a "heat island," meaning he thought that the city was warmer than its surrounding areas.

Over the course of his life, John Tyndall published numerous papers and essays on his scientific discoveries, as well as literature, religion, mountaineering, and travel. His accomplishments led him to receive five honorary doctorates and become a respected member of thirty-five scientific societies.

See also **Nephelometry**; and **Tyndall Effect**.

TYPHOID FEVER. An acute generalized infection due to the bacillus *Salmonella typhi*. Although this disease can occur worldwide, it is most frequently associated with unsanitary conditions and carriers. In times before there was effective inspection and control over water and milk, as well as other foods, great epidemics of the disease occurred, particularly in the summer. Since the bacillus can survive freezing and drying, it can be carried to food and drink from contaminated sources. In 1984, 380 cases were reported in the United States and 70% of this incidence was imported after being acquired overseas in underdeveloped countries. Typhoid is spread by excreta of persons with the disease. One month after recovery, 50% of the patients will pass some of the infectious organism in their stools; 20% after two months; and 10% after three months. Carriers, approximately 3% of persons who have been infected, will have a chronic infection, usually in the biliary tree or less frequently in the urinary tract. These sites are not usually responsive to chloramphenicol, although penicillin therapy may be effective.

Typhoid fever passes through five stages: (1) The *incubation period* varies from a few days to one week, during which stage the patient will have a mild fever (up to 100 °F; 39.4 °C). In this first stage, there is proliferation of the microorganisms in the gut and penetration into the gut mucosa. Diarrhea is present in only 10–20% of cases. (2) The *active invasion stage* varies in duration from one to two weeks, during which time the patient's temperature will range between 99 and 103 °F (37.2 and 39.4 °C). In this second stage, there is proliferation of the microorganisms within the gut lymphoidal tissue and spreading to regional lymphoidal tissue. Septicemia may be present. Symptoms during this period include headache, malaise, myalgia, loss of appetite, nausea, cough, sore throat, constipation, and sometimes diarrhea. A characteristic rash develops on the abdomen from the seventh to tenth day. The spots are flattened papules, slightly raised, of rose-red color, disappearing on pressure, and 2–4 mm (diameter). Sometimes each is capped by a small vesicle. These spots disappear after 2 to 3 days, leaving a brown stain. (3) During the *established disease stage*, varying from two to four weeks, the temperature will lie between 100 and 103 °F (37.8 and 39.4 °C). During this third stage, reticuloendothelial proliferation occurs. Sometimes the organism will metastasize and form focal points of infection. Necrosis and ulceration may occur at sites of previous lymphoid proliferation. Widespread lesions may occur elsewhere. In the liver, apart from cloudy swelling and small globules of fat, typhoid nodules are a characteristic finding. Symptoms may include toxemia, discomfort in the abdominal region, neuropsychiatric syndromes, intestinal ulceration, bronchitis, relative bradycardia, and possible intestinal perforation with hemorrhage. Symptoms vary in type and degree, depending somewhat upon intensity of initial infection. (4) The *convalescent stage* lasts between four and five weeks. There is a lowering of temperature to a range of 97–100 °F (36.1–37.8 °C). During this period, natural body defenses commence to repair and replace damaged tissue. Relapses of varying

duration and intensity may occur. There is also the possibility of late focal complications, including cholecystitis, osteomyelitis, and soft tissue abscesses. Spontaneous abortion and premature labor are common among untreated pregnant patients with typhoid fever.

Recovery from typhoid depends upon a number of factors, including the production of antibodies to the various antigenic compounds of the organism; the development of cell-mediated immunity; and the sensitivity of the strain of *S. typhi* responsible for the disease to the antibiotics chosen by the physician. Cell-mediated immunity appears to be a most important factor in determining the outcome.

Comparatively few antibiotics are effective against typhoid fever. Generally, the drug of choice is chloramphenicol, but strains of *S. typhi* resistant to the drug have started to appear. Amoxicillin has therefore appeared as a true alternative, which may be backed up by ampicillin and trimethoprim-sulfamethazole. Diagnosis is sometimes complicated where persons have recently used oral antibiotics. A small number of patients may relapse several weeks after apparent cure, but this recurrence is usually milder and of shorter duration than the initial infection.

Much work has been done on the preparation of effective vaccines, but none so far produced will give complete protection. See also **Bacterial Diseases**.

TYPHOON. See **Fronts and Storms**.

TYPHUS. See **Rickettsial Diseases**.

TYUYAMUNITE. An ore of uranium with the composition, $Ca(UO_2)_2(VO_4)_2 \cdot 5–8H_2O$, which occurs in yellow incrustations as a secondary mineral. The mineral is orthorhombic. It occurs as a secondary mineral as incrustations on limestones, and as disseminated impregnations in sandstones. Found abundantly in the Western United States, at Grants, New Mexico, and in Wyoming, Utah, Colorado, Nevada, Arizona and Texas. Also at Tyuya Muyan in Turkestan, the former U.S.S.R.

U

UBAC. A mountain slope so oriented as to receive the minimum available amount of light and warmth from the sun during the day, especially a north-facing slope of the Alps.

UDAD. See **Goats and Sheep**.

UDIC. Said of a soil moisture system that is characterized by not being completely dry for either 90 consecutive days or for 60 consecutive days in the 90-day period following summer solstice, when soil temperature at a depth of 50 cm is above 5 °C.

UGLI TREE. See **Citrus Trees**.

UGRANDITE. A group name for the calcium garnet minerals uvarovite, grossular, and andradite. See also **Andradite**; and **Garnet**.

UINTAHITE. A black, shiny asphaltite, with a brown streak and conchoidal fracture, which is soluble in turpentine. It occurs primarily in the veins in the Uintas Basin, Utah.

ULBRICHT SPHERE. When a light source is placed at a point inside a sphere with a perfectly diffusing surface, then every part of the surface appears equally illuminated when viewed through an opening in the surface. This principle is the basis of the *Ulbricht sphere*.

ULCER (Acid-Peptic Diseases). The word *ulcer* is sometimes used in lay circles as being synonymous with *sore*. More specifically, an ulcer is a break in the continuity of a surface (skin or mucous membrane) resulting from destruction of underlying tissue and loss of the covering epithelium. Ulcers are found in several parts of the body. Ulcerated tissue is found in ulcerative colitis (not to be confused with the peptic ulcers found in stomach and duodenum). See also **Colitis and Other Inflammatory Bowel Diseases**. Painful ulcers in the mouth may occur singly or in groups and may recur for years. This condition (*aphthous stomatitis*) arises when certain forms of bacteria in the oral cavity multiply, sometimes associated with vitamin deficiency and frequently accompanying ulcerative colitis. Fever or cold sores, which arise in the oral region from Herpes virus, more of the nature of blisters, are described in the entry on **Dermatitis and Dermatosis**. Open ulcerous sores are relatively common in tropical climates and are described toward the end of this entry. *Decubitus ulcers* are typified by the relatively common bedsore, which can be very painful and sometimes quite serious if left untreated over a long period. Decubitus ulcers have been implicated as a causative factor in acute bacterial arthritis. They also can be the source of serious anaerobic or polymicrobial bacteremia, infections which are more commonly found among diabetics. See also **Gangrene**.

Peptic ulcers, caused by action of the digestive juices on the mucosa of the stomach or duodenum, occur with considerable frequency. The size of peptic ulcers varies from $\frac{1}{4}$ inch (6 millimeters) to over 1 inch (2.5 centimeters) in diameter. The ulcer may be deep or shallow, depending largely upon the length of time it has existed. Peptic ulcers may invade gradually deeper and deeper into the stomach or duodenal wall until a large blood vessel is penetrated, causing hemorrhage; or the wall may be perforated. Thus, early treatment is obviously desirable. However, because of the chronic nature of peptic ulcer disease, patients may postpone consulting a physician for months, even years. Pain is the outstanding symptom of peptic ulcer. The pain is believed to result from contact of gastric acids with the base of the ulcer. Pain normally subsides with emptying of the stomach or after neutralizing the acids with antacid preparations.

Duodenal ulcers are rather frequently seen and occur in the duodenum (shortest and broadest part of small intestine, extending from the pyloric end of the stomach to the jejunum). See also **Digestive System (Human)**. Although the incidence of duodenal ulcer disease has declined, it is estimated that during the first half of this century, nearly 10% of the population of advanced, industrialized countries developed this disease at some time during their lifetime. It is believed that the disease has declined since the mid-1950s by at least 50%. The decline has not been satisfactorily explained.

An excellent review article describing the pathogenesis of peptic ulcer and implications for therapy is given in the Soll reference listed. In this article a number of specific questions pertaining to the therapy best suited for gastric and duodenal ulcers are answered.

Men between ages of 45 and 65 years account for about two-thirds of cases. In women, the disease is seen mostly during ages 55 and older. Although genetic connections have not been delineated, there appears to be some familial correlation. Mortality rate of duodenal ulcer disease ranges between 2 to 5 persons per 100,000 population.

In recent years, much rethinking has occurred as regards the therapy of the disease. The role of diet has been reevaluated. The topic remains somewhat controversial even among professionals. At one time, the ingestion of milk and cream at regular intervals throughout the day was considered excellent practice. It has now been established that milk is a poor antacid and actually may promote acid secretion. Bland and soft diets, taken at frequent intervals in small meals, also have been traditionally suggested — yet there is little, if any, hard evidence that this practice is effective. Studies have shown that citrus juices and spicy foods, once believed to be undesirable, probably do not accelerate acid secretion or inhibit the ulcer healing process. Some physicians stress the importance of patient reactions to specific foods, logically eliminating known antagonists. There is general consensus, however, that certain stimulants, such as alcohol and coffee, promote acid secretion and should be avoided. Aspirin antagonizes peptic ulcers in some people. Another point agreed upon is the desirability of avoiding late-evening snacks so that acid secretion will not be stimulated during the night.

The principal therapy is the administration of antacids. Patients vary in the length of time acid is retained in the stomach, in their overall secretory capacity, and in their gastric responses to eating. There is a wide range of antacids available and some experimentation may be required to find the proper preparations and strengths for given individuals. A review of antacids is given in **Antacids**.

Anticholinergics, which competitively inhibit the action of acetylcholine (stimulates gastrin-producing and acid-secreting cells), is a logical therapy, but unfortunately the anticholinergics may produce a number of undesirable side effects (dry mouth; blurred vision; slowness of urination). See also **Choline and Cholinesterase**. This therapy may be used in patients who have hypersecretion or where they do not respond to antacid therapy.

Some *synthetic histamine analogues* have been found effective as inhibitors of histamine-stimulated gastric acid secretion. Coincident with the development of these drugs, researchers have postulated that there may be two types of histamine receptors in tissues, one of these being the H_2 receptor, which can be blocked by specific histamine analogues. Extensive clinical tests have been made of metiamide and cimetidine.

Cimetidine the oral form of which is rapidly absorbed, has been effective in duodenal ulcer disease in many patients. Although the drug has side

effects, they appear to be relatively infrequent. Most physicians reserve the use of this drug for difficult situations (recurrent peptic ulcer disease; ulcerative esophagitis; pyloric channel obstruction; bleeding ulcer).

At one time, extensive *gastrectomies* were recommended for persons with continual pain and complications. In recent years, it has been found that relatively limited surgery is effective. The simplest and often effective technique is cutting vagus nerve fibers that go to the upper part of the stomach where acid is secreted.

Diseases sometimes associated with or predispose duodenal ulcer disease include chronic obstructive lung disease, rheumatoid arthritis, cirrhosis of liver, and hyperparathyroidism. In diagnosis of duodenal ulcer disease, the patient who gains relief from abdominal pain within a few minutes after ingesting an antacid preparation is immediately suspected of having the condition. There is an absence of hard evidence to associate stress as a major causative factor in peptic ulcer disease.

Gastric ulcers are peptic ulcers that occur in the stomach. Pain occurring within 30 to 60 minutes after eating is indicative of stomach ulcer, whereas the pain from a duodenal ulcer may not commence for 3 to 4 hours after a meal. Gastric ulcers are somewhat less common than the duodenal ulcer. Since gastric ulcers may occur even in patients with hypochlorhydria (acid secretion is below normal), it is believed that gastric ulcers in many instances are caused, not by excessive acid, but because of a change in the resistance of the stomach mucosa. The great majority of these ulcers occur on the portion of the stomach where orientation of the wall changes from the vertical to the horizontal. A chronic and diffuse gastritis frequently precedes and accompanies gastric ulcer, and it is considered by some authorities to be the contributing factor in ulcer formation.

With a few detailed exceptions, the symptoms of gastric ulcer essentially parallel those for duodenal ulcer. Because gastric carcinoma and benign gastric ulcer are difficult to distinguish, the physician will rely heavily upon laboratory evaluation (x-rays, fiber-optic gastroscopy, possibly biopsy). Gastric ulcers frequently are much larger than duodenal ulcers, accentuating need for early diagnosis and therapy. The recurrence rate for gastric ulcer at the same site is about 50% in the absence of continuing preventive measures. In the United States, duodenal ulcers far outnumber cases of gastric ulcers; the reverse is true in Japan.

D.M. McCarthy (University of New Mexico School of Medicine, Albuquerque) has observed, "The past 10 years have witnessed major changes in our understanding of the pathogenesis and treatment of what are commonly called the acid-peptic diseases. Schwarz's dictum to the effect that 'without acid gastric juice, no peptic ulcer' still applies. Increasingly, however, ulcers have come to be seen as areas of mucosa in which the effects of all noxious influences have exceeded the restorative capacities of all processes favorable to mucosal repair and integrity. A major stimulus to the growth of our knowledge in this area has been the development of drugs that have little or no effect on intragastric acidity, yet that have a clear ability to heal ulcers through mucosal protective effects. Chief among these is *sucralfate*."

Sucralfate is a complex salt of sucrose sulfate and aluminum hydroxide. Several different actions combine to enable sucralfate to prevent acute mucosal injury, reduce inflammation, and heal existing ulcers. Further detail on sucralfate can be found in the McCarthy reference listed.

Misoprostol. The first analogue of prostaglandin E to become commercially available was *misoprostal*. As of 1992, the drug was approved for the treatment of duodenal and gastric ulcers and for prophylaxis against NSAID (defined below) induced ulcers. The drug remains under scrutiny, but a number of promising reports have been published. As observed by R.P. Walt (Queen Elizabeth Hospital, Edgbaston, Birmingham, U.K.), "Much of the published literature about the drug is found in the proceedings of sponsored symposiums rather than in peer-reviewed journals, so caution is warranted in interpreting the data."

Nonsteroidal Anti-inflammatory Drugs (NSAIDS). It has been reported that patients who take NSAIDS may have an increased risk of mucosal damage in the upper gastrointestinal tract. The development of new lesions weeks after the initiation of treatment with NSAIDS has been confirmed in a study. In 1992, M.C. Allison (Royal Infirmary, Glasgow, Scotland) and a group of researchers concluded from their study of 713 patients that: "Patients who take NSAIDS have an increased risk of nonspecific ulceration of the small-intestinal mucosa. These ulcers are less common than ulcers of the stomach or duodenum, but can lead to life-threatening complications."

Helicobacter Pylori: Studies over the last few years have shown that a gram-negative, microaerophilic-curved bacillus, *Helicobacter Pylori*, is responsible for most cases of gastritis not associated with another known primary cause, such as autoimmune gastritis or eosinophilic gastritis and that it also may be a major factor in the pathogenesis of peptic ulcer disease. The probable importance of this microorganism currently is being scrutinized by a number of researchers. The situation has been summarized by W.L. Peterson (University of Texas Southwestern Medical School, Dallas): "*H. Pylori*" may be the most common cause of human gastrointestinal infection as well as the most frequent cause of gastritis. Furthermore, a persuasive argument can be made that, although most people have no health problems related to *H. pylori* gastritis, some have nonulcer dyspepsia or peptic ulceration. Why some have ulcers but most do not is probably related to other factors thought to be important in the pathogenesis of peptic ulcer (the use of nonsteroidal anti-inflammatory drugs, smoking, and acid hypersecretion, for example). On the other hand, it remains possible that *H. Pylori* gastritis and peptic ulcer are associated, but not casually. Until more data are available, and because antibiotic therapy can lead to side effects (such as pseudomembranous colitis or drug resistance), attempts to treat peptic ulcer or nonulcer dyspepsia by eradicating *H. Pylori* should be limited to randomized, controlled trials."

Tropical Ulcers. Open sores of the skin are quite common in tropical climates. Some are caused by specific bacteria, such as *yaws*; others by parasitic molds (*mandura foot*); a few by single-celled parasites (*leishmaniasis*); still others are the result of secondary invasion of the tissues by various bacteria which gain entrance through wounds and small breaks in the skin. Tropical ulcers develop almost exclusively on the feet and legs, following minor skin breaks and insect bites, the tunnels of itch mites, or the perforations of hookworm larvae. Tiny blisters first appear and then develop shortly into larger, odious sores. The ulcers become tender and painful, and spread rapidly in their early phases, with extensive damage to skin and underlying tissue. Diseased tissue gradually disintegrates and sloughs off, the eroded area becoming increasingly deeper. Unless treated, in some cases the infection may penetrate muscle, tendon, and bone. Fortunately, in a majority of situations, the infection heals spontaneously before it reaches such serious proportions.

Malnutrition is common among persons suffering from tropical ulcers. Severe deficiencies of vitamins, particularly A, B, and C, are considered contributing factors. Antibiotic therapy in recent years has been quite successful in treating a number of these infections.

ULEXITE. This mineral, a hydrated sodium calcium borate hydroxide, $NaCaB_5O_9 \cdot 8H_2O$, is a product of crystallization. Ulexite crystallizes in the triclinic system, but usually occurs in silky white rounded masses of fine-fibered acicular crystals. It was named after the 19th century German chemist George Ludwig Ulex (1811–1883) who first discovered it. Ulexite is a structurally complex mineral, with a basic structure containing chains of sodium, water and hydroxide octahedra. The chains are linked together by calcium, water, hydroxide and oxygen polyhedra and massive boron units. The boron units have a formula of $B_5O_6(OH)_6$ and a charge of -3, and are composed of three borate tetrahedra and two borate triangular groups. Hardness is 2-2.5 (softer than a fingernail) and specific gravity is approximately 1.97.

Ulexite is found with the mineral borax and is directly deposited in arid regions from the evaporation of water in intermittent lakes called playas. The playas form only during rainy seasons due to runoff from nearby mountains. The runoff is rich in the element boron and is highly concentrated by evaporation in the arid climate. Eventually the concentration is so great that crystals of ulexite, borax and other boron minerals form and accumulate to great thickness. The precipitated ulexite commonly forms a "cotton ball" tuft of acicular crystals. Ulexite is also found in a vein-like bedding habit composed of closely-packed fibrous crystals, also known as "TV rock" due to its unusual optical characteristics. The fibers of TV rock act as fiber optics, transmitting light along their lengths by internal reflection, and when a piece of TV rock is cut with flat polished faces perpendicular to the orientation of the fibers a good-quality specimen will display an image of whatever surface is adjacent to its other side.

The fiber-optic effect is the result of the polarization of light into slow and fast rays within each fiber, the internal reflection of the slow ray, and the refraction of the fast ray into the slow ray of an adjacent fiber. An interesting consequence is the generation of three cones, two of which are polarized, when a laser beam obliquely illuminates the fibers. These cones can be seen when viewing a light source through the mineral as discovered by E. Aalto and explained by D. Garlick and B. Kamb (J.Geol.Ed. 1991).

The mineral is found abundantly in Chile and Argentina and in Nevada and California in the United States. Ulexite is a source of boron.

ULMACEAE. See **Elm Trees**.

ULMIN. One of a class of amorphous substances resulting from the decomposition of the cellulose and lignite tissues of plants. Ulmins represent on of the initial changes by which vegetable matter is converted into coal.

ULTIMATE PERIOD. When the gain of a control system is such that the controlled variable has a continuous oscillation, the period of this oscillation will be the ultimate period. The term is frequently used in process control work and is equal to the reciprocal of the system's natural frequency.

ULTIMATE STRENGTH. The maximum conventional stress in tension, compression, or shear that a material is capable of undergoing.

ULTRABASIC. A term proposed by Judd, in 1881, for exceedingly mafic igneous rocks composed largely, if not entirely, of the ferromagnesium minerals such as olivine and pyroxene. The limiting figure of total silica is approximately 45%, or barely sufficient to supply the needs of the basic silicates. See also **Ultramafic**.

ULTRACENTRIFUGE. A high speed rotational separating device, usually of laboratory size, capable of developing a force of 250,000 times gravity. Its major uses are in research on molecular weight distribution, macromolecular structure and properties (proteins, nucleic acids, viruses) and separation of solutes from solutions. See also **Centrifuging**.

ULTRAFILTRATION. Ultrafiltration (UF) is a variety of membrane filtration in which hydrostatic pressure forces a liquid against a semipermeable membrane, occurring on a molecular scale. Typically, a liquid including small dissolved molecules is forced through a porous membrane. Large dissolved molecules, colloids, and suspended solids that cannot pass through the pores are retained.

Ultrafiltration separations range from ca 1 to 100 nm. Above ca 50 nm, the process is often known as microfiltration. Below ca 2 nm, interactions between the membrane material and the solute and solvent become significant. That process, called reverse osmosis or hyperfiltration, is best described by solution–diffusion mechanisms. See also **Filtration**; and **Reverse Osmosis**.

Membrane-retained components are collectively called concentrate or retentate. Materials permeating the membrane are called filtrate, ultrafiltrate, or permeate. It is the objective of ultrafiltration to recover or concentrate particular species in the retentate (e.g., latex concentration, pigment recovery, protein recovery from cheese and casein wheys, and concentration of proteins for biopharmaceuticals) or to produce a purified permeate (e.g., sewage treatment, production of sterile water or antibiotics, etc.). Diafiltration is a specific ultrafiltration process in which the retentate is further purified or the permeable solids are extracted further by the addition of water or, in the case of proteins, buffer to the retentate.

Membrane filtration has been used in the laboratory for over a century. The earliest membranes were homogeneous structures of purified collagen or zein. The first synthetic membranes were nitrocellulose (collodion) cast from ether in the 1850s. By the early 1900s, standard graded nitrocellulose membranes were commercially available. Their utility was limited to laboratory research because of low transport rates and susceptibility to internal plugging. They did, however, serve a useful role in the separation and purification of colloids, proteins, blood sera, enzymes, toxins, bacteria, and viruses. See also **Dialysis**.

In the late 1950s and 1960s, a technique was developed that produced highly anisotropic or asymmetric structures, ie, membranes constructed of a very thin, tight surface skin having a porous substructure. The substructure provided the necessary mechanical support for the skin without the hydraulic resistance of previous isotropic structures. Flux rates improved by orders of magnitude, and inherent resistance to plugging increased. A molecule entering a pore through the skin traverses a channel of increasing diameter. Both high flux and plugging resistance are important for achieving an economical membrane performance in industrial applications.

The subsequent improvement of the physical and chemical characteristics of these membranes, their incorporation into machines, and the development of procedures to prevent or clean surface-fouling films have seen significant advancement.

Media

Most ultrafiltration membranes are porous, asymmetric, polymeric structures produced by phase inversion, i.e., the gelation or precipitation of a species from a soluble phase. See also **Membrane Separations Technology**. Membrane structure is a function of the materials used (polymer composition, molecular weight distribution, solvent system, etc) and the mode of preparation (solution viscosity, evaporation time, humidity, etc.). Commonly used polymers include cellulose acetates, polyamides, polysulfones, dynels (vinyl chloride–acrylonitrile copolymers) and poly(vinylidene fluoride).

Modification of the membranes affects the properties. Cross-linking improves mechanical properties and chemical resistivity. Fixed-charge membranes are formed by incorporating polyelectrolytes into polymer solution and cross-linking after the membrane is precipitated, or by substituting ionic species onto the polymer chain (e.g., sulfonation). Polymer grafting alters surface properties. Enzymes are added to react with permeable species and reduce fouling.

Polyelectrolyte complex membranes are phase-inversion membranes where polymeric anions and cations react during the gelation. Inorganic ultrafiltration membranes are formed by depositing particles on a porous substrate. Dynamic membranes are concentration–polarization layers formed *in situ* from the ultrafiltration of colloidal material analogous to a precoat in conventional filter operations. Track-etched membranes are made by exposing thin films (mica, polycarbonate, etc.) to fission fragments from a radiation source.

Process

Pore-flow models most accurately describe ultrafiltration processes. Other membrane transport mechanisms, which may occur simultaneously although generally at a much lower rate, include dialysis (diffusion), osmosis (solvent by osmotic gradient), anomalous osmosis (osmosis with a charged membrane), reverse osmosis (solvent by pressure gradient larger and opposite to osmotic gradient), electrodialysis (solute ions by electric field), piezodialysis (solute by pressure gradient), electroosmosis (solvent in electric field), Donnan effects, Knudsen flow, thermal effects, chemical reactions (including facilitated diffusion), and active transport.

The addition of small membrane-permeable solutes to the water affects permeate transport in the following ways. (*1*) Solute–solvent interactions change the permeating fluid viscosity. (*2*) Solute adsorption reduces the apparent membrane-pore diameter. Because of high interfacial tension between water and certain materials, the water phase in the pores can be replaced. Surfactants suppress hydrophobic adsorption. Adsorption of permeate species is characterized by a lag in permeate concentration as a function of time. (*3*) The interfacial charge between the membrane-pore wall and the liquid affects permeate transport when the Debye screening length approaches (ca 10%) the membrane-pore size. (*4*) High surface tension on hydrophobic membranes forces water molecules to form large clusters in the pores. (*5*) Solvents, swelling agents, and plasticizers that diffuse into the polymer structure can change the apparent pore size or increase the rate of long-term compaction.

If the solute size is approximately the (apparent) membrane-pore size, it interferes with the pore dimensions. The solute concentration in the permeate first increases, then decreases with time. The point of maximum interference is further characterized as a minimum flux. If the solute size is greater than the pore dimensions, the solute is retained by mechanical sieving, forming a gel-polarization layer.

The gel usually has a much lower hydraulic permeability and smaller apparent pore size than the underlying membrane. (The gel layer and the concentration gradient between the gel layer and the bulk concentration are called the gel-polarization layer.)

The gel-layer thickness is limited by mass transport back into the solution bulk at the rate.

In a static system, the gel-layer thickness rapidly increases and flux drops to uneconomically low values.

Flux is independent of pressure when the process flux is much less than the wafer flux.

Fouling. If the gel-polarization layer is not in hydrodynamic equilibrium with the fluid bulk, the membrane may be fouled. Fouling is caused either by adsorption of species on the membrane or on the surface of the pores, or by deposition of particles on the membrane or within the pores. Fouled systems are characterized as follows: flux is a function of total permeate production when hydrodynamic conditions are constant; if hydrodynamic conditions are changed, hydraulic permeability response of the gel layer is not reversible; and theoretical permeate flux (TPF) changes with time. A sensitive test for predicting fouling or process instability is to measure change in TPF after subjecting the system to process extremes.

Fouling is controlled by selection of proper membrane materials, pretreatment of feed and membrane, and operating conditions. Control and removal of fouling films is essential for industrial ultrafiltration processes.

When fouling is present or possible, ultrafiltration is usually operated at high liquid shear rates and low pressure to minimize the thickness of the gel polarization layer.

Fouling films are removed from the membrane surface by chemical and mechanical methods. Dissolved fouling material may pass into the membrane pores. Reprecipitation upon rinsing must be avoided. Membrane-swelling agents, such as hypochlorites, flushout material which may be lodged in the pores.

Certain applications require that the equipment meet FDA and USDA sanitary requirements. These requirements ensure that the products are not contaminated by extractables or microorganisms from the equipment. Special considerations are given to the design of such equipment.

Practical Aspects

The theoretical models cannot predict flux rates. Plant-design parameters must be obtained from laboratory testing, pilot-plant data, or in the case of established applications, performance of operating plants.

Electroultrafiltration

Electroultrafiltration (EUF) combines forced-flow electrophoresis. See also **Electrophoresis** with ultrafiltration to control or eliminate the gel-polarization layer. Placing an electric field across an ultrafiltration membrane facilitates transport of retained species away from the membrane surface. Thus, the retention of partially rejected solutes can be dramatically improved. See also **Electrodialysis**.

Electroultrafiltration has been demonstrated on clay suspensions, electrophoretic paints, protein solutions, oil–water emulsions, and a variety of other materials.

Diafiltration

Diafiltration is an ultrafiltration process where water or an aqueous buffer is added to the concentrate and permeate is removed. The two steps may be sequential or simultaneous. Diafiltration improves the degree of separation between retained and permeable species.

Constant-volume batch diafiltration is the most efficient process mode. Sequential batch diafiltration is a series of dilution–concentration steps. Continuous diafiltration practiced in one or more stages of a cascade system has the same volume turnover relationship for overall recoveries as sequential batch diafiltration. The residence time however is dramatically reduced. If recovery of permeable solids is of primary importance, the permeate from the last stage may be used as diafiltration fluid for the previous stage. This countercurrent diafiltration arrangement results in higher permeate solids at the expense of increased membrane area.

Membrane Equipment

Commercial industrial ultrafiltration equipment first became available in the late 1960s. Since that time, the industry has focused on five different configurations.

The Parallel-Leaf Cartridge that consists of several flat plates, each having membrane sealed to both sides. Plate-and-frame systems consist of plates each with a membrane on both sides. A spiral-wound cartridge has two flat membrane sheets (skin side out) separated by a flexible, porous permeate drainage material.

There are three types of supported tubular membranes: cast in place (integral with the support tube), cast externally and inserted into the tube (disposable linings), and dynamically formed membranes. The most common supported tubes are those with membranes cast in place.

Depending on the membrane material and operating pressure, Self-supporting tubes are less than 2-mm ID; inside diameters as small as 0.04 mm are commercially available.

Each of the membrane devices may be assembled by connecting the modules into combinations of series, parallel-flow paths, or both. These assemblies are connected to pumps, valves, tanks, heat exchangers, instrumentation, and controls to provide complete systems.

Because of the broad differences between ultrafiltration equipment, the performance of one device cannot be used to predict the performance of another. Comparisons can only be made on an economic basis and only when the performance of each is known.

Uses

Applications of ultrafiltration are summarized in Table 1.

TABLE 1. ULTRAFILTRATION APPLICATION

Application	Process
Electrophoretic paint	Control of properties, recovery of solids from rinse systems
Dairy wheys	Protein recovery, concentration, purification, diafiltration
Milk	Cheese and yogurt mfg, 15–20% yield improvement, standardization
Oil–water emulsions	Concentration
Effluents of wool, yarn scouring	Lanolin recovery, pollution abatement
Enzymes	Concentration, purification
Biological reactors	Antibiotic mfg, alcohol fermentation, sewage treatment
Vegetable proteins	
Latex concentration	
Production of pure[a] water	
Pulp and paper	Lignosulfonate sprn from spent liquor
Blood and blood products	Fractionation, purification
Vaccines	Conc, purification
Biotechnology products	Conc, purification

ULTRAHIGH VACUUM. See **Vacuum**.

ULTRAMAFIC. Ultramafic (or ultrabasic) rocks are igneous rocks with very low silica content (less than 45%), generally >18% MgO, high FeO, low potassium and are composed of usually greater than 90% mafic minerals, (dark colored, high magnesium and iron content). The Earth's mantle is considered to be composed of ultramafic rocks. See also **Earth**. The majority of ultramafic rocks are exposed in orogenic belts, and predominate in Archaean and Proterozoic terranes. Ultramafic magmas in the Phanerozoic are rarer, and there are very few recognised true ultramafic lavas in the Phanerozoic. Many surface exposures of ultramafic rocks occur in ophiolite complexes where deep mantle-derived rocks have been obducted into continental crust along and above subduction zones.

Where ultramafic rocks are exposed on the surface, the high metal content of the rocks creates unique vegetation. Examples are the Ultramafic woodlands and Ultramafic barrens of the Appalachian mountains and piedmont, the "wet maquis" of the New Caledonia rain forests, and the Ultramafic forests of Mount Kinabalu and other peaks in Sabah, Malaysia. Vegetation is typically stunted, and is sometimes home to endemic species adapted to the metallic soils. Often thick, magnesite-calcrete caprock, clayey laterite and duricrust forms over ultramafic rocks in tropical and subtropical environments. Particular floral assemblages associated with highly nickeliferous ultramaic rocks are indicative tools for mineral exploration.

Intrusive ultramafic rocks Anorthosite; Dunite; Gabbro; Hornblendite; Norite; Peridotite; Phlogopitite; and Proxenite are often found in large, layered ultramafic intrusions where differentiated rock types often occur in layers. Such cumulate rock types do not represent the chemistry of the magma from which they crystallised.

Volcanic ultramafic rocks Komatiite and Picritic basalt are rare outside of the Archaean and are essentially restricted to the Neoproterozoic or earlier, although some boninite lavas verge on being ultramafic. Subvolcanic ultramafic rocks and dykes persist longer, but are also rare.

Ultrapotassic ultramafic rocks and melilitic rocks Kimberlite; Lamproite; Lamprophyre; and Carbonatite are considered a separate group, based on melting model criteria, but there are ultrapotassic and highly silica-undersaturated rocks with >18% MgO. which can be considered "ultramafic". Most of these rocks occur as dykes, diatremes, lopoliths or laccoliths, and very rarely, intrusions. Most Kimberlite and Lampproite occurrences are as volcanic and subvolcanic diatremes and maars; lavas are virtually unknown.

See also **Anorthosite**; **Carbonatite**; **Dunite**; **Gabbro**; **Hornblendite**; **Kimberlite**; **Komatiite**; **Lamproite**; **Lamprophyre**; **Norite**; **Peridotite**; **Picritic Basalt**; and **Pyroxenite**.

ULTRAMICROSCOPE. The ultramicroscope is not an instrument of extraordinary magnifying power, as its name might suggest. The term has reference rather to a special system of illumination for very minute objects. Such objects as colloidal particles, fog drops, or smoke particles are held in liquid or gaseous suspension in an enclosure with an intensely black background (usually of the black-body type). They are illuminated by a convergent pencil of very bright light entering from one side and coming to focus in the field of view — the so-called "Tyndall cone" familiar in experiments on scattering. With this arrangement, objects too small to form visible images in the microscope produce small diffraction ring systems, which appear as minute bright specks on a dark field. Ultramicroscopes are used in the study of Brownian motion, in the Millikan droplet experiment for measuring the electric charge of the electron, and in observing ionization tracks in cloud chambers.

ULTRASONICS. Sound waves above the frequency normally detectable by the human ear, that is, above 16 to 20 kHz are referred to as *ultrasonic waves*. The particles of matter transmitting a *longitudinal wave* move back and forward about mean positions in a direction parallel to the path of the wave. Alternate compressions and rarefactions in the transmitting material exist along the wave propagation direction. In *shear waves*, the particles move perpendicularly to the direction of wave propagation. In *surface waves*, in seismological studies and in waves through thin stock, the *Rayleigh* and *Lamb waves*, respectively, the particles undergo much more complex vibratory motions than in longitudinal and transverse waves. In most practical applications of ultrasonics, pulses or packets containing a number of oscillation cycles are sent through the solid or liquid under investigation. See also **Cavitation**. A longitudinal wave pulse, when incident on the boundary between two materials having different sound velocities, is transformed into reflected and refracted shear and longitudinal waves. Snell's law governs the angles of reflection and refraction for both types of waves:

$$\frac{\sin\theta}{V} = \text{Constant}$$

where θ is the angle the beam makes with a plane normal to the intervening surface and V is the sound velocity. Therefore, in Fig. 1,

$$\text{Constant} = \frac{\sin\theta_1}{V\text{L}_1} = \frac{\sin\theta_2}{V\text{L}_2} = \frac{\sin\theta}{V\,S_2} = \frac{\sin\phi_2}{V\text{L}_2}$$

The practical application of ultrasonics requires effective transducers to change electrical energy into mechanical vibrations and vice versa. Transducers are usually piezoelectric, ferroelectric, or magnetostrictive. The application of a voltage across a piezoelectric crystal causes it to deform with an amplitude of deformation proportional to the voltage. Reversal of the voltage causes reversal of the mechanical strain. Quartz and synthetic ceramic materials are used.

Ferroelectric crystals are also electrostrictive. Barium titanate, for example, has an electrical mechanical conversion efficiency about 100

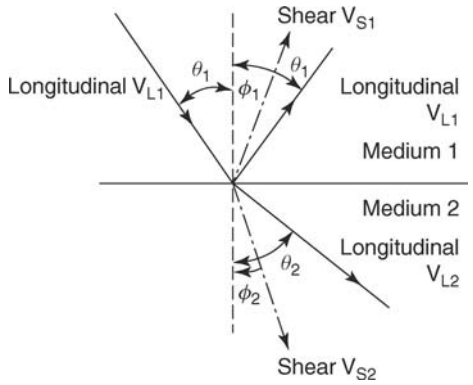

Fig. 1. Reflection and refraction of ultrasonic waves.

times that of quartz. Unlike the piezoelectric mode of oscillation, in ferroelectric crystals, application of a voltage in either direction across the crystal causes expansion of the crystal. This mode, however, can be converted to the piezoelectric by biasing the expansion in one direction, either by application of a strong dc field, or more commonly by cooling the ferroelectric crystal through its Curie temperature while it is under the influence of a strong electric field (on the order of 10^6 volts/meter).

Transducer crystals are normally cut to a resonant frequency, the thickness being one-half the acoustic wavelength. A bond between the crystal transducer and the specimen matches the acoustic impedance, and carries the acoustic power into the latter. Backing layers may be fixed to the rear surface of the transducer. These layers are selected to reflect power forward into the crystal and specimen in some applications. On the other hand, they may be selected to absorb power so as not to complicate signals received in material testing applications.

Ultrasonic Applications

An appreciation of useful applications of ultrasound dates back to the development of radar and sonar in the late 1930s and early 1940s World War II era. One of the very earliest uses was for detecting flaws in materials. Today ultrasound is one of several effective methods used in the field of nondestructive testing and inspection. Later, the use of ultrasound was extended to include a number of detectors, probes, and transducers for measuring such variables as fluid flow, liquid level, viscosity, density, proximity, and material thickness, among others. Most of these applications are described in other articles in this encyclopedia, notably **Flow Measurement**; **Nondestructive Testing (NDT)**; and **Thickness Measurement and Gaging Systems**. Ultrasonic devices also are used in industrial processing applications, such as cleaning, drilling, emulsifying, soldering, and welding. Possible the most noteworthy of ultrasonic devices are found in the medical field for use in diagnostics where ultrasound vies with x-ray and other diagnostic procedures. Ultrasound is also applied in some security systems to detect intruders.

Some industrial instrumentation applications for ultrasound not described elsewhere are included in the following paragraphs to illustrate the basic principles in applying ultrasonics for a variety of measurements.

Ultrasonic Density Sensors. A useful application is found in the density measurement of lime slurries for the purpose of adjusting the pH in acid water neutralization processes. Where traditional measurement methods are not suited, control engineers will often turn to more sophisticated techniques, such as ultrasound.

Slurries are difficult to handle, have a strong tendency to settle out and to coat equipment with which they come in contact. An ultrasonic density control sensor can be fully immersed in an agitated slurry, thus avoiding coating and clogging. Use of the ultrasound device for controlling the specific gravity of slurries within $\pm 0.01\%$ of the desired value has been demonstrated. In the usual application, the specific gravity ranges between 1.05 and 1.10. Actually, the ultrasonic sensor measures the percentage of suspended solids in the slurry, thus providing a very close approximation of the true specific gravity. The suspended solids present in the slurry attenuate the ultrasonic beam, with the resulting electronic signal being proportional to the solids in suspension.

Ultrasonic Level Detectors. In the ultrasound system shown in Fig. 2, one transmitting sensor creates a sonic beam, the waves of which are picked up by a receiving sensor. This can be accomplished by a direct path or by the reflective waves from the transmitter, which strike a fluid surface and are reflected back to the receiving sensor. Sensors can be spaced as close as $\frac{1}{4}$ in. (6 mm) or as far apart as 10 ft (3 m) in a direct beam path. They can pipe their beams through tubing where sensor beams cannot be direct, but generally the tubing length is limited to several feet (few meters). The sensor's sound beam is unaffected by mist, smoke, dust, or fumes, since it is interrupted only by a solid or fluid entering the beam path. This type of system is often used in connection with measuring the level of dry bulk solids.

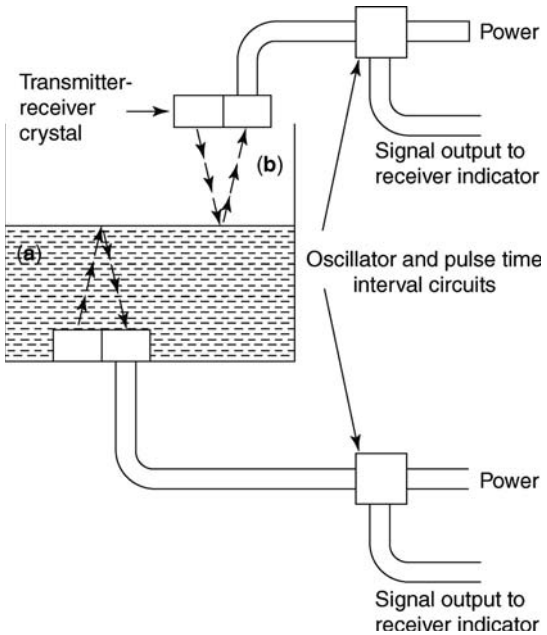

Fig. 2. Continuous sonic-type level measuring device: (**a**) Liquid phase; (**b**) vapor phase.

Ultrasonic Thermometers. These are usually designed to respond to the temperature dependence of sound speed. In special cases where only one particular temperature is of interest, such as the temperature of a phase change, or the recrystallization temperature of a substance, the temperature dependence of attenuation may be utilized. Ultrasonic thermometers have found applications in the range -80 to $+250\,^{\circ}\mathrm{C}$, where the so-called quartz thermometer offers resolution of 0.1 millidegree and linear superiority to platinum resistance thermometers.

Ultrasonic Pressure Transducers. Advantage is taken of the fact that pressure influences sound propagation in solids, liquids, and gases, but in different ways. In solids, applied pressure leads to so-called stress-induced anisotropy. In liquids, the effects of pressure are usually small (relative to effects in gases), but the frequency of relaxation peaks can be shifted significantly.

Sonochemistry. Where liquids and solids must react, researchers are finding that energy in the ultrasound range often promotes such reactions. K.S. Suslick (University of Illinois), who has pioneered in the field, observes, "Ultrasound causes high-energy chemistry. It does so through the process of acoustic cavitation; the formation, growth and implosive collapse of bubbles in a liquid. During cavitational collapse, intense heating of the bubbles occurs. These localized hot spots have temperatures of roughly $5000\,^{\circ}\mathrm{C}$, pressures of about 500 atmospheres, and lifetimes of a few microseconds. Shock waves from cavitation in liquid-solid slurries produce high-velocity interparticle collisions, the impact of which is sufficient to melt most metals." In recent research, Suslick also reports that ultrasound creates clean, highly reactive surfaces on metals. In both homogeneous and heterogeneous situations, ultrasound assists in initiating and enhancing a number of catalytic reactions.

In investigating the phenomenon of acoustic cavitation in homogeneous liquids, researchers find that the velocity of sound in liquids typically is about 1500 m/s. Ultrasound spans the frequencies of approximately 15 kHz to 10 MHz, with acoustic wavelengths of 10 to 0.01 cm. Researchers in sonochemistry stress that these are not molecular dimensions and thus no direct coupling of the acoustic field with chemical species takes place on a molecular level. Rather, the effects of ultrasound arise from a number of physical mechanisms, including the production of cavitation. Cavitation, originally investigated by Lord Rayleigh (1895), can produce inordinate local temperatures of 10,000 K and pressures up to 10,000 atmospheres when cavities collapse. These physical parameters indeed are conducive to promoting chemical reactivity. Considerable research over the years has been directed toward investigating the chemical effects of ultrasound on inorganic liquids, notably water. Little effort to date has been directed toward organic liquids.

In his summary of an excellent review article on sonochemistry (reference listed), Suslick points out, "Chemical applications of ultrasound are just beginning to emerge. The very high temperatures and very short times of cavitational collapse makes sonochemistry a unique interaction of energy and matter. In addition, ultrasound is well suited to industrial applications. Since the reaction liquid itself carries the sound, there is no barrier to its use with large volumes. In fact, ultrasound is already heavily used industrially for the physical processing of liquids, such as emulsification, solvent degreasing, solid dispersion, and sol formation. It is also extremely important in solids processing, including cutting, welding, cleaning and precipitation." See also **Cavitation**.

Ultrasonic Nondestructive Characterization (NDC) of Materials. The use of ultrasonics for the nondestructive characterization (testing) of metals and other materials was one of the first practical applications for ultrasound and dates back to the 1950s. The detailed properties of materials that can be measured with ultrasound include microstructure, surface characteristics, elastic properties, density, porosity, mechanical properties, process characteristics, and overt flaws. Ultrasound waves transmitted may take the form of longitudinal, shear, and surface waves. Wave characteristics include ultrasonic velocities and frequency dependence of ultrasonic attenuation/absorption. Specific reactions occurring within a tested material may include ultrasound reflection, transmission, refraction, diffraction, interference, scattering, and absorption. In applying ultrasound to testing, the characteristics of the radiation source that can be manipulated include wave type, frequency, bandwidth, pulse shape, and pulse size.

By comparison with other NDC methods, such as liquid penetrant examination, magnetic particle, eddy current testing, and radiography, the ultrasonic method is the only technique that is applicable to a wide range of materials.

The success of an ultrasonic NDC application depends upon the selection of the best-qualified transducer (i.e., one with optimum frequency response, pulse width and shape). Transducer characteristics can be customized through the use of the best-suited piezoelectric material, such as lead zirconate-lead titanate, lead metaniobates, polymer piezoelectrics, and other advanced ferro-electric materials.

Acoustic Microscopy. The microstructural variation in the acoustic properties of materials (including biological material) has been the key to the development of a new class of microscopes that utilize acoustic waves in some fashion for obtaining microscopic images. The images so obtained are quite different from those obtained in conventional light or electron microscopies. Different types of acoustic microscopes use different energy sources such as electron beams or piezoelectric transducers for generating the acoustic images and are descriptively named — for example, the scanning acoustic microscope, the scanning electron acoustic microscope, the thermoacoustic microscope, and the scanning laser acoustic microscope. Although the image contrast and spatial resolution attainable in such microscopes are in large measure dictated by the details of energy-source–material interactions, the dependence on the local variations in the material elastic or thermoelastic properties, including residual stresses, is a necessary consideration in such interactions.

Scanning Acoustic and Laser Acoustic Microscopies. In scanning acoustic microscopy (SAM) plane acoustic waves are generated by a piezoelectric transducer attached to a cylindrical rod (typically made of sapphire) as shown in Fig. 3. The opposite end of the rod is made into a concave spherical surface to form an acoustic lens. Coupling fluid (usually water) is placed between the rod surface and the specimen surface. Wave refraction at the acoustic lens–coupling fluid interface provides a focusing action for the plane waves incident from the transducer. The focused waves impinge on the specimen surface. In general, the waves incident on the specimen surface are specularly (geometrically) reflected back to the transducer. At certain critical angles of incidence (if the material properties permit), leaky surface waves (usually leaky Rayleigh waves) can also be generated. Under proper defocus conditions (lens–specimen distance) the leaky surface waves find their way back to the transducer. The total acoustic signal reaching the transducer in this mode of operation is composed of contributions from the geometrically reflected waves and the leaky surface waves. The interference of these two waves give rise to the SAM output signal. If the acoustic lens–specimen distance is allowed to vary, the periodic variation in the signal amplitude as a function of this distance can be used to obtain the surface-wave velocity of the material.

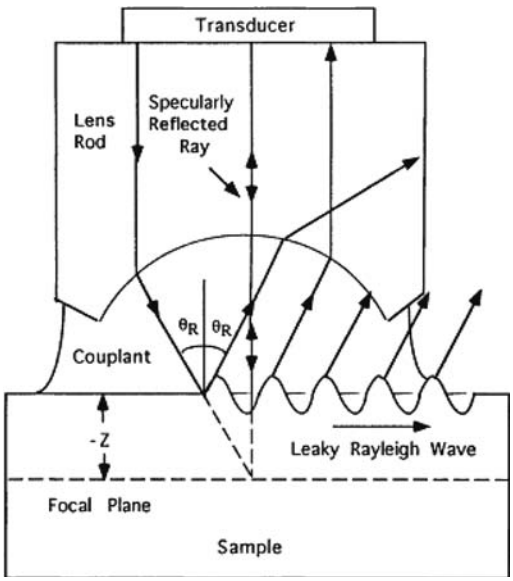

Fig. 3. Scanning acoustic microscope acoustic lens configuration for generating signals via the interference between "leaky" Rayleigh waves generated at the Rayleigh critical angle θ_R and specularly reflected waves (illustrated by the central specularly reflected wave) (adapted from Briggs, 1992).

If the focused acoustic beam is rastered over the specimen surface, variations in the acoustic impedance of the specimen or in the surface-wave velocity or geometrical irregularities in the specimen surface can change the magnitude and phase of the output signal. The variations in output signal at each point on the surface are recorded on a visual display to generate an SAM image. The images can be analyzed to obtain information related to the variations in the mechanical properties of the specimen over micron-scale regions. Commercially available scanning acoustic microscopes use acoustic waves with frequencies as high as 2 GHz. For more information on SAM see Briggs 1992.

The scanning laser acoustic microscope (SLAM) uses unfocused plane acoustic waves (usually in the range 100–500 MHz) to insonify the specimen. Internal elastic microstructures or other acoustic inhomogeneities in the specimen cause the propagating sound wave to locally scatter, distort, or attenuate. The sound field then impinges on and deforms a flat, polished area of the specimen surface producing a surface pattern reflective of the specimen inhomogeneity. A laser beam reflected from this surface is rastered to trace out an optical phase replica of the sound field at the surface. The laser signals are electronically processed and displayed on a television monitor to produce a visual image of the surface pattern. For more information on the SLAM see Kessler and Yuhas 1979.

Underwater Acoustics. Because of the relative opacity of water to electromagnetic signals in the visible, infrared, radio, and radar ranges of frequencies, sound waves are used as the means of propagating information in underwater environments. The development of underwater sound systems has been among the most long-standing applications of ultrasound.

Among the many developments are ultrasonic systems for both passive and active sound navigation ranging (sonar), depth sounding, mapping and profiling of the ocean floor, underwater geophysical prospecting, and fish detection.

Other Transducers. Ultrasound also has been used for the measurement of force, vibration, acceleration, interface location, position changes, differentiation between the composition of differing materials, grain size in metals, and evaluation of stress and strain and elasticity in materials. Sonic devices can used to detect gas leaks, and to count discrete parts by means of an interrupted sound beam. Frequently, an ultrasonic device can be applied where photoelectric devices are used. Particularly in situations where light-sensitive materials are being processed (hence presence of light must be avoided), ultrasonic devices may be the detectors of choice.

Ultrasonic Flowmeters. These instruments are described in **Flow Measurement (Fluids)**.

Ultrasonic Applications in Medicine

Ultrasonic imagery is one of the earlier tools used in the medical field for noninvasively probing body organs and tissues. Experience with this technique dates back at least to the 1970s.

The nonionizing character of ultrasonic radiation is particularly attractive, permitting the use of the technique repeatedly with a given patient at low risk. The sound frequency used for most diagnostic instruments ranges from 1 to 10 MHz. These frequencies are generated by piezoelectric transducers that reversibly convert electrical to vibratory mechanical (sound) energy. Short sound pulses propagate through the body, but a small portion of the energy is reflected back to the instrument where there are interfaces between tissues having different acoustic impedances.

Ultrasonic examination has become a well-established diagnostic tool in many abdominal diseases. In recent years, the degree of resolution attainable with ultrasonic equipment has been improved considerably, making more accurate diagnoses possible. As a consequence, transabdominal sonography has become increasingly important for diagnosing diseases of the gastrointestinal tract. It is noteworthy to observe that even acute appendicitis usually can be diagnosed by ultrasonic examination.

As noted by B. Limberg (University of Frankfurt), "With the use of sonography alone, it is impossible to detect diseases of the colon reliably, since the large bowel cannot be visualized in its entirety and detailed evaluation of wall structures and intra-aluminal lesions is difficult. The method can be improved considerably, however, by the retrograde instillation of water into the colon, a method known as *hydrocolonic sonography*. Studies have shown that this method permits not only the diagnosis of colonic tumors, but also that of inflammatory colonic diseases, such as Crohn's disease and ulcerative colitis." The detailed test of 300 patients in which conventional sonography and hydrocolonic sonography were used are given in the Limberg reference listed.

In order to facilitate surgery, preoperative imaging procedures, such as ultrasonography, computed tomography (CT), and angiography, have been used to localize the primary tumor in the case of pancreatic endocrine tumors. Because of their size, insulinomas and gastrinomas cannot be identified in up to 30% of patients. As pointed out by T. Rösch (Technical University of Munich), a large team made a comparative study involving some 37 patients. Some of the study results included: "The introduction of endoscopic ultrasonography has allowed high-resolution imaging of the pancreas that can distinguish structures as small as 2 to 3 mm in diameter. The accuracy of this procedure in diagnosing small pancreatic carcinomas has been reported to be close to 100 percent. The method also seems to be useful for the preoperative localization of small endocrine tumors of the pancreas, given the experience in this research. We report here the collective experience at six centers where endoscopic ultrasonography has been used for the preoperative localization of small tumors of the pancreas. Only patients with normal results on transabdominal ultrasonography and CT were included."

Ultrasound in Surgery. The use of extracorporeal shock waves in a procedure known as *lithotripsy* for breaking up gall stones into fragments is described in an article on **Gallbladder and Biliary Tract Diseases**. Percutaneous lithotripsy to remove stones and fragments from the kidney and urinary tract are described in an article on **Kidney and Urinary Tract**.

Ultrasound May Reduce Need for Amniocentesis. In many countries ultrasonography is routinely performed between the 16th and 24th weeks of gestation and can identify over 94% of fetuses with spina bifida, encephalocele, gastroschisis, or omphalocele. Therefore, the risk of one of these anomalies is substantially reduced for a given maternal serum alphafetoprotein level if the results of ultrasonography are normal. Where abnormalities may appear, it is not uncommon to perform a Level 2 ultrasonography, prior to proceeding with the more complex, higher-risk, and greater-cost procedure, amniocentesis.

Ultrasound Assists Drug Implants. Plastic materials infused with drugs are used for a number of purposes where drugs are gradually diffused into the bloodstream. Such implants are used for contraceptions and various chemotherapies. The effects of exposure to ultrasound of biodegradable implant materials have been studied at several teaching hospitals with interesting results.

Human Perception of Ultrasonic Speech. The upper range of human air-conduction hearing has been estimated to be no higher than approximately 24,000 Hz, although there have been a conservative number of reports that indicate hearing well into the ultrasonic range, but only when signals are delivered by bone conduction. M.L. Lenhardt (Medical College of Virginia) and a team of researchers has reported that "Bone-conducted ultrasonic hearing has been found capable of supporting frequency discrimination and speech detection in normal, older hearing-impaired and profoundly deaf human subjects. When speech signals were modulated into the ultrasonic range, listening to words resulted in the clear perception of the speech stimuli and not a sense of high-frequency vibration. These data suggest that ultrasonic bone-conduction hearing has potential as an alternative communication channel in the rehabilitation of hearing disorders." Further details are given in the Lenhardt reference listed.

Glossary

An abridged glossary of terms used to describe Ultrasonics would include:

Absorption — The loss of amplitude (or energy) of an acoustic wave that results in an increase in temperature (however slight) in the propagation medium. See also **Absorption (Process)**.

Acoustic Impedance — Ratio of the pressure to the particle velocity of the acoustic wave field. See also **Acoustics**.

Affinity — A measure of the ability of a reaction to occur, defined as the sum of the products of the chemical potential for a reaction and the number of moles of reactant-product involved. See also **Affinity**.

Attenuation — The loss of acoustic amplitude (or energy) of a sound wave along its propagation path resulting from all mechanisms responsible for such losses, including but not limited to absorption, scattering, and diffraction. See also **Attenuation**.

Diffraction — Wave scattering associated with objects having dimensions that are large compared to the wavelength of sound. See also **Diffraction**.

Dispersion — The variation of phase velocity with wavelength or wave number. See also **Dispersion**.

Elasticity — A material property characterized by a thermodynamically reversible relationship between stress and strain. See also **Elasticity**.

Evanescent Wave — A sound wave with an amplitude that decays exponentially in a direction perpendicular to the propagation direction.

Group Velocity — The velocity associated with the propagation of wave energy and defined as the derivative of the angular frequency with respect to the wave number.

Phase Velocity — The sound velocity of a monochromatic wave defined as the ratio of the angular frequency to the wave number.

Refraction — The deviation in the propagation direction of a sound wave as the wave crosses the boundary between two propagation media having different sound velocities. See also **Refraction**.

Relaxation — A reaction process whereby the energy state of the material is caused to change from one state of equilibrium to another state of equilibrium by the driving action of an ultrasonic wave.

Relaxation Time — Time constant characterizing the time exponential approach to equilibrium following a sudden deviation from equilibrium of a relaxing medium. See also **Relaxation Time**.

Scattering — That phenomenon whereby an inhomogeneity in the path of a sound wave produces secondary waves spreading out from the inhomogeneity in various directions. See also **Scattering**.

Viscoelastic Material — A material possessing both elastic and viscous properties. See also **Viscoelasticity**.

Viscosity — A material property characterized by the dependence of the stress on the strain rate. See also **Viscosity**.

ULTRAVIOLET ASTRONOMY. For many decades, astronomers postulated that ultraviolet and extreme ultraviolet radiation emanating from the stars and other objects in the cosmos could yield information that could answer some fundamental questions: "How are galaxies formed? What material makes up the ubiquitous clouds of interstellar dust grains? How does the grouping of galaxies into clusters influence the birth rate of new stars?" And, with the answers to these questions on hand, one could be led to scores of answers pertaining to other aspects of the cosmos.

Earnest research dates back to the 1960s and is reviewed briefly later in this article. The astronomical problem of viewing the cosmos in the UV region of the spectrum is not as simple as the problem that, at one time, plagued optical telescopes, which operate in the visual light range — namely, overcoming the effects of the Earth's atmosphere. Orbiting telescopes, a gross improvement in telescope optics, and the use of adaptive optics have markedly overcome that problem. See also **Telescope (Astronomical-Optical)**.

When searching the cosmos with a UV and extreme UV instrument, there is the so-called "haze of hydrogen atoms," which, at one time, was believed to be present throughout space. Further, it was reasoned that photons at wavelengths of between 100 and 912 angstroms have just sufficient energy to ionize and thus are swept up by neutral hydrogen. But a remarkable discovery was made in 1975 by the Apollo-Soyuz mission, which carried an extreme ultraviolet telescope designed by Stuart Bowyer (University of California, Berkeley). Although it is reported that some scientists had expected a patchy medium when observed, the telescope detected four distinct stars other than the sun. This marked the first time that extreme UV light had been detected beyond the solar system. Without immediate analysis, this event showed that certainly, under certain circumstances, extreme ultraviolet astronomy could be done.

It was not until Priscilla Frish and Donald York (University of Chicago) reported that the sun resides in a void that has been swept clear of neutral hydrogen. One explanation offered was that of nearby supernova explosions. The void (clear of hydrogen) stretches for some 100 light years in most directions. In more recent findings, Barry Welsh (University of California, Berkeley) determined that the void is elongated into an interstellar "tunnel" at least 1000 light-years long. Thus, there is a window for future valuable UV exploration. This is touched on later in this article.

Chronology — UV Astronomy

Ultraviolet observations have been carried out since the beginning of the 1960s, mainly of the sun, using sounding rockets. The first UV space observatory was the *Orbiting Astronomical Satellite* (*OAO-2*), a photometric instrument launched in the late 1960s. Its primary function was ultraviolet filter photometry and low dispersion spectroscopy, largely concentrating on the ultraviolet continuum of stars and the details of dust absorption in the interstellar medium. Its major contribution was the determination of the properties of the enhanced absorption from interstellar dust grains at $\lambda = 2200$ Å.

The next major instrument in this series was *COPERNICUS*, launched in 1973, which was designed to perform high resolution spectroscopic observations of interstellar absorption lines at wavelengths less than $\lambda = 1200$ Å. The major achievements of this instrument included the discovery of the hot phase of the diffuse interstellar gas, and the first determination of the abundance of deuterium in the interstellar medium. It was also capable of studying for the first time absorption from hydrogen (H_2), the molecular component of the diffuse gas. Its high wavelength resolution permitted study, to an unprecedented accuracy, of the dynamics of the gas in the interstellar medium. It also provided considerable information about the dynamics of the atmospheres of luminous hot stars.

The *Netherlands Astronomical Satellite* (*ANS*) and the *TD-1* satellite have performed both photometric and spectrophotometric surveys of large numbers of stars.

Astronomers have also used manned flights as an opportunity to carry out ultraviolet imaging experiments. There were several UV cameras used during the *Apollo* lunar missions. During the *Skylab* mission, in addition to high resolution far-UV observations of the sun, objective prism spectra were obtained during the S-019 experiment and UV imaging was performed during the S-301 project. Imaging was also obtained during the *Apollo-Soyuz* mission.

Copernicus. The third Orbiting Astronomical Observatory the *Copernicus* satellite, otherwise known as the Orbiting Astronomical Observatory 3 (OAO-3), was launched by NASA from Cape Canaveral on August 21, 1972 and operated until February 1981. At that time, the spacecraft was the heaviest (2.2 tonnes) unmanned space observatory launched. The satellite, named *Copernicus*, was designed to seek answers to some of the fundamental questions concerning stars and interstellar matter by obtaining high resolution ultraviolet spectra, especially in the 900–1200 Å wavelength region. The principal experiment was a 32-inch (0.8 m) diameter reflecting telescope and ultraviolet spectrometer system designed, built, and operated by the Princeton University Observatory. Between August 1972 and February 1981 a total of 549 different objects were observed

(plus measurements of air-glow and geocoronal Lyman-alpha emission), and 687,960 separate scans were obtained.

Copernicus also contained a set of X-ray detectors co-aligned with the ultraviolet telescope. Further information about this set of experiments is available from Goddard's High Energy Astrophysics Science Archive Research Center (HEASARC).

International Ultraviolet Explorer Observatory (IUE). Space UV astronomy was revitalized by the launch of the IUE observatory, a joint project of the National Aeronautics and Space Administration (NASA) and the European Space Agency (ESA), as well as of the Science and Engineering Research Council of the United Kingdom (SERC). The IUE satellite was launched on January 26, 1978. It had an expected lifetime of 3 years, with a goal of 5 years, but exceeded that beyond anyone's wildest dreams. When it was shut down on September 30, 1996, it had been in continuous operation for 18 years and 9 months. It was the most successful scientific satellite to date.

The small (45 cm) telescope operated as a photometrically accurate spectrograph from $l = 1150-3300$ Å. It provided a low-resolution spectrophotometer (7 Å resolution) and a high-dispersion spectrograph (0.15 Å resolution) over this entire wavelength range. The satellite was in a geostationary orbit which was under direct NASA control for 16 hours per day and under ESA-SERC control for the remaining eight hours.

IUE contributed to the understanding of virtually all types of astronomically interesting objects, from planets to quasars. Here it is possible only to highlight some of its major contributions. It was used during the International Halley Watch to monitor the UV spectrum of Comet Halley during the 1986 close satellite encounters. It revealed the long-term structure of the plasma in the vicinity of Jupiter (the Iotorus), and provided information about the UV reflectivity of the major planets.

It is known from optical observations of solar-type stars that the outer atmospheres of main sequence stars with temperatures less than about 8000 K are extremely hot, tenuous plasmas. These regions, the chromospheres, reach temperatures of over 105 K. The longevity of *IUE* permitted the determination of temperature and structural changes in these atmospheres during the starspot cycles of many cool stars. It also was used to study the emission from regions connected with large-scale magnetic loop structures in close, active binary stars like RS Canes Venaticorum stars. It was also the first instrument to demonstrate the existence of active chromospheres in pre-main sequence T Tauri stars.

Following up on the discovery by *COPERNICUS* of the hot (105–106 K) component of the galactic interstellar medium, IUE played a key role in mapping out the extent of the galactic corona, and in tying the observations of the diffuse interstellar medium of our galaxy into a cosmic context. It is now possible to compare the structure of the interstellar gas along many lines of sight with that detected by observations of extragalactic systems. It is also possible to add to the *COPERNICUS* data a large number of previously inaccessible elements whose abundances in the diffuse gas between the stars can now be determined.

COPERNICUS showed that most luminous stars have strong mass outflows, reaching terminal velocities of thousands of kilometers per second. With *IUE*, a greater sample of these stars, both in our Galaxy and the neighboring Magellanic Clouds, have been studied. These observations support the idea that radiation, being absorbed and scattered in the stellar envelope, is responsible for transferring sufficient momentum to the gas that it is expelled from the star. The more luminous the star, the stronger its wind, among stars hotter than about 10,000 K. *IUE* observations have also showed that these winds are not stable, and that they display waves or blobs which can be traced for several hours to days through the wind by the absorption they produce against the light emitting surface of the star. Because the ground state transitions of a number of important atomic species occurred in the *IUE* wavelength region, like C IV and Si IV, it was possible to obtain information over a greater radial extent of stellar winds than can be understood by using optical emission profiles. *IUE* also was instrumental in studying the structure and dynamics of extended envelopes around emission line stars. It was the first satellite to be used in the same manner as a ground-based observatory would be — that is, implemented to carry out both survey and monitoring programs.

FAUST Telescope. As early as 1983, the Far Ultraviolet Space Telescope, designed to observe the far ultraviolet emanations of stars and galaxies over great swathes of sky, was ready for launching. Because of shuttle problems and the priorities given to other science projects, FAUST was not launched until March 30, 1992. By March 30, investigators had completed 20 of the 34 planned observations, at which time a faulty fuse (not reparable in orbit) malfunctioned and put the telescope completely out of service. Although very disappointed, researchers claim that they have sufficient data to analyze over the next few years.

Astro-1 and 2 Space Shuttle Mission. In February 1978, NASA issued an Announcement of Opportunity for instruments that could travel aboard the Space Shuttle and utilize the unique capabilities of Spacelab. Many teams responded, and over 40 proposals were selected for further study. Three telescopes, Hopkins Ultraviolet Telescope (HUT), Ultraviolet Imaging Telescope (UIT), and Wisconsin Ultraviolet Photo-Polarimeter Experiment (WUPPE), evolved as a single payload and the mission was assigned to Goddard Space Flight Center (GSFC). Because the Instrument Pointing System (IPS) and other Spacelab facilities were needed for the mission, management of the payload was moved to Marshall Space Flight Center (MSFC) in 1982, where it was given the name Astro.

The ASTRO-1 mission was flown on the space shuttle Columbia during 2–10 December, 1990. The same three instruments were later flown on the space shuttle Endeavor from 3–17 March, 1995 as part of the ASTRO-2 mission.

The *Hopkins Ultraviolet Telescope Project* (HUT) was conceived, designed, and built by astronomers and engineers at JHU to perform astronomical observations in the far-ultraviolet portion of the electromagnetic spectrum, wavelengths of light that are inaccessible to ground-based telescopes. HUT consists of a 90-centimeter (36-inch) f/2 mirror that focuses light from celestial sources onto a prime focus spectrograph.

Covering the 825–1850 Å region with about 3 Å resolution, HUT opened the astrophysically important 912 to 1200 Å window to detailed scrutiny for the first time. In typical 1800 s integrations, HUT observed faint astronomical objects with visual magnitudes of about 16.

Originally designed to explore the far- and extreme-ultraviolet ranges on Astro-1, HUT was modified for Astro-2 to concentrate on the far-ultraviolet. The changes made to HUT for Astro-2 included a new detector system and new silicon carbide coatings on the mirror and grating which replaced the original iridium and osmium. These improvements provided a factor of 2.3 increase in sensitivity in the primary operating range of 825 to 1850 angstroms, especially in the 912- to 1200-angstrom region unique to HUT.

The telescope has been used to observe objects as diverse as planets in our own solar system, individual and binary stars, star clusters, gaseous nebulae, normal and active galaxies, and even the enigmatic quasars (the most distant objects in the Universe!).

The exciting findings of the Astro-1 mission are reported in some detail by Davidsen. (See reference.) Particularly with reference to the *HUT*, Davidsen reports, "Among the new insights concerning the origin of the ultraviolet light from the old stellar population in elliptical galaxies, new evidence for a hot, gaseous corona surrounding the Milky Way was found as well as improved views of the physical conditions in active galactic nuclei, and a measurement of the ionization state of the local interstellar medium."

The *Ultraviolet Imaging Telescope* (UIT) consisted of an f/9 Ritchey-Chretien telescope with an aperture of 38 cm. Two detectors covered the near-ultraviolet and far-ultraviolet wavelength ranges from 1200 to 3300 Å. Six filters were available for each camera. Magnetically focussed two-stage image intensifiers produced images that were recorded on 70 mm film (Kodak IIa-O). The resulting images cover a 40 arcmin field of view, with a resolution of 3 arcsec. For comparison, the Wide Field Camera #2 on HST has much smaller field of view, 2.5 arcmin × 2.5 arcmin, with a higher resolution of about 0.1 arcsec. UIT could therefore obtain ultraviolet imaging of much larger, more extended objects, than HST. In addition, a diffraction grating was used for full field low resolution spectroscopy. The film images were digitized, linearized and flat fielded through a standard reduction system.

Further details about UIT may be obtained from The Ultraviolet Imaging Telescope: Instrument and Data Characteristics, an article written by UIT mission personnel describing the design, operation, data reduction, and calibration of the instrument. http://adsbit.harvard.edu/cgi-bin/nph-iarticle_query?bibcode =1997PASP..109..584S

The *Wisconsin Ultraviolet Photo-Polarimeter Experiment* (WUPPE) was a pioneering effort to explore polarization and photometry in the ultraviolet (UV) spectrum. It was the first and most comprehensive effort to exploit the unique powers of polarimetry at wavelengths not visible on Earth. The instrument was designed and built at the University of Wisconsin Space Astronomy Laboratory in the 1980's. WUPPE flew on two NASA Space Shuttle missions: ASTRO-1 and ASTRO-2.

WUPPE obtained medium resolution spectropolarimetry to study the interstellar medium, hot stars, stars with circumstellar material, interacting binaries, novae, solar system objects, and active galaxies. It was a unique instrument, obtaining a large amount of the ultraviolet spectropolarimetry data currently available.

WUPPE obtained simultaneous spectral and polarization measurements from 1400 to 3300 Å. The instrument included a 0.5 m f/10 Cassegrain telescope and a modified Monk-Gilleson spectropolarimeter. Two rotating wheels were used to select the focal plane aperture and the polarimetric analyzer. A magnesium fluoride Wollaston polarizing beam-splitter placed between the aperture and the relay mirror split the beam into two orthogonally-polarized spectra. The detector consisted of dual Reticon arrays of 1024 pixel photodiodes coupled by fiber optics to a microchannel plate intensifier. A set of halfwave plates at 6 different angles provided spectropolarimetric modulation with 16 Å spectral resolution. In addition, a Lyot analyzer was used to provide low resolution (50–100 Å) spectropolarimetry on fainter objects. However the Lyot had calibration problems and no useful polarimetry data were obtained from that mode.

During Astro-1, WUPPE obtained 98 observations of 75 targets. Thirty-three of the observations resulted in usable polarimetric data (as well as spectroscopy). Forty-two of the pointings resulted in only UV spectra. During Astro-2, WUPPE obtained 369 observations of 254 targets. One hundred-fifty of the pointings resulted in polarimetric data. Forty-seven pointings produced only UV spectra.

For more information about WUPPE, please see Web References.

Hubble Space Telescope (HST). The HST is an orbiting astronomical observatory operating from the near-infrared into the ultraviolet. Launched in 1990 and scheduled to operate through 2010, HST carries and has carried a wide variety of instruments producing imaging, spectrographic, astrometric, and photometric data through both pointed and parallel observing programs.

The Hubble Space Telescope is a cooperative program of the European Space Agency (ESA) and the National Aeronautics and Space Administration (NASA) to operate a long-lived space-based observatory for the benefit of the international astronomical community. HST is an observatory first dreamt of in the 1940s, designed and built in the 1970s and 80s. Since its preliminary inception, HST was designed to be a different type of mission for NASA — a long term space- based observatory. To accomplish this goal and protect the spacecraft against instrument and equipment failures, NASA had always planned on regular servicing missions. Hubble has special grapple fixtures, 76 handholds, and stabilized in all three axes. HST is a 2.4-meter reflecting telescope which was deployed in low-Earth orbit (600 kilometers) by the crew of the space shuttle Discovery (STS-31) on 25 April 1990.

Responsibility for conducting and coordinating the science operations of the Hubble Space Telescope rests with the Space Telescope Science Institute (STScI) on the Johns Hopkins University Homewood Campus in Baltimore, Maryland. STScI is operated for NASA by the Association of Universities for Research in Astronomy, Inc. (AURA). See also **Hubble Space Telescope (HST)**.

ROSAT, the Roentgen SATellite. This satellite was an X-ray observatory developed through a cooperative program between Germany, the United States, and the United Kingdom. The satellite was designed and operated by Germany, and was launched by the United States on June 1, 1990. It was turned off on February 12, 1999. The ROSAT mission began with a 6-month, all sky Position Sensitive Proportional Counter (PSPC) survey, after which the satellite began a series of pointed observations that continued for the duration of the project. See also **ROSAT (Roentgen Satellite)**.

Extreme Ultraviolet Explorer (EUVE). This satellite, mentioned earlier, was launched in June 1992. The EUVE conducted the first extreme ultraviolet (70–760 Angstroms) survey of the sky and subsequently began a Guest Observer Program of pointed spectroscopy, that ended on January 31, 2001. The satellite has four photometric imaging systems and a three-channel EUV spectrometer. The imaging instruments were used to complete the sky survey. The spectrometers were used for the pointed spectroscopic programs, which collected data from over 350 unique astronomical targets.

At any time, *EUVE* can shift to a nonsurvey mode, and target specific sources and record detailed spectroscopic data. *EUVE* has taken the first extreme UV snapshots of the moon and the Cygnus loop, a circular glow produced by the outrushing gaseous shell from an exploding supernova careening into the interstellar medium. *EUVE* has proved that the interstellar medium can be probed by peering through gaps in the medium.

The Far Ultraviolet Spectroscopic Explorer (FUSE). FUSE is a NASA-supported astronomy mission that was launched on June 24, 1999, to explore the Universe using the technique of high-resolution spectroscopy in the far-ultraviolet spectral region. The Johns Hopkins University has the lead role in developing and now operating the mission, in collaboration with The University of Colorado at Boulder, The University of California at Berkeley, international partners the Canadian Space Agency (CSA) and the French Space Agency (CNES), and corporate partners. FUSE is part of NASA's Origins Program under the auspices of NASA's Office of Space Science. FUSE is planned for a 3 year lifetime with funding for an additional 2 years expected.

FUSE will cover the 905–1187 Å spectral region and will obtain high resolution spectra of hot and cool stars, AGNs, supernova remnants, planetary nebulae, solar system objects as well as perform detailed studies of the interstellar medium. FUSE will be able to observe sources 10,000 times fainter than *Copernicus*, an early FUV mission, and has superior resolving power than the Hopkins Ultraviolet Telescope (HUT) and the Orbiting Retrievable Far and Extreme Ultraviolet.

The FUSE satellite consists of two primary sections, the spacecraft and the science instrument. The spacecraft contains all of the elements necessary for powering and pointing the satellite: the attitude control system, the solar panels, communications electronics, and antennas. The science instrument collects the light of distant objects and contains the equipment necessary to disperse and record the light: the telescope mirrors, the spectrograph (and its electronic detectors), and an electronic guide camera called the *Fine Error Sensor* (or FES). The spacecraft and the science instrument each have their own computers, which together coordinate the activities of the satellite.

Astronomers will view the Universe in a whole new light using the unique data obtained with FUSE. In particular, they seek answers to long-standing questions such as: "*What were the conditions like in the first few minutes after the Big Bang?", "How are the chemical elements dispersed throughout galaxies, and how does this affect the way galaxies evolve?", and "What are the properties of the interstellar gas clouds out of which stars and solar systems form?*" All of these questions, and many others, can be addressed by observing the far ultraviolet light from stars, interstellar gas, and distant galaxies with FUSE.

The scientific approach of the FUSE mission is special because a science team has been charged by NASA with providing answers, or at least partial answers, to intriguing questions like those posed above. Toward this end, the FUSE science team will undertake a comprehensive study of the cosmic abundance of deuterium, a rare form of "heavy hydrogen" formed only in the Big Bang. The team will also study the hot gas content of our galaxy, the Milky Way, and its nearest neighbor galaxies, the Magellanic Clouds. To conduct these large studies, the FUSE science team will observe hundreds of astronomical objects, using about half of the observing time during the three-year mission. The remaining observing time is devoted to a Guest Investigator program where NASA selects scientific investigations proposed by astronomers world-wide. For additional information on FUSE see http://fusewww.gsfc.nasa.gov/.

ULTRAVIOLET PHOTOGRAPHY AND IMAGERY. See **Photography and Imagery**.

ULTRAVIOLET RADIATION. This region of the electromagnetic spectrum is subdivided into: (1) the near-ultraviolet, 4,000 to 3,000 Å, present in sunlight, producing important biological effects, but not detectable by the human eye; (2) the middle-ultraviolet, 3,000 to 2,000 Å, not present in sunlight as it reaches the Earth's surface, but well transmitted through air; and (3) the long- or extreme-ultraviolet (XUV), 2,000 to 100 Å. The latter borders on x-radiation. The latter is also called the far-ultraviolet and it is not transmitted through air. The region between 2,000 and 1,350 Å is sometimes referred to as the Schumann region after its discoverer. The boundary between far-ultraviolet and x-rays is arbitrary.

The name means "beyond violet" (from Latin *ultra*, "beyond"), violet being the color of the shortest wavelengths of visible light. Some of the UV wavelengths are colloquially called **black light**, as it is invisible to the human eye. Some animals, including birds, reptiles, and insects such as bees, can see into the near ultraviolet. Many fruits, flowers, and seeds stand out more strongly from the background in ultraviolet wavelengths as compared to human color vision. Many birds have patterns in their plumage that are invisible at usual wavelengths but seen in ultraviolet, and the urine of some animals is much easier to spot with ultraviolet.

Soon after infrared radiation had been discovered, the German physicist Johann Wilhelm Ritter began to look for radiation at the opposite end of the spectrum, at the short wavelengths beyond violet. In 1801 he used silver chloride, a light-sensitive chemical, to show that there was a type of invisible light beyond violet, which he called chemical rays. At that time, many scientists, including Ritter, concluded that light was composed of three separate components: an oxidising or calorific component (infrared), an illuminating component (visible light), and a reducing or hydrogenating component (ultraviolet). The unity of the different parts of the spectrum was not understood until about 1842, with the work of Macedonio Melloni, Alexandre-Edmond Becquerel and others. During that time, UV radiation was also called "actinic radiation". Ultraviolet radiation is emitted by nearly all light sources to some degree. Generally, the higher the temperature of the source, or the more energetic the excitation, the shorter are the wavelengths produced. Tungsten lamps in quartz envelopes radiate in the ultraviolet in accordance with Planck's law, slightly modified by the emissivity function of tungsten. Because of its high temperature (3,800 K), the crater of an open carbon arc is an excellent source of ultraviolet radiation, extending to the air cutoff. Electrical discharges through gases produce intense ultraviolet emission, mainly in lines and bands. A widely used source is the quartz mercury arc. Magnetically compressed plasma, as produced by devices such as zeta and theta pinch and which reach an extremely high temperature, are also sources of highly ionized atoms and emission lines in the far-ultraviolet. Such radiation is also produced by a synchrotron.

Solids, liquids, and gases normally transmit effectively in the near-ultraviolet range, but become opaque in the middle or extreme ultraviolet range. For constructing lenses and prisms used in ultraviolet instruments, the unusual transmittance of crystal and fused quartz, fluorite, and lithium fluoride are an immense advantage. Gases vary considerably in their absorption characteristics. Oxygen molecules cause air to become opaque below about 1,850 Å. Molecular nitrogen is relatively transparent down to 1,000 Å. Hydrogen absorbs in the Lyman series lines, and in an ionization continuum beyond the series limit, 911.7 Å. Helium is the most ultraviolet-transparent of all gases. Absorption first takes place in the resonance lines, the longest lying at 584 Å, and in a continuum beyond the series limit, 504 Å. The more complex gaseous molecules, such as CO_2, NO, and N_2O are rather opaque throughout most of the far-ultraviolet. Water vapor commences to absorb at wavelengths below 1,850 Å.

As with all visible radiation, reflection occurs for ultraviolet. Reflectance becomes less as the wavelength decreases. Aluminum is the best reflector over much of the long-wavelength region, reaching 90% down to 2,000 Å (when the metal is properly prepared), and 80% down to 1,200 Å when the aluminum is coated with a thin layer of magnesium fluoride to prevent growth of aluminum oxide. Platinum is the best reflector below 1,000 Å, achieving 20% at 600 Å, but only about 4% at 300 Å.

The simplest way to detect and measure ultraviolet radiation is by using the fluorescence process, converting the ultraviolet into radiation that can be seen; or into the near-ultraviolet range, which can be easily photographed or measured with conventional photomultipliers. Materials used for the extreme ultraviolet include oil and sodium salicylate, the latter particularly valuable because its quantum efficiency of fluorescence is high and nearly independent of wavelength. Thus, an ordinary photomultiplier with a sodium salicylate coated glass window becomes a sensitive radiometer for use throughout the entire ultraviolet region.

Ionization chambers and Geiger counters can be used for detecting extreme ultraviolet radiation. Knowledge of the ionization efficiency of the gas makes it possible to use them for measurement of absolute energy. Ultraviolet radiation also can be detected with a thermocouple, thermopile, or bolometer.

The Sun emits strongly throughout the ultraviolet, but only the near-ultraviolet reaches the Earth's surface, wavelengths shorter than 2,900 Å being absorbed by a layer of ozone in the atmosphere. See also **Oxygen**. Possible disturbance of the ozone layer by various air-polluting chemicals is considered of major importance because of the possibility of eliminating this effect and thus exposing the Earth's surface to the shorter, more dangerous ultraviolet radiation. In addition to producing sunburn, exposure of the eye to ultraviolet can cause a painful burn of the cornea and conjunctivitis. Snow blindness is caused by reflection of intense sources of middle-ultraviolet radiation from snowfields and glaciers. Ultraviolet radiation also enters into the photochemical processes which contribute to the production of smog.

Health and Safety Concerns and Protection

Small amounts of UV are beneficial for people and essential in the production of vitamin D. UV radiation is also used to treat several diseases, including rickets, psoriasis, eczema and jaundice.

In humans, prolonged exposure to solar UV radiation may result in acute and chronic health effects on the skin, eye, and immune system. Sunburn (erythema) is the best-known acute effect of excessive UV radiation exposure. Over the longer term, UV radiation induces degenerative changes in cells of the skin, fibrous tissue and blood vessels leading to premature skin aging, photodermatoses and actinic keratoses.

Tungsten-halogen lamps have bulbs made of quartz, not of ordinary glass. Tungsten-halogen lamps that are not filtered by an additional layer of ordinary glass are a common, useful, and possibly dangerous, source of UVB light.

UVC rays are the highest energy, most dangerous type of ultraviolet light. Little attention has been given to UVC rays in the past since they are filtered out by the atmosphere. However, their use in equipment such as pond sterilization units may pose an exposure risk, if the lamp is switched on outside of its enclosed pond sterilization unit.

Skin. UVA also called Long Wave or "blacklight"; UVB also called Medium Wave; and UVC also called Short Wave or "germicidal", all can damage collagen fibers and thereby accelerate aging of the skin. In general, UVA is the least harmful, but can contribute to the aging of skin, DNA damage and possibly skin cancer. It penetrates deeply and does not cause sunburn. Because it does not cause reddening of the skin (erythema) it cannot be measured in the SPF testing. There is no good clinical measurement of the blocking of UVA radiation, but it is important that sunscreen block both UVA and UVB.

UVA light is known as "dark-light" and, because of its longer wavelength, can penetrate most windows. It also penetrates deeper into the skin than UVB light and is thought to be a prime cause of wrinkles.

UVB light in particular has been linked to skin cancers such as melanoma. The radiation excites DNA molecules in skin cells, causing covalent bonds to form between adjacent thymine bases, producing thymidine dimers. Thymidine dimers do not base pair normally, which can cause distortion of the DNA helix, stalled replication, gaps, and misincorporation. These can lead to mutations, which can result in cancerous growths. The mutagenicity of UV radiation can be easily observed in bacteria cultures.

This cancer connection is one reason for concern about ozone depletion and the ozone hole.

As a defense against UV radiation, the body tans when exposed to moderate (depending on skin type) levels of radiation by releasing the brown pigment melanin. This helps to block UV penetration and prevent damage to the vulnerable skin tissues deeper down. Suntan lotion that partly blocks UV is widely available (often referred to as "sun block" or "sunscreen"). Most of these products contain an "SPF rating" that describes the amount of protection given. This protection applies only to UVB light. In any case, most dermatologists recommend against prolonged sunbathing. See also **Dermatitis and Dermatosis**; **Skin**; and **Skin Cancer**.

Eye. High intensities of UVB light are hazardous to the eyes, and exposure can cause *welder's flash* (photokeratitis or arc eye) and may lead to cataracts, pterygium, and pinguecula formation.

Protective eyewear is beneficial to those who are working with or those who might be exposed to ultraviolet radiation, particularly short wave UV. Given that light may reach the eye from the sides, full coverage eye protection is usually warranted if there is an increased risk of exposure as in high altitude mountaineering. Mountaineers are exposed to higher than ordinary levels of UV radiation, both because there is less atmospheric filtering and because of reflection from snow and ice.

Ordinary eyeglasses give some protection, and most plastic lenses give more protection than glass lenses. Some plastic lens materials, such as polycarbonate, block most UV. There are protective treatments available for eyeglass lenses that need it to give better protection. Most intraocular lenses help to protect the retina by absorbing UV radiation.

Uses

Possibly the most effective use of the characteristics of ultraviolet radiation is in optical and instrumentation applications. See also **Ultraviolet Spectrometers**. Other uses include:

Black Lights. A black light is a lamp that emits long wave UV radiation and very little visible light. Fluorescent black lights are typically made in the same fashion as normal fluorescent lights except that only one phosphor is used and the normally clear glass envelope of the bulb is replaced by a deep bluish purple glass called Wood's glass.

Fluorescent Lamps. Fluorescent lamps produce UV radiation by the emission of low-pressure mercury gas. A phosphorescent coating on the inside of the tubes absorbs the UV and becomes visible. See also **Illumination**.

The main mercury emission wavelength is in the UVC range. Unshielded exposure of the skin or eyes to mercury arc lamps that do not have a conversion phosphor is quite dangerous.

The light from a mercury lamp is predominantly at discrete wavelengths. Other practical UV sources with more continuous emission spectra include xenon arc lamps (commonly used as sunlight simulators), deuterium arc lamps, mercury-xenon arc lamps, metal-halide arc lamps, and tungsten-halogen incandescent lamps.

Pest Control. Ultraviolet fly traps are used for the elimination of various small flying insects. They are attracted to the UV light and are killed using an electrical shock or trapped once they come into contact with the device.

Photolithography. Ultraviolet radiation is used for very fine resolution photolithography, a procedure where a chemical known as a photoresist is exposed to UV radiation which has passed through a mask. The light allows chemical reactions to take place in the photoresist, and after development (a step that either removes the exposed or unexposed photoresist), a geometric pattern which is determined by the mask remains on the sample. Further steps may then be taken to "etch" away parts of the sample with no photoresist remaining.

UV radiation is used extensively in the electronics industry because photolithography is used in the manufacture of semiconductors, integrated circuit components and printed circuit boards.

Checking Electrical Insulation. A new application of UV is to detect corona discharge (often simply called "corona") on electrical apparatus. Degradation of insulation of electrical apparatus or pollution causes corona, wherein a strong electric field ionizes the air and excites nitrogen molecules, causing the emission of ultraviolet radiation. The corona degrades the insulation level of the apparatus. Corona produces ozone and to a lesser extent nitrogen oxide which may subsequently react with water in the air to form nitrous acid and nitric acid vapour in the surrounding air.

Sterilization. Ultraviolet lamps are used to sterilize workspaces and tools used in biology laboratories and medical facilities. Commercially-available low pressure mercury-vapor lamps emit about 86% of their light at 254 nanometers (nm) which coincides very well with one of the two peaks of the germicidal effectiveness curve (i.e., effectiveness for UV absorption by DNA). One of these peaks is at about 265 nm and the other is at about 185 nm. Although 185 nm is better absorbed by DNA, the quartz glass used in commercially-available lamps, as well as environmental media such as water, are more opaque to 185 nm than 254 nm. UV light at these germicidal wavelengths causes adjacent thymine molecules on DNA to dimerize, if enough of these defects accumulate on a microorganism's DNA its replication is inhibited, thereby rendering it harmless (even though the organism may not be killed outright). Since microorganisms can be shielded from ultraviolet light in small cracks and other shaded areas, however, these lamps are used only as a supplement to other sterilization techniques.

Disinfection. UV radiation can be an effective viricide and bactericide. Disinfection using UV radiation was more commonly used in wastewater treatment applications but is finding increased usage in drinking water treatment. It used to be thought that UV disinfection was more effective for bacteria and virus, which have more exposed genetic material, than for larger pathogens which have outer coatings or that form cyst states (e.g., *Giardia lamblia*) that shield their DNA from the UV light. However, it was recently discovered that ultraviolet radiation can be somewhat effective for treating the microorganism Cryptosporidium. The findings resulted in two US patents and the use of UV radiation as a viable method to treat drinking water. Giardia in turn has been shown to be very susceptible to UV-C when the tests were based on infectivity rather than excystation. It turns out that protists are able to survive high UV-C doses but are sterilized at low doses.

Food Processing. As consumer demand for fresh and "fresh like" food products increases, the demand for nonthermal methods of food processing is likewise on the rise. In addition, public awareness regarding the dangers of food poisoning is also raising demand for improved food processing methods. Ultraviolet radiation is used in several food processes to remove unwanted microorganisms. UV light can be used to pasteurize fruit juices by pumping the juice over a high intensity ultraviolet light source. The effectiveness of such a process depends on the UV absorbance of the juice. See also **Beer's Law**.

Other. Certain adhesives and coatings are formulated with photoinitiators. When exposed to the correct wavelengths of UV light, polymerisation occurs, and so the adhesives harden or cure. Usually, this reaction is very quick, a matter of a few seconds. Applications include glass and plastic bonding, optical fiber coatings, the coating of flooring, and dental fillings.

UV lights have been installed in some parts of the world in public restrooms for the purpose of deterring substance abuse. The blue color of these lights make it impossible for intravenous drug users to find a

vein. The efficacy of these lights for that purpose has been questioned, with some suggesting that drug users simply find a vein outside the public restroom and mark the spot with a marker for accessibility when inside the restroom. There is currently no published evidence supporting the idea of a deterrent effect.

Fire Detection. Ultraviolet (UV) detectors generally use either a solid-state device, such as one based on silicon carbide or aluminum nitride, or a gas-filled tube as the sensing element. UV detectors which are sensitive to UV light in any part of the spectrum respond to irradiation by sunlight and artificial light. A burning hydrogen flame, for instance, radiates strongly in the 185 to 260 nanometre) range and only very weakly in the IR region, while a coal fire emits very weakly in the UV band yet very strongly at IR wavelengths; thus a fire detector which operates using both UV and IR detectors is more reliable than one with a UV detector alone. Virtually all fires emit some radiation in the UVB band, while the Sun's radiation at this band is absorbed by the Earth's atmosphere. The result is that the UV detector is "solar blind", meaning it will not cause an alarm in response to radiation from the Sun, so it can easily be used both indoors and outdoors.

UV detectors are sensitive to most fires, including hydrocarbons, metals, sulfur, hydrogen, hydrazine, and ammonia. Arc welding, electrical arcs, lightning, X-rays used in nondestructive metal testing equipment (though this is highly unlikely), and radioactive materials can produce levels that will activate a UV detection system. The presence of UV-absorbing gases and vapors will attenuate the UV radiation from a fire, adversely affecting the ability of the detector to detect flames. Likewise, the presence of an oil mist in the air or an oil film on the detector window will have the same effect.

For the use of ultraviolet radiation in astronomy, see also **Ultraviolet Astronomy**. See also specific planets.

For the use of ultraviolet lasers in chemistry, see also **Photochemistry and Photolysis**.

ULTRAVIOLET SOLAR ENERGY (MUSE). See **Nimbus Satellite Program**.

ULTRAVIOLET SPECTROMETERS. Ultraviolet instruments are based upon the selective absorbance of ultraviolet radiation by various substances. The absorbance of a substance is directly proportional to the concentration of the substance which causes the absorption in accordance with the Lamber-Beer law (or simply Beer's law):

$$A = abc = \log \frac{I_0}{I} \log \frac{1}{T}$$

where A = absorbance; a = molar absorptivity, 1/(mole)(centimeter); b = path length, centimeters; c = concentration, moles/1; I_0 = intensity of radiation striking detector with nonabsorbing sample in light path; I = intensity of radiation striking detector with concentration c of absorbing sample in light path b; and T = transmittance = I/I_0.

For the vapor phase,

$$A = \frac{abc'}{2{,}450}$$

at 25 °C and 760 torr pressure, where c' = volume percent or mole percent, or

$$A = \frac{abc'}{2{,}450} \times \frac{P + 14.7}{14.7} \times \frac{298}{t + 273}$$

at any temperature or pressure, where P = pressure, psig; and t = temperature °C.

For the liquid and solid phases.

$$c = \frac{c'' \times d}{\text{M.W.}} \times 10 = \text{moles/1}$$

where c'' = weight percent in liquid; d = density of liquid; and M.W. = molecular weight of material to be measured.

$$A = \frac{10abc''d}{\text{M.W.}}$$

The fundamental elements of an ultraviolet-absorption analyzer include: (a) a radiation source; (b) suitable optical filters; (c) a sample cell; and (d) an output meter. A transmittance measurement is made by calculating the ratio of the reading of the output with the sample in the cell to the reading with the cell empty (of ultraviolet-absorbing materials). The concentration can be calculated from the known absorptivity of the substances as previously demonstrated by the equations; or it may be determined by comparison with known samples.

Sources of ultraviolet radiation include: (a) tungsten-filament incandescent lamps; (b) tungsten-iodine cycle lamps with quartz envelopes; (c) mercury-vapor lamps; and (d) the zinc discharge lamp. Other types are available, but enjoy only limited application. The hydrogen or deuterium lamps are used in the laboratory, but are delicate and costly for process uses.

The analytical radiation in an ultraviolet analyzer must be as nearly monochromatic as possible in the interest of high linearity, long-time stability, and sustained accuracy. Monochromatic radiation is obtained by proper selection of sources, filters, and phototubes, each of which is selective in regard to the wavelengths that it respectively emits, transmits, or responds to. For lenses and windows, fused quartz is the most commonly used for windows and for some lenses. Corning 7910 glass and synthetic sapphire transmit throughout the near-ultraviolet range. Mirrors of rhodium or special alloys may be less reflecting in certain regions, but are preferred over silver and aluminum because of their high resistance to scratching and corrosion. Semitransparent mirrors for beamsplitting are made of special alloys or chromium coatings evaporated upon quartz or glass.

Vacuum phototubes are preferred as detectors over barrier-layer photocells because of their higher signal-to-noise ratio, greater stability, longer life, and freedom from fatigue. Simple tubes are preferred over multiplier types because they are less costly, are more stable, and can be used in simpler circuits.

The simplest ultraviolet-absorption analyzer is the *single beam* type. The output of this type of instrument will be affected by fluctuations and drift of the light source, dirt or bubbles in the sample cell, and any drift in the detector or detector circuit. Thus, single-beam instruments operate on relatively low sensitivity (high absorbance) levels to provide reasonably stable analyses. Improved single-beam instruments have found extensive applications where only a "go-no-go" or broad range measurement will suffice. The *split-beam* analyzer overcomes most of the foregoing shortcomings and is based upon a differential absorption measurement at two wavelengths. The optical diagram of a double-beam grating ultraviolet spectrophotometer is shown in Fig. 1. Each band of wavelengths, isolated by the grating monochromator, is split into two beams, which pass alternately through the sample and reference paths. The two beams are then recombined along a single path, but separated in time. Thus, the detector receives an alternating optical signal consisting of radiant power P through the sample and P_0 through the reference. This output is converted into an electrical signal that is related to the transmittance of the sample P/P_0.

One of the more important areas of use of ultraviolet instruments is the identification and determination of biologically active substances. Many components in body fluids can be determined either directly or through colorimetric methods. Drugs and narcotics can be measured both in the body as well as in formulations. Vitamin assay is another related activity. Nearly all metals and nonmetals can be determined through their ultraviolet absorption or by colorimetric methods. In recent years, ultraviolet instruments have been used extensively for the determination of air and water pollutants, such as aldehydes, phenolics, and ozone; for the analysis of dyestuffs; for studies on polyaromatics and other carcinogenic

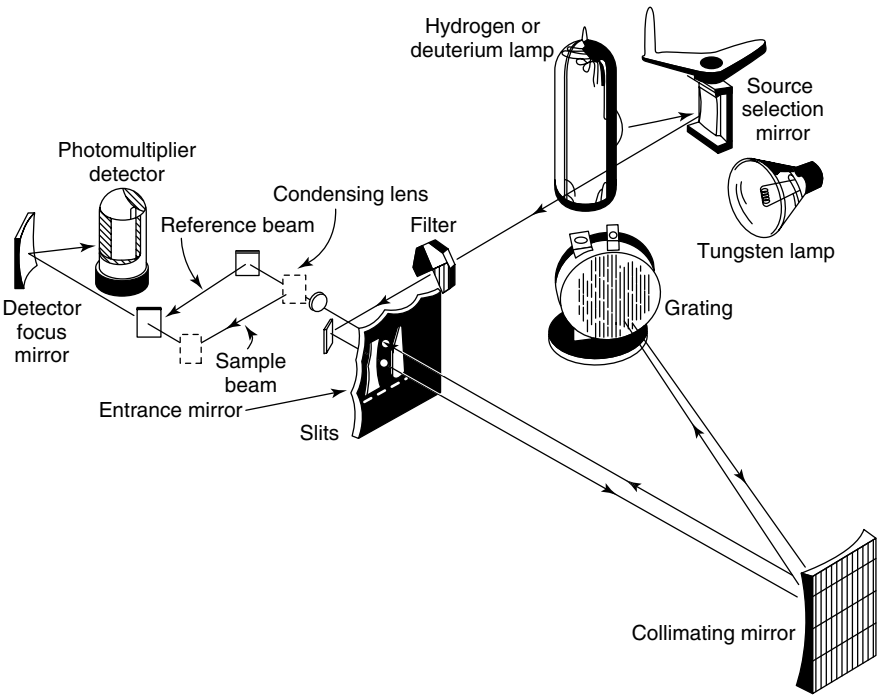

Fig. 1. Optical path of double-beam grating ultraviolet spectrophotometer. (*Beckman*.)

substances; for the determination of food additives; for the analysis of petroleum fractions; and for the detection and determination of pesticide residues.

ULTRAVIOLET STABILIZERS. When a polymer absorbs light, it may reradiate the absorbed energy at much longer wavelengths (heat), at slightly longer wavelengths (luminescence), or the energy may be transferred to another molecule. When none of these processes is operative, the absorbed light energy may cause bond breaking leading to degradation. By incorporating an ultraviolet absorbing compound into the plastic, it is possible to essentially eliminate all of the above processes, since the absorber even at concentrations as low as 0.5% can effectively compete for the incident ultraviolet radiation, thus protecting the plastic from degradation. A second approach to stabilization is to incorporate an additive which, though not an absorber in itself, can accept energy from the polymer substrate, and thus, leave the polymer intact. Since protection of plastics against light degradation can be achieved by these two mechanisms, the broader term *ultraviolet stabilizer* or *light stabilizer* is used to refer to such additives.

Ultraviolet absorbers continue to be the most widely used stabilizers. Such products must have long-term stability to ultraviolet light, be relatively nontoxic, heat stable, have little color, must not sensitize the substrate, and must be priced at levels which the plastics processor can tolerate. The principal classes of chemicals meeting these requirements at present are the 2-hydroxybenzophenones, and 2-(2′-hydroxyphenyl)benzotriazoles, substituted acrylates, and aryl esters. Typical compounds representative of these classes are 2-hydroxy-4-octoxybenzophenone, 2-(2′-hydroxy-5′-methylphenyl) benzotriazole, ethyl-2-cyano-3,3-diphenyl acrylate, dimethyl *p*-methoxybenzylidene malonate, and *p-tert*-octylphenyl salicylate.

The particular absorber to be used in a given application depends on several factors. One important criterion is whether the absorber will strongly absorb that portion of the ultraviolet spectrum responsible for degradation of the plastic under consideration. Compatibility, volatility, thermal stability, and interactions with other additives and fillers are other items that must be considered. When used in food wrappings, Food and Drug Administration approval must be obtained. While one or more of these considerations may rule out a given stabilizer or influence the choice of one class over another, the final selection must await the results of extensive accelerated and long-term tests.

Much effort has gone into the development of accelerated testing procedures. Many of the devices and techniques employed are based on knowledge gained in the evaluation of dyes, textiles, and rubber.

For extended outdoor applications, most polymers require some degree of light stabilization. There are wide variations in the inherent stability of different polymers ranging from less stable ones, such as polypropylene, to the highly light-stable poly(methyl methacrylate). Because of the dramatic growth of polyolefins, and particularly polypropylene, over the past several years, there has been an upsurge in requirements for ultraviolet absorbers. The hydroxybenzophenones, such as 2-hydroxy-4-octoxy benzophenone, have been widely used for stabilization of polypropylene. The benzotriazoles have also achieved commercial importance in this application. End uses of polypropylene requiring ultraviolet absorbers include upholstery fabrics, indoor-outdoor carpeting, lawn furniture, ropes, and various crates and boxes. Polyethylene is also stabilized with the hydroxy benzophenone absorbers. Applications include baskets, beverage cases, bags for fertilizer, and films for greenhouses.

Polystyrene light stabilization has been achieved with a variety of ultraviolet absorbers including the benzophenones, benzotriazoles, and salicylates. While yellowing of polystyrene occurs in many applications, it is particularly noticeable in diffusers used with fluorescent lights. This problem has been effectively solved by using ultraviolet light absorbers. In this instance, superior stabilization is achieved when the ultraviolet absorber is used in conjunction with specific antioxidants.

The hydroxybenzophenones, hydroxyphenylbenzotriazoles, and substituted acrylates are all used for stabilization of polyvinyl chloride. This polymer is growing at a substantial rate, and increasing uses are developing for light-stabilized grades. Among current uses, may be mentioned auto seat covers, floor tiles, light diffusers, vinyl-coated fabrics, siding, and exterior trim. Since the processing of polyvinyl chloride requires the use of a heat stabilizer, care must be exercised to avoid undesirable interactions between the heat and light stabilizers.

The stabilization of polyesters is generally achieved with the hydroxybenzophenone and hydroxyphenylbenzotriazole absorbers. The choice of absorber depends on the curing catalysts and promoters used. The stabilization of fire retardant grades of polyesters offers a greater problem than the standard grades because the halogenated monomer acids used are appreciably more sensitive to ultraviolet light than the unhalogenated acids (phthalic, isophthalic). Applications for light-stabilized polyesters include sheets for roofs and skylights and various surface coatings.

Cellulosic plastics are used in a number of outdoor applications with signs being one of the principal areas of use. This plastic can be stabilized

reasonably well with the aryl esters of salicyclic acid. It is of interest to note that these esters undergo a photochemical rearrangement in the plastic to derivatives of hydroxy benzophenone. The hydroxy benzophenones may be added initially to effect stabilization.

Poly(methyl methacrylate) plastic has excellent resistance to ultraviolet radiation. Nevertheless, in long-term outdoor applications or in lighting fixtures, small amounts of ultraviolet absorbers are employed to retard the yellowing and degradation in physical properties which would otherwise occur.

The previous discussion illustrates how widely ultraviolet absorbers are used for stabilization of plastics against degradation by ultraviolet light. The second principal method for light stabilization is the use of energy transfer agents. Important stabilizers currently in use which function by this mechanism are nickel complexes of 2, 2′-thiobis(4-*tert*-octylphenol). For example, the butyl amine adduct of this complex is widely used. The nickel salts of mono alkyl esters of 3,5-di-*tert*-butyl-4-hydroxy-benzyl phosphonic acid are also useful stabilizers. When color is not a consideration, nickel dialkyl dithiocarbamates, and nickel acetophenone oximes may be used. Thus far, the nickel stabilizers have been used primarily in polypropylene and to some extent in polyethylene. They are especially useful in polypropylene fibers since stabilization by energy transfer is less dependent on sample thickness than is stabilization by ultraviolet absorption. Some of the nickel stabilizers have the further advantage that they act as dye acceptors and thus aid printing and dyeing of fibers and other items made from polyolefins.

Thus far, the discussion on ultraviolet stabilizers has been concerned only with their use for stabilization of plastics. While this is the principal use, the stabilizers which function by absorption are also widely used to prevent ultraviolet light from damaging furniture, clothing, and other articles. For example, a thin plastic film (6–10 mil) containing a high concentration of absorber is useful for covering a store window exposed to the sun. Such a film absorbs the ultraviolet radiation and thus prevents damage to the articles behind the film. The clarity and lack of color of the film permits customers to see the articles readily. Surface coatings containing ultraviolet absorbers are used in the same way to protect items such as flooring and furniture. Ultraviolet absorbing coatings may also be used to protect plastics, but generally, it is more practical to incorporate the absorber in the plastic itself. The incorporation of ultraviolet absorbers into plastic sunglasses is important for protecting the eye from ultraviolet radiation damage. Suntan lotions contain compounds such as monoglyceryl *p*-aminobenzoate that permit the longer wave lengths (330–400 nm) in the ultraviolet which cause tanning to pass through to the skin. At the same time, the more highly energetic short wave lengths (290–330 nm) which cause burning are strongly absorbed. When no tanning is desired, creams containing hydroxy benzophenones may be used, since these products remove a high percentage of the 290–400 nm radiation.

***ULYSSES* MISSION.** *Ulysses* is a joint United States National Aeronautics and Space Administration (NASA) and European Space Agency (ESA) mission to explore and accurately assess the total solar environment. The primary mission of the *Ulysses* spacecraft is to characterize the heliosphere as a function of solar latitude. The heliosphere is an immense magnetic area of interplanetary space occupied by the Sun's atmosphere and dominated by the outflow of the solar wind. Solar wind may be defined as the stream of charged particles that flows continuously away from the Sun in all directions at speeds of up to one million miles per hour (up to 600–800 kilometers per second).

The *Ulysses* spacecraft was launched on October 6, 1990 by the space shuttle *Discovery* with two upper stages. See Fig. 1. Dornier Systems of Germany built the spacecraft for ESA, which is responsible for the launch and on-orbit operations of the spacecraft. In addition to the spacecraft, ESA provided five of the nine instruments and was responsible for instrument integration. NASA provided the space shuttle *Discovery* as the launch vehicle, and the IUS and (PAM) upper stages along with four of the science instruments and the mission operations facilities. In addition, NASA provided the Radioisotope Thermoelectric Generator (RTG) power source, which was built for the U.S. Department of Energy by the General Electric Company. Jet Propulsion Laboratory (JPL) manages the U.S. portion of the mission for NASA's Office of Space Science. *Ulysses* is being tracked and data is being gathered by NASA's Deep Space Network, which is operated by JPL. See also **Antenna (Communications)**; and **Deep Space Network**. Investigation teams both in Europe and the USA provided scientific experiments. Spacecraft operations and data analysis are being performed at JPL by a joint ESA/JPL team.

Mission Objectives. The primary scientific objectives of the *Ulysses* mission are to investigate as a function of solar latitude:

1. the properties of the solar corona;
2. the solar wind;

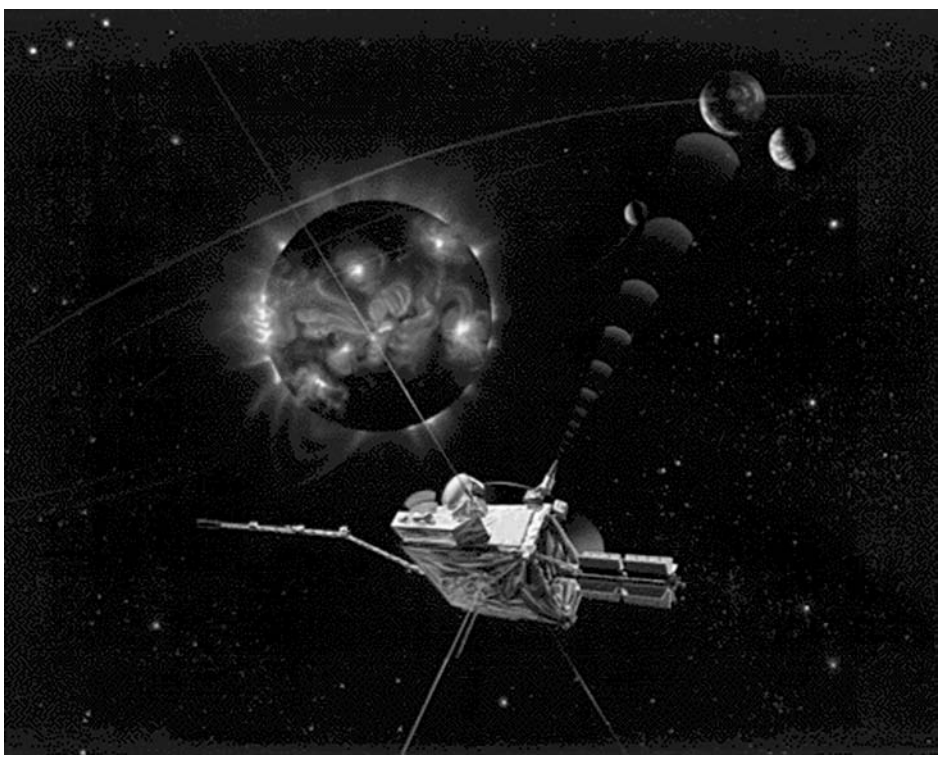

Fig. 1. The Sun as seen by a X-ray telescope, the *Ulysses* spacecraft, and the Earth–Moon system. (*NASA, JPL.*)

3. the structure of the Sun–wind interaction;
4. the heliospheric magnetic field;
5. solar and non-solar cosmic rays;
6. solar radio bursts and plasma waves;
7. solar x-rays; and
8. interstellar/interplanetary neutral gas and dust.

The *Ulysses* Mission is the first spacecraft to explore interplanetary space at high solar latitudes. It will enable measurements to be made far out of the ecliptic plane over the solar poles. Specifically, the space physics goals are to:

1. Gain knowledge of the interplanetary medium at high solar latitudes due to the solar chromospheric and photospheric conditions, sunspots, solar flares, prominences, and coronal holes.
2. Characterize various particles from the ecliptic to the Sun's poles, including solar wind, galactic cosmic rays, interplanetary dust, and solar energetic particles.
3. Analyze the heliospheric medium from the ecliptic to the poles, including plasma waves, solar radio waves, and heliospheric magnetic fields.

To reach high solar latitudes, the spacecraft was aimed close to Jupiter so that Jupiter's huge gravitational field would accelerate *Ulysses* out of the ecliptic plane to high latitudes; a feat no man-made launch vehicle alone could accomplish. Such a tremendous amount of energy is required that even with the powerful launch vehicles available today, direct launch to high latitudes from the Earth cannot be achieved. This is because the Earth itself orbits the Sun at a speed of 65,000 miles per hour (30 kilometers per second) in a plane perpendicular to the desired solar polar orbit. The energy imparted to a space probe must cancel out this motion in addition to providing the correct polar trajectory.

Encounter with Jupiter occurred on February 8, 1992 (See also **Jupiter**), where a gravity-assist maneuver placed the spacecraft in a unique solar polar orbit, allowing it to fly over the south pole of the Sun in 1994 and over the north pole in 1995. Since then *Ulysses* traveled to higher latitudes. See Fig. 2. The periods of primary scientific interest are when *Ulysses* is at or higher than 70 degrees latitude at both the Sun's south and north poles. On June 26, 1994, *Ulysses* reached 70 degrees south. There it began a four-month observation from high latitudes of the complex forces at work in the Sun's outer atmosphere, the corona. Maximum southern latitude of 80.2 degrees was achieved on September 13, 1994. *Ulysses* traveled through high northern latitudes during June through September of 1995. The high latitude observations were obtained during the quiet (minimum) portion of the 11-year solar cycle. The spacecraft's orbital period is six years and, if kept in operation, high latitude observations will be obtained during the active (maximum) portion of the solar cycle. Prior to the *Ulysses* mission, studies of the Sun were made from Earth using Earth-based sensors. More recently, solar studies have been conducted from space stations; however, these investigations have been mostly from the ecliptic plane (the plane in which most of the planets travel around the Sun). No previous spacecraft have been able to reach solar latitudes higher than 32 degrees. Now that *Ulysses* high latitude data is available, scientists are obtaining a new understanding of the processes occurring at high solar latitudes.

Scientists have long been aware of differences between the Polar Regions of the Sun and lower latitudes. For example, sunspots are only seen at lower latitudes, and photographs of the solar corona taken during solar eclipses often show dark regions over the poles.

Solar Corona. The solar corona consists of hot gasses at such high temperatures that the gravitational field of the Sun can not prevent escape of coronal gas as the solar wind. However, the Sun has a global magnetic field. Many of the solar magnetic field lines that leave the solar surface return to the surface, but some of the field lines, particularly those over the poles, extend deep into interplanetary space. The solar wind expands into interplanetary space along these field lines, and the regions of the *corona* from which the hot gas escapes are dark because of the low gas density. These regions are known as coronal holes. See Fig. 3.

The properties of the Sun's polar magnetic field are poorly understood, although the magnetic field has an important influence on the escape of

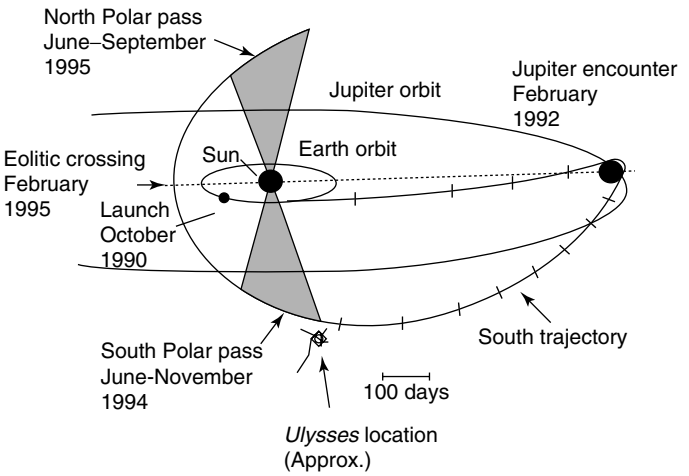

Fig. 2. Trajectory of the *Ulysses* spacecraft. (*NASA, JPL.*)

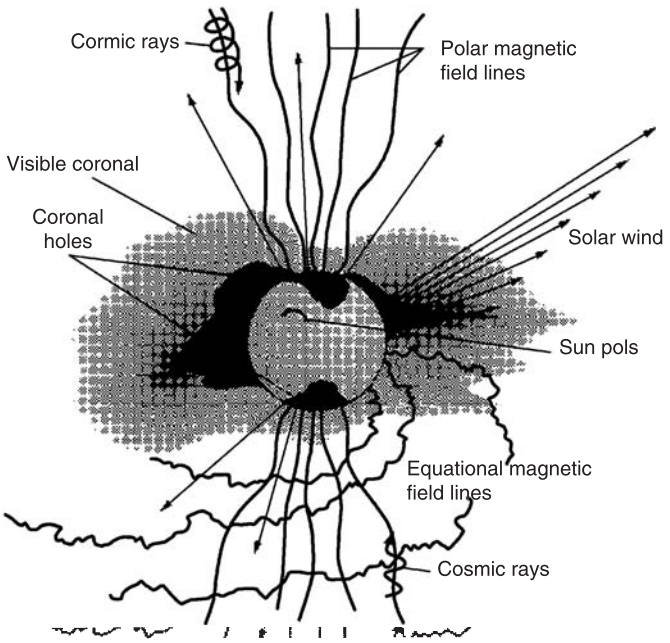

Fig. 3. A composite of the Solar phenomena being investigated by the *Ulysses* mission. Previous Earth-based observations and theory indicated that there would be quite significant differences between the low latitude regions and the poles. (*NASA, JPL.*)

the solar wind. In addition, the complex processes that serve to both heat and accelerate the solar wind are not well understood. *Ulysses* observations over the poles should provide important new information on how the solar wind expands from the Sun, which will aid scientists in understanding these processes. The magnetic field also has a tremendous influence on matter approaching the Sun from the Milky Way galaxy and from the nearby interstellar medium. Incoming cosmic rays are subjected to forces exerted by the magnetic field. Scientists believe that the structure of the Sun's magnetic field is such that entry of cosmic rays occurs by way of the Sun's Polar Regions. Scientists hope that *Ulysses* findings can provide new information as to the extent to which the galactic cosmic rays use this route, and on the ways in which their properties are modified as a result. Scientists also hope to gain more knowledge of the intensity and properties of the cosmic rays far from the Sun.

With the first phase of its mission successfully completed, *Ulysses* has now embarked on a second orbit of the Sun; it will for the first time investigate the high latitude properties of the solar wind during the maximum of the solar activity cycle. The spacecraft and its scientific payload are

in excellent condition. The ultimate goal of this next phase of the mission is the study of the Sun's polar regions under conditions of high solar activity, culminating in polar passes in 2000 and 2001 (South Polar pass: September 2000 to January 2001; North Polar pass: September to December 2001). Much before this, however, with *Ulysses* descending slowly in latitude after the northern polar pass, there is a unique opportunity to make coordinated observations with ESA's SOHO spacecraft, which carries an extensive complement of experiments dedicated to studying the Sun's corona and the solar wind. The period around aphelion (1997–98) was also of great interest. During this interval *Ulysses* spent many months close to the ecliptic at almost constant radial distance (~5 AU) from the Sun, enabling the scientists to study the evolution and development of many interplanetary phenomena, free of concern about spatial variations. The out-of-ecliptic orbit of *Ulysses* is expected to cover a period of 6.2 years, corresponding to approximately half a solar cycle.

As noted above, the high-latitude passes of the second solar orbit will occur close to the maximum of solar cycle 23. The conditions in the Polar Regions are expected to be dramatically different from those encountered during the prime mission. In particular, the rather simple configuration of the corona found at solar minimum, with large coronal holes over the polar caps, will have been replaced by a much more complex arrangement, probably including high-latitude streamers. Transient events (solar flares, coronal mass ejections, etc.) related to the increase in solar activity will dominate, greatly disturbing the underlying structure of the solar wind and influencing the transport of cosmic rays and energetic solar particles. *Ulysses* is clearly in a unique position to study the evolution of the three-dimensional heliosphere from the current solar minimum to maximum activity conditions. No other space mission in the foreseeable future will address these goals.

Ulysses Mission fast facts are given in Table 1.

TABLE 1. ULYSSES MISSION FAST FACTS

Launch date	October 6, 1990
Payload	11 instruments
Orbit	Heliocentric, 5 by 1.3 astronomical units
Design life	5 years (prime mission)
Length	7.3 feet (2.2 meters)
Weight	805 pounds (366 kilograms)
Diameter	13.5 feet (4.1 meters), including booms
Launch vehicle	Space Shuttle/inertial upper stage/payload assist module
International participation	United Kingdom, Germany, Italy, Switzerland, United States

A complete descriptions of the following *Ulysses* Scientific Instruments can be found at http://ulysses.jpl.nasa.gov/ULSHOME/ESAULS/instruments. html. See Fig. 4.

- Magnetometer (VHM/FGM)
- Solar Wind Plasma Experiment (SWOOPS)
- Solar Wind Ion Composition Instrument (SWICS)
- Unified Radio and Plasma Wave Instrument (URAP)
- Energetic Particle Instrument (EPAC)
- Low-Energy Ion and Electron Experiment (HISCALE)
- Cosmic Ray and Solar Particle Instrument (COSPIN)
- Solar X-ray and Cosmic Gamma-Ray Burst Instrument (GRB)
- Dust Experiment (DUST)
- Coronal-Sounding Experiment (SCE)
- Gravitational Wave Experiment (GWE)

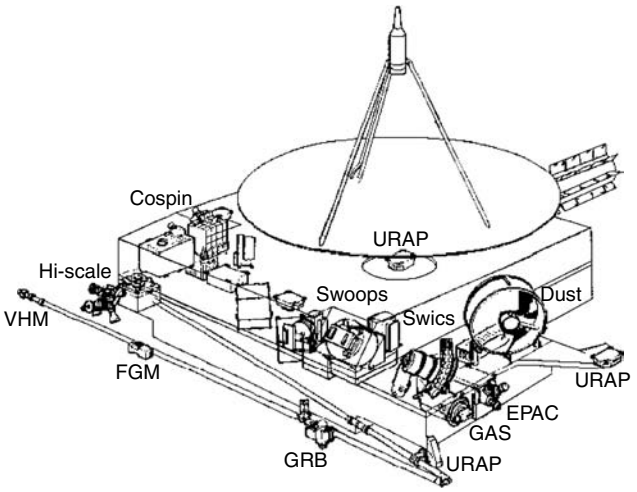

Fig. 4. *Ulysses* Scientific Instruments (*NASA, JPL*).

UMBELLIFERAE (Carrot Family). The plants of this family, mostly found in the north Temperate Zone, are nearly all annual or biennial herbs, with a few trees or shrubs. They are characterized by having stems hollow except at the nodes, alternate leaves that are either pinnately or ternately compound, and large numbers of small flowers produced in simple or compound umbels. The distinctive umbel is an influorescence in which the pedicels of the individual flowers arise from a very short axis and are of nearly equal length, producing a flat-topped or rounded cluster.

The single flowers are small and regular, the calyx being either absent or fused to the ovary, and five-toothed, the corolla composed of five separate petals, the stamens five and the single pistil with inferior ovary, with two one-seeded carpels. The flowers are insect-pollinated. The fruit is a form known as a schizocarp, a dry fruit having two carpels which separate at

maturity into two mericarps, each of which usually has five longitudinal ridges. Between the ridges are found longitudinal oil canals containing the volatile oils which give the odors characteristic of many members of this family.

Many members of this family are important food plants to people and domestic animals. Among these are plants grown for their roots, the carrot, *Daucus carota*, and parsnip, *Pastinaca sativa*, both natives of Europe; also celery, *Apium graveolens*, grown for its leaf stalk, and parsley, *Petroselinum crispum*, grown for the much dissected leaves which are used as a garnish and for flavoring. A large number of plants in this family are frequently cultivated, especially in Europe, for flavorings and medicinal use, though possibly their therapeutic value is rather overrated. Among these are anise (*Pimpinella anisum*), caraway (*Carum carvi*), coriander (*Coriandrum sativum*), fennel (*Foeniculum officinale*), and dill (*Anethum graveolens*). Many of these are also used for flavoring foods. *Ferula asafoetida* produces a drug, asafoetida.

In contrast to these, which are useful to humans, are many members of the family which contain violent poisons. *Conium maculatum*, the Poison Hemlock, is reputed to have been the source of the poison which Socrates drank. *Cicuta maculata* and related species are sometimes eaten by livestock with fatal results.

UMBILICAL CORD. Any of the servicing electrical or fluid lines between the ground or a tower and an uprighted rocket vehicle before the launch. Often shortened to umbilical.

UMBILICAL TOWER. A vertical structure supporting the umbilical cords running into a rocket in launching position.

UMBILICUS. The scar on the ventral surface of the abdomen where the umbilical cord is severed at birth in the placental mammals. The navel.

UMBRA. 1. The darkest part of a shadow in which light is completely cut off by an intervening object. A lighter part surrounding the umbra, in which the light is only partly cut off, is called the *penumbra*.

2. The darker central portion of a sun spot, surrounded by the lighter penumbra. See also **Eclipse**.

UMKEHR EFFECT. Due to the presence of the ozone layer, an anomaly of the relative zenith intensity of scattered sunlight at certain wavelengths in the ultraviolet as the sun approaches the horizon.

UNAVAILABLE ENERGY. When an irreversible process takes place, the effect on the universe is the same as that which would be produced if a certain quantity of energy in a form completely available for work were converted to a form in which it was completely unavailable for work. This amount of energy is called the unavailable energy.

UNCERTAINTY PRINCIPLE. It is sometimes referred to as the *Heisenberg indeterminancy principle* (a name preferred by Niels Bohr). The uncertainty principle is one of the cornerstones of quantum mechanics and was discovered by Werner Heisenberg in 1927, in connection with the position and momentum of an electron. In essence, the postulate states that it is impossible to determine simultaneously both the exact position and the exact momentum of an electron and thus these values must be expressed as a probability. If, for example, one determines the precise location of an electron, all information about the electron's velocity is lost. On the other hand, knowledge of the electron's velocity can be obtained only at the expense of knowledge of its location.

The concept of probability distributions pervades the science of measurement. No treatment of any scientific subject, experiment, or measurement is said to be accurate without disclosing the nature of the probability distribution (sometimes called the error) of the measurement. Uncertainty is the characterization of the relative narrowness or broadness of the distribution function applied to a physical observation.

Illustrative of this is an experiment in which a particle is prepared in a definite state and two successive measurements are performed on the particle. The first one measures the particle's position and the second immediately after measures its momentum. Each time the experiment is performed, some value x is obtained for position and some value p is obtained for momentum. Depending upon the precision of the instrument taking the measurements, each successive measurement of the positions and momenta respectively should be nearly identical, but in practice they will exhibit some deviation due to constraints of measurement using a real world instrument that is not infinitely precise. However, Heisenberg showed that, even in theory with a hypothetical infinitely precise instrument, no measurement could be made to arbitrary accuracy of both the position and the momentum of a physical object.

The Heisenberg uncertainty principle provides a quantitative relationship between the uncertainties of the hypothetical infinitely precise measurements of p and x as measured by the sizes of their distributions in the following way: If the particle state is such that the first measurement yields a dispersion of values Δx, then the second measurement will have a distribution of values whose dispersion Δp is at least inversely proportional to Δx. For the limiting case, the constant of proportionality is derivable using commutator arithmetic. It is equal to Planck's constant divided by 4π.

This stipulates that the product of the uncertainties in position and velocity is equal to or greater than about 10^{-35} joule-seconds. Therefore, the product of the uncertainties only becomes significant for regimes where the uncertainty in position or momentum measurements is small. Thus, the uncertainty principle governs the observable nature of atoms and subatomic particles while its effect on measurements in the macroscopic world is negligible and can be usually ignored.

The Heisenberg uncertainty relations are a theoretical bound over all measurements. They hold for so-called ideal measurements, sometimes called von Neumann measurements. They hold even more so for non-ideal or Landau measurements.

Classical Newtonian mechanics assumes that a physical system can be kept under continuous observation without thereby disturbing it. This is reasonable when the system is a planet or even a spinning top, but is unacceptable for microscopic systems, such as an atom. To observe the motion of an electron, it is necessary to illuminate it with light of ultrashort wavelength (gamma rays); momentum is transferred from the radiation to the electron and the particle's velocity is, therefore, continuously disturbed. The effect upon a system of observing it can not be determined exactly, and this means that the state of a system at any time cannot be known with complete precision. As a consequence, predictions regarding the behavior of microscopic systems have to be made on a probability basis and complete certainty can rarely be achieved. This limitation is accepted and is made one of the foundation stones upon which the theory of quantum mechanics is constructed.

This principle can be extended to other phenomena of a like nature, that is, in the simultaneous determination of the values of two canonically conjugated variables, the product of the smallest possible uncertainties in their values is of the order of magnitude of the Planck constant h. If Δq is the range of values that might be found for the coordinate q of a particle, and Δp is the range in the simultaneous determination of the corresponding component of its momentum p, then $\Delta p \cdot \Delta q \geq h$. Similarly, if ΔE and Δt are the uncertainties in the simultaneous determination of the energy and the time, $\Delta E \cdot \Delta t \geq h$. In the same way, the principle applies to any other pair of canonically conjugated variables. See also **Quantum Mechanics**.

UNCONFORMITY (Geological). If deposition in a given area is interrupted for a time by erosional processes, then renewed, a dissected surface will separate the two groups of beds, which are then said to be unconformable, and the erosion surface marking their contact is called an unconformity. If this unconformable relationship of two rock groups is of limited extent, the unconformity is then said to be local; if of wide extent it is called a regional unconformity. If two groups of sedimentary rocks are separated by an unconformity on tilted beds, it is then called a nonconformity or angular unconformity. When the plane of erosion occurs between relatively horizontal formations it is called a disconformity. Principal types of unconformities are illustrated in Fig. 1. *A* represents a nonconformity having an irregular erosion surface, developed on the upturned edges of different formations, and covered with a basal conglomerate which grades through sandstone and shale into limestone. In *B* the nonconformable series has also been deformed together with the second wave of deformation which affected the already deformed beds beneath the unconformity. *C* represents a major nonconformity in which the erosion surface truncates highly metamorphosed formations and batholithic intrusives. The basal conglomerate rests upon a plane of erosion which, in itself, must represent a great physical hiatus or lack of stratigraphic record for this region. *D* and *E* represent disconformities that have been developed upon a prelithified surface. In *E* the disconformable formations have been subsequently deformed (tilted). *F* represents a graduational contact, or one in which erosion and depositions have been relatively continuous. *G* represents a graduational contact developed in plastic sediments, with the development of mud cracks and intraformational conglomerates. *H* represents a disconformity in which the basal breccia is composed of the lithified fragments of the older formations, plus foreign clastic material. As the fossils above and below the disconformity are the same, the disconformity, though pronounced, signifies slight, if any, hiatus (diastem). Disconformities of types *F*, *G*, and *H* may represent either slight or great hiatus. Note: The true amount of hiatus can only be measured by paleontological means. With the exception of a major nonconformity, the physical evidence of hiatus (unconformity) is seldom a safe criterion alone. Thus the terms nonconformity and disconformity have structural but not necessarily stratigraphic, or time, significance.

UNDERWING *(Insecta, Lepidoptera).* A moth whose fore wings are colored in dull shades of gray or brown, but whose hind wings are in most species brightly banded with black and some shade of yellow, orange or red. The name is used for the large moths of the family *Noctuidae* and the genus *Catocala*, although members of other genera are colored in a similar way. The genus *Catocala* is so extensive, with more than 100 species in North America alone, that it has attracted the attention of specialists and has been studied in detail. For the same reason the moths are very likely to be seen without special search. They hide about buildings in the daytime, as well as on the trunks of trees.

UNIMODULAR GROUP. See **Lie Group**.

UNIT. A unit is a physical quantity that serves as a reference quantity in terms of which other quantities of the same kind can be expressed. The aim of a measurement of a physical quantity is to obtain an expression of that quantity as a numerical multiple or submultiple of the unit.

The choice of a unit is in principle quite arbitrary. The mass of a given body may be expressed in terms of the rest mass of the electron or the mass of the moon. But to achieve uniformity in measurement and direct comparability of results of measurement, the same convenient unit should be used for all measurements of quantities of the same kind. In practice, a unit is therefore a physical quantity that is defined and adopted by convention. An ideal unit is a physical quantity that not varies with time and is independent of position. Fundamental constants satisfy these requirements.

The expression of a physical quantity was clearly described by James Clerk Maxwell 1873 in his "Treatise on Electricity and Magnetism":

Every expression of a quantity consists of two factors or components. One of these is the name of a certain known quantity of the same kind as the quantity to be expressed, which is taken as a standard of reference. The other component is the number of times the standard is taken in order to make up the required quantity. The standard quantity is technically the Unit and the number is called the Numerical Value of the quantity.

This may be expressed by the following notation:

$$\text{physical quantity} = \text{numerical value} \times \text{unit}$$

or

$$Q = \{Q\} \times [Q],$$

where the symbol $[Q]$ is the stand-in for the unit in terms of which the quantity Q will be represented and $\{Q\}$ is the stand-in for the corresponding numerical value of Q. As soon as a specific unit is chosen, its agreed symbol replaces $[Q]$. For example, if I is a given electric current, then $[I]$ will be replaced by the symbol A if the SI unit ampere for the electric current is chosen. The numerical value $\{Q\}$ corresponding to the unit $[Q]$ may be written as $\{Q\} = Q/[Q]$. ((SI: abbreviation for "International System of Units").

It is evident that the same quantity can always be expressed in more than one way by choosing different appropriate units. In this sense, a physical quantity is said to be invariant with respect to a change in units.

As an example, the same electric current I may be expressed in terms of the SI unit A or in terms of a unit of current A_L maintained in the laboratory. Thus, in obvious notation,

$$I = \{I\}_{\mathrm{SI}} A = \{I\}_L A_L .$$

If $\mathrm{A}_\mathrm{L} = k\mathrm{A}$, then the relation $\{I\}_{\mathrm{SI}} = k\{I\}_\mathrm{L}$ follows for the numerical values. In general, if a quantity is expressed in another unit that is k times

the first unit, the new numerical value becomes $1/k$ times the first numerical value.

The result of measurement is an expression of the measured quantity in terms of an appropriate unit, usually a SI unit. But this expression in most cases must be viewed as an estimate for the unknown accurate expression in that unit. Thus, the result of measurement must be completed by the statement of the uncertainty (of measurement) that is due to the incomplete information about the accurate expression of the quantity. The uncertainty usually is expressed in the same unit in terms of which the quantity is expressed but may also be stated using appropriate multiples or submultiples of that unit.

In the course of time, a host of units had been independently introduced in various societies for reasons of expediency. The slowly extending trade relations then forced a reduction. Either a uniform measure was agreed on or fixed rates of conversion for the units were introduced.

In science, developing rapidly in the 19th century, it was realized that a unit preferably should consist not of an artifact created by man, but of a physical quantity occurring in a specified physical phenomenon that could be reproduced at any time and position with the greatest accuracy possible. Suitable unit-defining phenomena are not, however, easy to find. So an early suggestion that the oscillation period of a pendulum 1 m in length should be introduced as the unit of time did not sufficiently comply with the requirement that a unit should be position independent.

Metrology today aims at discovering and using such defining physical phenomena and effects for which the units can be traced back to time- and space-independent fundamental constants of physics taking into account the principle of the continuity of the units. See also **Metrology**. Within the system of SI units, this was possible for the units of length, time, electric voltage, and electric resistance. The effect of tunneling of individual electrons in suitable nanostructures might lead to a redefinition of the unit of electric current that is based on the elementary charge. The unit of mass is given until now by an artifact. In spite of all efforts at replacing this untimely unit, it has hitherto not been possible to realize a satisfactory alternative.

If a unit is not defined as an artifact but as a quantity of a defining phenomenon, it must be represented by the accurate realization of the specified phenomenon. To realize the SI unit second, for example, an exactly specified transition must be generated in the cesium-133 atom. Only the properties of the radiation pertaining to this transition are to be used to define the SI unit of time, the second. As it is not exactly known to what extent the experimental realization of the specified phenomenon deviates from this phenomenon, it is not exactly known either to what extent the actual unit agrees with the defined one. In the measurement of a quantity, the uncertainty obtained can never be smaller than the corresponding uncertainty of the unit when the measurand (*a physical parameter being quantified by measurement*) is to be expressed by the defined unit. This lower limit for the uncertainty of measurement of a measurand is really reached in the very accurate experimental determinations of some fundamental constants.

The capability to realize the units with an ever smaller uncertainty, which has been acquired on the basis of thorough research work, has had a most stimulating effect on the whole area of metrology. But this has not changed the hierarchic structure of metrology: Within the scope of the dissemination of the units, the less precise measuring instrument is calibrated ("linked up") against the more accurate measuring instrument.

At the top of the hierarchy are the international measurement standards, which are covered by international comparison measurements. The national standards are generally available in a national metrology institute. For industry and trade the working standards are derived over several intermediate stages, the uncertainty of realization increasing from stage to stage. The complete traceability (with documentation) of the comparison measurements of a measuring instrument over all intermediate stages to the national or international standards has become today an important notion of quality. It has also become significant for metrology as an important component of quality assurance within the meaning of ISO 9000 (quality management and quality assurance standards, guidelines for selection and rules).

In the 19th century, it was also found that for a special area, such as mechanics, units can be chosen such that they form a system of units. In a system of units all derived units are power products formed from a set of suitably selected base units.

Thus, for example, the following systems of units were used:

- cgs system with the base units centimeter, gram, and second;
- mks system with the base units meter, kilogram, and second;
- ft-lb-s system with the base units foot, pound, and second.

If the derived units are exclusively derived from the base units by means of power products using the numerical factor 1, a so-called coherent system of units will be obtained. The three systems of units referred to above are coherent. Noncoherent systems of units are, for example, the "centimeter-pond-second system" (cm-p-s) and the "meter-kilopond-second system" (m-kp-s) as the derivation of some derived units contains the factor 9.81. The use of a coherent system of units offers the advantage that the unit equations corresponding to the quantity equations have the same form.

With the foundation of the bodies of the Meter Convention in 1875, http://www.bipm.fr/en/convention/, the metric system with the units meter, kilogram, and second acquired particular importance. See also **Convention du Métre**. Its decimal structure in the formation of multiples and submultiples of units is an important advantage over other systems. This so-called Metric System, which was first introduced only to represent mechanics, was extended by an additional unit for every additional area: for the realization of electrodynamics, with the unit ampere; for the realization of thermodynamics, with the unit kelvin; for the realization of photometry, with the unit candela; for the realization of chemistry, with the unit mole. So the International System of Units (SI) was formed, http://www.bipm.fr/en/si/. This is a system of units that was developed pragmatically and that is not based on a higher knowledge of nature than the systems used up to then. Together with the SI, a few units outside the SI are also used. Add to this old units that are occasionally used independently of the SI. In most countries, the SI underlies current laws. See also **Units and Standards**.

UNITS AND STANDARDS. Before weights and measures could be constructed, it was necessary for the Treasury Department to decide upon certain units and to adopt standards, that is, the material representatives of these units.

A clear understanding of the difference between "units" and "standards" is discussed below.

A *unit* is a determinate quantity (that is, one established by definition) in terms of which values, quantities, amounts, or magnitudes are expressed.

Being fixed by definition, a unit is itself independent of physical conditions — as, for example, temperature — even though it may be defined in relation to some object that is affected by such conditions. Thus a particular unit of capacity may be defined as a volume of a specified number of cubic inches; the U. S. gallon is so defined — as a unit of 231 cubic inches. Or a again, a particular unit of length may be defined as a distance corresponding to the interval between certain engraved lines on a certain metal bar when measured under specified conditions, including those of the support and temperature of the bar; until October 1960 the meter unit was so defined in relation to the international meter bar. See also **Unit**.

A *standard* is the physical embodiment of a unit. In general a standard is not independent of physical conditions and is a true embodiment of the unit only under specified conditions. Thus a 1-gallon metal standard will have a capacity of 1 gallon only when the standard is at a certain temperature; at any other temperature the capacity of the standard will have been increased or decreased as a result of the expansion or contraction of the metal caused by the temperature change. Or again, a length standard having a nominal value of one yard will have an actual value of one yard only when at one particular temperature and when supported in a certain manner, a lowering of its temperature will cause the standard to shorten, a raising of its temperature will cause it to lengthen, and a change of the manner in which it is supported may introduce a change in its length.

When a unit is defined in terms of a standard, the latter acquires a fundamental character; the International Prototype Meter was such a standard until the meter unit was redefined in 1960. Standards are classified into groups, according to their character, the order of their accuracy, and the order of their legal or other importance. Thus there are, for example, international and national "prototypes," State "reference" standards, "laboratory working" standards, "field standards, and various "classes" of standards established largely on the basis of design and accuracy.

The early U.S. standards were finally adopted by the Treasury Department in 1832. The next and perhaps the most important legislation enacted by Congress was the act of 1866 legalizing the metric system of weights and measures in the United States. The act was passed July 28, 1866.

See also http://ts.nist.gov/WeightsAndMeasures/Metric/upload/SP_447.pdf.

In 1960 the General Conference on Weights and Measures, to which the United States adheres by treaty, has established the International System of Units, called SI units. The SI units are used to derive units of measurement for all physical quantities and phenomena. There are only seven basic SI "base units". The base quantities of this system and the corresponding units and symbols are illustrated in Table 1 and Fig. 1.

TABLE 1. SI BASE UNITS

Base quantity	Name SI base unit	Symbol
length	meter	m
mass	kilogram	kg
time	second	s
electric current	ampere	A
thermodynamic temperature	kelvin	K
amount of substance	mole	mol
luminous intensity	candela	cd

The units radian (rad) for plane angle and steradian (sr) for solid angle are described as supplementary units and are normally treated as though they were base units, although the corresponding quantities may be treated as dimensionless. The coherent SI unit system consists of the foregoing, plus all of the units derived from them by multiplication and division without introducing numerical factors.

A number of derived units have been given special names and symbols. See Table 2.

UNITS, NOT PART OF COHERENT SYSTEM, BUT GENERALLY ACCEPTED FOR USES WITH SI UNITS

Quantity	Name of Unit	Unit Symbol	Value in SI Units
time	minute	min	1 min = 60 s
	hour	h	1 h = 60 min = 3600 s
	day	d	1 d = 24 h = 86400 s
Plane angle	degree	$^\circ$	$1^\circ = (\pi/180)$rad
	minute	$'$	$1' = (1/60)^\circ = (\pi/10800)$rad
	second	$''$	$1'' = (1/60)' = (\pi/648000)$rad
volume	liter/litre	L	1 L = 1dm^3 = 10^{-3} m3
mass	metric ton[1]	T	1t = 10^3 kg
energy	electron volt[2]	eV	1 eV = 1.60219 × 10^{-19} J, approx.
mass of an atom	Unified atomic mass unit[3]	u	1 u = 1.66054 × 10^{-27} kg, approx.
length	astronomical unit (AU, au, a. u. or sometimes ua)[4]	AU	1 AU=1495 98×10^{11} m, approx.
sound	neper[5]	Np	1 Np − 1
	bel[6]	B	1 B=(1/2) ln 10 Np

[1]In many countries, this unit is called "tonne."
[2]The electronvolt is the kinetic energy acquired by an electron passing through a potential difference of 1 V in vacuum. The value must be obtained by experiment, and is therefore not known exactly.
[3]The unified atomic mass unit is equal to 1/12 of the mass of an unbound atom of the nuclide ^{12}C, at rest and in its ground state. The value must be obtained by experiment, and is therefore not known exactly.
[4]The astronomical unit is a unit of length. Its value is such that, when used to describe the motion of bodies in the solar system, the heliocentric gravitation constant is $(0.017\ 202\ 098\ 95)^2$ ua^3 · d^{-2}. The value must be obtained by experiment, and is therefore not known exactly.
[5]Although the neper is coherent with SI units and is accepted by the CIPM, it has not been adopted by the General Conference on Weights and Measures (CGPM, *Conférence Générale des Poids et Mesures*) and is thus not an SI unit.
[6]The bel is most commonly used with the SI prefix deci: 1 dB=0.1 B.

TABLE 2. UNITS DERIVED FROM BASE SI QUANTITIES

Quantity	Name of SI Derived Unit	Symbol	Expressed in Terms of SI Base or Derived Units
frequency	hertz	Hz	1 Hz = 1s^{-1}
force	newton	N	1 N=1 kg · m/s^2
pressure and stress	pascal	Pa	1Pa=1 N/m^2
work, energy, quantity of heat	joule	J	1 J=1 N· m
power	watt	W	1 W=1 J/s
quantity of electricity	coulomb	C	1 C=1A· s
electromotive force, potential difference	volt	V	1V=1 W/A
electric capacitance	farad	F	1F=1A·s/V
electric resistance	ohm	Ω	1 Ω =1V/A
electric conductance	siemens	S	1 S=1 Ω^{-1}
flux of magnetic induction, magnetic flux	weber	Wb	1Wb=1V·s
magnetic flux density, magnetic induction	telsa	T	1 T=1Wb/m^2
inductance	henry	H	1H=1V·s/A
luminous flux	lumen	Im	1lm=1cd·sr
illuminance	lux	Ix	1lx=1lm/m^2

The liter in Table 2 deserves comment. This unit and its symbol l were adopted by the CIPM in 1879. The alternative symbol for the liter, L, was adopted by the CGPM in 1979 in order to avoid the risk of confusion between the letter l and the number 1. Thus, although *both* l and L are internationally accepted symbols for the liter, to avoid this risk the

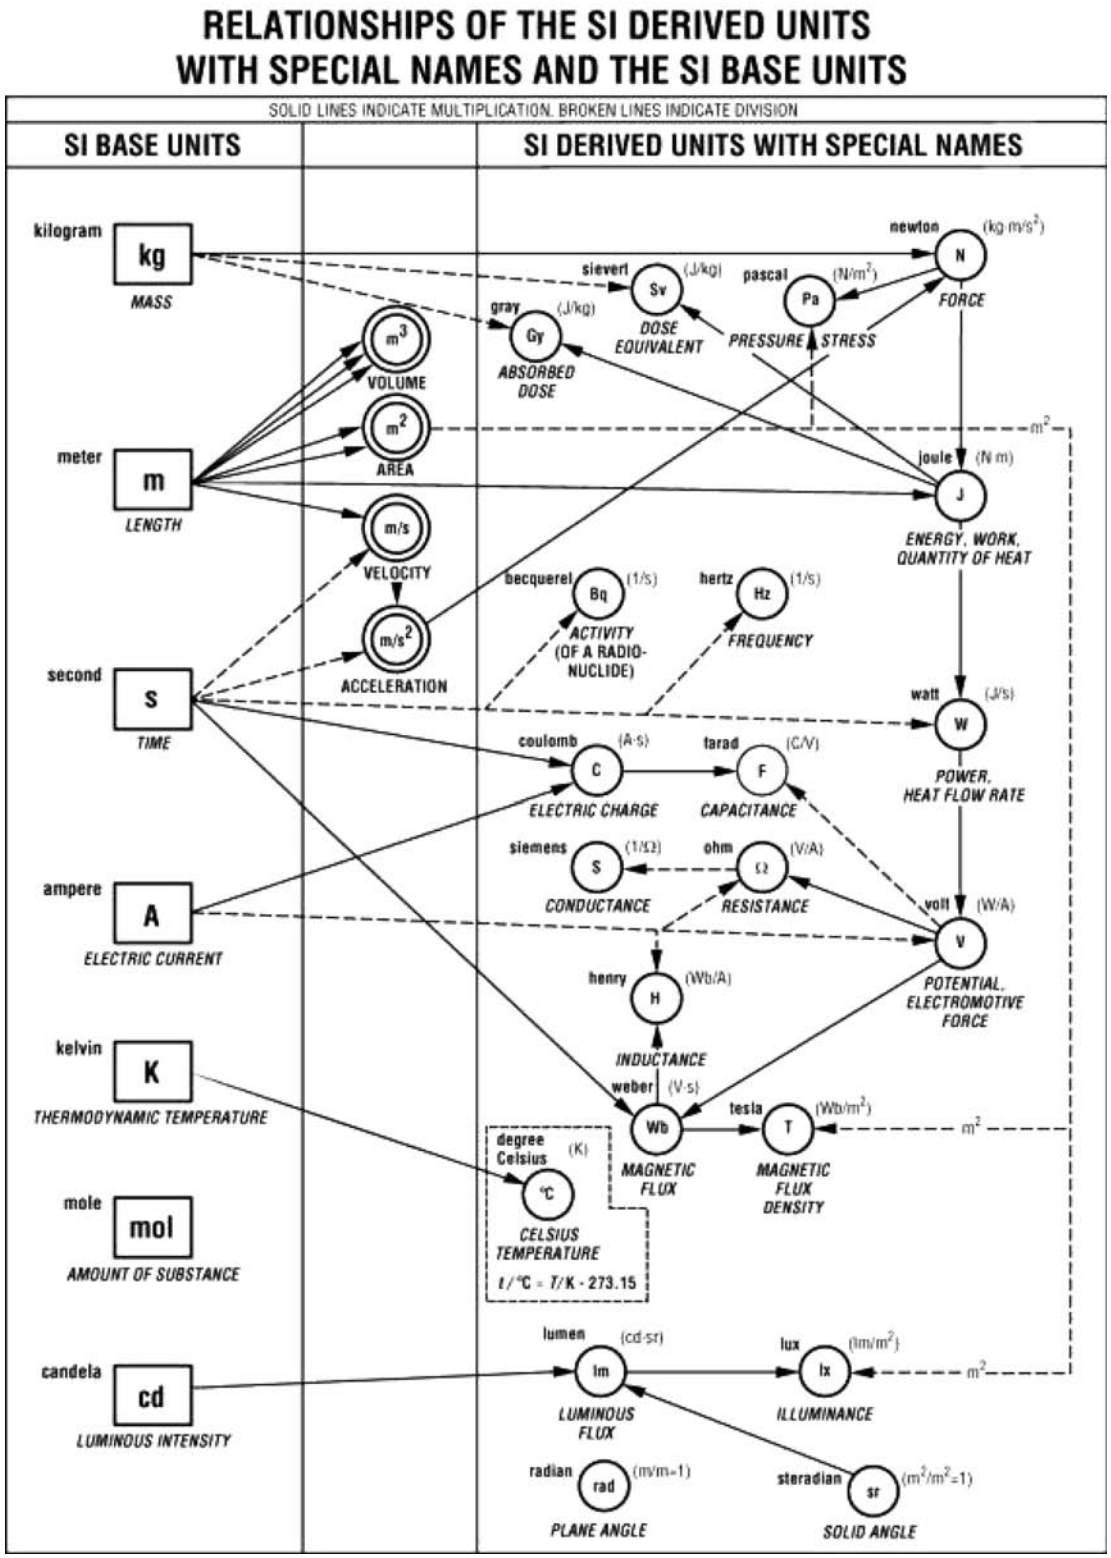

Fig. 1. The diagram above shows graphically how the 22 SI derived units with special names and symbols are related to the seven SI base units.

preferred symbol for use in the United States is L. Neither a lowercase script letter l nor an uppercase script letter L are approved symbols for the liter.

Decimal multiples of the coherent base and derived SI units are formed by attaching to these units the prefixes shown in Table 3.

The following units were accepted by the International Committee of Weights and Measures for use with the SI units for a transitional period: angstrom (1 Å $= 10^{-10}$ m), barn (1b$=10^{-28}$ m^2), bar (1bar$=10^5$ Pa), standard atmosphere (1 atm$=$101 325 Pa), curie (1Ci$=3.7\times10^{10}$s^{-1}), roentgen (1 R$=2.58\times10^{-4}$ C/kg), rad (1rad$=10^2$ J/kg).

Scientists have adopted the metric system to simplify their calculations and promote communication across national boundaries. However, there have been two ideas as to which metric units should be preferred in science. Scientists working in laboratories, dealing with small quantities and distances, preferred to measure distance in centimeters and mass in grams. Scientists and engineers working in larger contexts preferred larger units: meters for distance and kilograms for mass. Everyone agreed that units of other quantities such as force, pressure, work, power, and so on should be related in a simple way to the basic units, but which basic units should be used?

TABLE 3. STANDARD PREFIXES USED WITH SI UNITS

Factor by Which the Unit is Multiplied	Prefix Name	Symbol	Times 1, Is Equal To:
10^{24}	yotta	Y	1 000 000 000 000 000 000 000 000
10^{21}	zetta	Z	1 000 000 000 000 000 000 000
10^{18}	exa	E	1 000 000 000 000 000 000
10^{15}	peta	P	1 000 000 000 000 000
10^{12}	tera	T	1 000 000 000 000
10^{9}	giga	G	1 000 000 000
10^{6}	mega	M	1 000 000
10^{3}	kilo	k	1 000
10^{2}	hecto	h	100
10^{1}	deka	da	10
0	—	—	1 (unity)
10^{-1}	deci	d	.1
10^{-2}	centi	c	.01
10^{-3}	milli	m	.001
10^{-6}	micro	u	.000 001
10^{-9}	nano	n	.000 000 001
10^{-12}	pico	p	.000 000 000 001
10^{-15}	femto	f	.000 000 000 000 001
10^{-18}	atto	a	.000 000 000 000 000 001
10^{-21}	zepto	z	.000 000 000 000 000 000 001
10^{-24}	yocto	y	.000 000 000 000 000 000 000 001

The result was two clusterings of metric units in science and engineering. One cluster, based on the centimeter, the gram, and the second, is called the *CGS system*. The other, based on the meter, kilogram, and second, is called the *MKS system*.

In daily life, the customary units in the United States are those based on the foot, pound-force, and second, but these units are rarely used in physics except for the description of equipment (e.g., "a 2-inch pipe"). Considerable effort has been going forth in the United States and a number of other countries that are not accustomed to using the metric system to ultimately adopt it.

Over one hundred of the most frequently used units are defined in Table 4. Common equivalents and conversions are given in Table 5.

TABLE 4. PRINCIPAL UNITS — SYMBOLS, DEFINITIONS, DIMENSIONS

ACRE (ac or A). A unit of area used for measuring real estate in English-speaking countries. "Acre," an Old English word meaning a field, is derived from the Latin *ager* and Greek *agros*, also meaning a field. The acre was originally defined as the area that could be plowed in a day by a yoke of oxen. It was in use in England at least as early as the eighth century, and by the end of the ninth century it was generally understood to be the area of a field one furlong (40 rods or 10 chains) long by 4 rods (or 1 chain) wide. *Thus an acre is 10 square chains, 160 square rods, 43 560 square feet or 4840 square yards. There are exactly 640 acres in a square mile. In metric countries the unit corresponding to the acre is the hectare, which is 10,000 square meters (the area of a square 100 meters on each side). One acre is equal to 0.404 687 3 hectare.*

ACRE FOOT (ac ft or af). A unit of volume used to measure the capacity of reservoirs. One acre foot is a volume one foot deep covering an area of one acre.*Thus an acre foot contains exactly 43 560 cubic feet, about 325 851.4 U.S. gallons, or about 1233.482 cubic meters (0.123 348 hectare meter). The symbol* af *is widely used in reservoir management in the U.S., often in combinations such as* kaf *(1000 acre feet) or* maf *(million acre feet; this symbol should be* Maf).

AMPERE (A). *The constant current that, if maintained in two straight parallel conductors that are of infinite length and negligible cross section and are separated from each other by a distance of 1 meter in a vacuum, will produce between these conductors a force equal to* 2×10^{-7} *newton per meter of length*. The SI unit of electric current, named for the French physicist André-Marie Ampére (1775–1836), one of the pioneers in studying electricity.

AMPERE PER METER (A/m). *The magnetic field strength in the interior of an elongated uniformly wound solenoid which is excited with a linear current density in its winding of 1 ampere per meter of axial distance*. (The SI unit of magnetic field strength.)

AMPERE-HOUR (Ah). *The quantity of electricity represented by a current of 1 ampere flowing for 1 hour. This is equivalent to exactly 3600 coulombs.*

ANGSTROM (Å or A). *A metric unit of length, equal to 0.1 nanometer or* 10^{-10} *meter.** Angstroms are used most often to measure the wave length of light waves. There is a technique called spectroscopy for identifying chemical substances by the wave lengths of light which they absorb (or emit, depending on the circumstances). Light shining through or from the substance is passed through a prism, which separates the various wave lengths to form a colorful spectrum. The spectrum often includes bright bands corresponding to wave lengths at which the substance emits light, or dark bands if the substance is absorbing light. The pattern of bands identifies the substance in somewhat the same way a fingerprint identifies a person. One of the pioneers of spectroscopy was the Swedish physicist Anders Jon Ångström (1814–1874), and in his honor the wave lengths of light waves are customarily stated in angstroms. Although English speakers usually pronounce the word as if it were English, the Swedish pronunciation is closer to "ong-strerm."

ANGSTROM STAR ((Å* or A*). *A unit used to measure the wavelength of X-rays. Because it's easier to measure the ratio between two X-ray wavelengths than it is to measure the wavelengths themselves, the wavelengths are usually stated as multiples of a standard wavelength. The X unit and the angstrom star are the units used for this purpose. Å* was defined by J.A. Bearden in 1965 to provide a unit approximately equal to the angstrom (*10^{-10} *meter or 0.1 nanometer). Later measurements have shown that in fact A* is equal to approximately 1.0000015* $\times 10^{-10}$ *meter or 100.000 15 picometers.*

APOSTILB (asb). *A unit of luminance. One lumen per square meter leaves a surface whose luminance is 1 apostilb in all directions within a hemisphere*. (The candela per square meter is the preferred unit of luminance.)

ARE (a). *A unit of area equal to 100 square meters.* The word is pronounced the same as "air." Being the area of a square 10 meters on each side, the are is a little large for measuring areas indoors and a little small for measuring areas outdoors. As a result, the are is not used as often as its multiple, the hectare (ha). *One are is approximately 1076.3910 square feet, 119.5990 square yards, or 0.02471 acre.*

ATMOSPHERE (atm or atmos). *A unit of pressure designed to equal the average pressure of the Earth's atmosphere at sea level. In other pressure units, one atmosphere equals exactly 1013.25 millibars (mb), 101.325 kilopascals (kPa), approximately 29.92 inches of mercury (in Hg), 760.0 millimeters of mercury (mm Hg), or 14.6959 pounds of force per square inch (lbf/in*^{2}*). This is the* standard atmosphere *; it equals 1.0332 technical atmosphere.*

ATOMIC MASS UNIT (u or amu). The unit of mass used by chemists and physicists for measuring the masses of atoms and molecules. Early in the nineteenth century, scientists discovered that each chemical element is composed of atoms, and that each chemical compound is composed of molecules in which atoms are combined in a fixed way. No one knew then just how small atoms and molecules really are, but as long as the relative weights of the different atoms were known, the outcome of chemical reactions could be predicted. These relative masses were determined by careful study of various reactions. The general idea was that atoms of hydrogen, known to be the lightest element, should have a mass of 1 amu, and all the other atoms should have masses which are whole-number multiples of this (then unknown) mass of the hydrogen atom. For a long time, physicists and chemists disagreed on the details of this definition. In 1960 they agreed on the definition of the **unified atomic mass unit** as 1/12 the mass of the most common atoms of carbon, known as carbon-12 atoms. (Most elements are mixtures of atoms which have different masses because they contain different numbers of neutrons; these varieties are called isotopes.) *Careful experiments have measured the size of this unit; the currently accepted value (1998) is 1.660 538 73*$\times 10^{-24}$ *grams. (This number equals 1 divided by Avogadro's number; see ***mole.) In addition, 1 amu equals approximately 931.494 MeV (see electron volt). In biochemistry, the atomic mass unit is called the dalton (Da).*

BAR (b). *A metric unit of atmospheric pressure, equal to one million dynes per square centimeter, 100 kilopascals, 750.062 torr, 1.019 72 kilograms of force per square centimeter (kgf/cm*^{2}*), or about 14.503 78 pounds per square inch (lbf/in*^{2}*).* The word comes from the Greek *baros*, "weighty."

BARN (b). A slightly humorous unit of area used in nuclear physics. When atoms are bombarded with smaller particles such as electrons, the electrons are scattered as if the nucleus of the atom was a tiny solid object. The barn is used to express the apparent cross-sectional area of this scattering object. *One barn equals 10^{-28} square meter. Using this unit, physicists can say that such and such a nucleus is "as big as a barn," or 10 barns, or whatever. The proper SI unit to use for these measurements is the square femtometer (fm^2); one barn equals 100 fm^2.*

BARREL. (bbl or brl or bl) [1]. *A commercial unit of volume. The official U. S. definition of the barrel is 31.5 gallons, which is about 4.211 cubic feet or 119.24 liters.*

BAUD (Bd). *A unit of signaling speed. One baud equals one element per second.* (The signaling speed in bauds is equal to the reciprocal of the signal element length in seconds.)

BEL (B). *A dimensionless unit for expressing the ratio of two values of power, being the logarithm to the base 10 of the power ratio.* (The more commonly used unit, decibel (dB), is 10 times the logarithm to the base 10 of the power ratio. A bel is 10 decibel.)

BIT (b). *A unit of information, generally represented by a pulse. A bit is a binary digit, i.e., a 1 or 0 in computer technology.* (In information theory, the bit is the smallest possible unit of information.)

BIT PER SECOND (b/s). *A unit of signaling speed. A transference rate of 1 bit per second.*

BOARD FOOT (bd ft, fbm, or BF). *A unit of volume used for measuring lumber. One board foot is the volume of a one-foot length of a "standard board" twelve inches wide by one inch thick. Thus a board foot equals 144 cubic inches, or 1/12 of a cubic foot, or approximately 2.360 liters.*

BOTTLE (btl). *A unit of volume. Like actual bottles, this unit varies according to the nature of the contents. For a long time in the U.S., a bottle of milk was 1 quart (1/4 gallon or 946.36 milliliters), a bottle of whiskey was 1 fifth (1/5 gallon or 757.1 milliliters), and a bottle of champagne was 2/3 quart (1/6 gallon or 630.91 milliliters). In the British Empire, a common bottle size was 2/3 Imperial quart (1/6 gallon or 757.68 milliliters), a unit known as the* **reputed quart**. *Today wine is customarily sold in bottles containing 750 milliliters (about 25.3605 U.S. fluid ounces or 26.3963 British Imperial fluid ounces).*

BRITISH THERMAL UNIT (Btu). *A unit of heat. The heat required to warm 1 pound of pure water through an interval of 1 degree Fahrenheit. In America the British thermal unit is sometimes called the* **heat unit**. *In defining the Btu, it is necessary to specify the temperature of the water; thus there have been several definitions over the years. However, one Btu is equal to about 251.996 (small) calories, or 0.251 996 of the (kilo-)calories counted by dieters. Using the current definition of the calorie (the IT calorie), one Btu equals approximately 778.169 foot pounds, 1.055 056 kilojoules or 0.293 071 watt hour.*

CABLE. *A unit of distance formerly used at sea. The traditional U.S. mariner's cable was 120 fathoms long. This is equal to 720 feet, or 0.1185 nautical mile, or about 219.4 meters. The British Admiralty, in 1830, defined the cable to equal exactly 0.1 nautical (Admiralty) mile, which is 608 feet or about 185.3 meters. Some navies are now using a metric cable equal to exactly 200 meters (about 656.17 ft).*

CALORIE (International Table) (cal_{IT}). *A unit of heat. One International Table calorie equals 4.1868 joules.* (The 9th Conférence Générale des Poids et Mesures adopted the joule as the unit of heat.)

CALORIE(Thermochemical Calorie) (cal). *A unit of heat. One calorie equals 4.1840 joules.* (See foregoing note.)

CANDELA (cd). The SI unit for measuring the intensity of light. *Candela* is the Latin word for "candle." The unit has a long and complicated history. *Originally, candela represented the intensity of an actual candle, assumed to be burning whale tallow at a specified rate in grains per hour. Later this definition was replaced with a definition in terms of the light produced by the filament of an incandescent light bulb. Still later a standard was adopted defining the candela as the luminous intensity of 1/6000,000 of a square meter of a radiating cavity at the temperature of freezing platinum (2042 K) and a pressure of 1 atmosphere. This definition has also been discarded, and the candela is now defined to be the luminous intensity of a light source producing single-frequency light at a frequency of 540 terahertz (THz) with a power of 1/683 watt per steradian, or 18.3988 milliwatts over a complete sphere centered at the light source.*

CENTIARE (ca). *A metric unit of area. The centiare equals 0.01 are, which is exactly 1 square meter (about 10,7639 square feet).*

CHAIN (ch). A unit of distance formerly used by surveyors. The traditional British surveyor's chain, also called *Gunter's chain* because it was introduced by the English mathematician Edmund Gunter (1581–1626) in 1620. *A chain is 4 rods long: that's equal to exactly 1/80 mile, 1/10 furlong, 22 yards, or 66 feet (20.1168 meters).*

CIRCULAR MIL (cmil). *The area of a circle whose diameter is 0.0001 inch. One circular mil equals $\pi/4 \cdot 10^{-6}$ square inches.*

CORD (cd). *A traditional unit of volume used to measure stacked firewood. In the United States, the cord is defined legally as the volume of a stack of firewood 4 feet wide, 8 feet long, and 4 feet high. One cord is a volume of 128 cubic feet, about 3.6247 cubic meters, or 3.6247 steres.*

COULOMB (C). *The quantity of electric charge which passes any cross section of a conductor in 1 second when the current is maintained constant at 1 ampere.* (The SI unit of electric charge.)

CUBIC CENTIMETER (cm^3 or cc). *The CGS unit of volume, equal to 10^{-6} cubic meter, 1 milliliter, or about 0.061 023 7 cubic inch.*

CUBIC FOOT (ft^3, cu ft, or cf). *A traditional unit of volume in English speaking countries. One cubic foot equals 1728 in^3, 1/27 yd^3, 0.028 316 85 m^3, or 28.316 85 liters. The cubic foot also holds about 7.4805 U.S. liquid gallons or about 6.2288 British Imperial gallons.*

CUBIC INCH (in^3, cu in, or ci). *A traditional unit of volume in English speaking countries. One cubic inch equals 1/1728=5.787 037$\times 10^{-4}$ ft^3, 16.3871 cm^3, 16.3871 milliliters, 0.5541 U.S. fluid ounce, or 0.5767 British Imperial fluid ounce.*

CUBIC METER (m^3). *The SI unit of volume, equal to 10^6 cm^3, 1000 liters, 35.3147 ft^3, or 1.307 95 yd^3. A cubic meter holds about 264.17 U.S. liquid gallons or 219.99 British Imperial gallons.*

CUBIC YARD (yd^3). A *traditional unit of volume in English speaking countries. One cubic yard equals 27 ft^3, 46 656 in^3, 0.764 555 m^3, or 764.555 liters. A cubic yard holds about 201.97 U.S. liquid gallons or about 168.20 British Imperial gallons.*

CUP. *One cup equals 1/2 (liquid) pint, or 8 fluid ounces. Technically, one cup equals exactly 14.4375 cubic inches or approximately 236.6 milliliters. In Canada, a cup is equal to 8 Imperial fluid ounces (13.8710 cubic inches or 227.3 milliliters).*

CURIE (Ci). *The unit of activity in the field of radiation dosimetry. One curie equals* 3.7×10^{10} atomic *disintegrations per second, or 37 gigabecquerels (GBq).*

(The activity of 1 gram of ^{226}Ra is slightly less than 1 curie.)

CYCLE (c). *An interval of space of time in which is completed 1 round of events or phenomena.*

CYCLE PER SECOND (Hz, c/s). *The number of cycles per second.* (The name hertz (Hz) is the accepted international term. The abbreviation Hz is preferred to c/s.)

DARCY (D). *A unit of permeability of a porous medium. One darcy equals 1 cP (cm/s)(cm/atm) equals 0.986923 square micrometers.* (A permeability of 1 darcy will allow the flow of 1 cubic centimeter per second of fluid of 1 centipoise viscosity through an area of 1 square centimeter under a pressure gradient of 1 atmosphere per centimeter.)

DAY (d). *A unit of time, the exact definition of which is dependent upon which system of time measurement is referred to, i.e., apparent solar time, mean solar time, universal time, apparent sidereal time, ephemeris time, or atomic time.* See Time. With exception of atomic time, the time base is referenced to rotation of the Earth. For general purposes, a day is considered the period taken for 1 revolution of the Earth about its axis.

DEGREE CELSIUS (°C). *One unit of temperature on the Celsius temperature scale*, which is derived from the thermodynamic of Kelvin scale of temperature and related by: Temperature (degrees Celsius) equals Temperature (Kelvin units) minus 273.15. See Temperature.

The freezing point of water (at one atmosphere of pressure) was originally defined to be 0°C, while the boiling point is 100°C. Thus the Celsius degree is 1/100 of the difference between these two temperatures. (The scale actually used by Celsius was inverted, so that 0°C was the boiling point of water and 100°C the freezing point.) In the SI system, the Celsius scale is defined so that the temperature of the triple point of water (the temperature at which water can exist simultaneously in the gaseous, liquid, and solid states) is exactly 0.01°C, and the size of the degree is 1/273.16 of the difference between this temperature and absolute zero (the temperature at which all molecular motion ceases).

DEGREE FAHRENHEIT (°F). *One unit of temperature on the Fahrenheit temperature scale*, which is related to the Celsius temperature scale by: Temperature (degrees Fahrenheit) equals 1.8×(degrees Celsius) plus 32. See Temperature.

DEGREE RANKINE (°R). *One unit of temperature on the Rankine temperature scale*, which is related to the Fahrenheit temperature scale by: Temperature (degrees Rankine) equals Temperature (degrees Fahrenheit) plus 459.67. *One unit of Rankine is equal to exactly 5/9 kelvin.* The unit is named for the British physicist and engineer William Rankine (1820–1872). See Temperature.

DEKARE or DECARE. *A metric unit of area equal to 10 ares, that is, 1000 square meters or 0.1 hectare. In English units, the dekare equals approximately 10 763.91 square feet, 1195.99 square yards, or 0.247 105 acres.*

DEKATHERM or DECATHERM (DTH). *A unit of energy equal to 10 therms, 1 million Btu, or about 1.055 057 gigajoules (GJ). This unit is used in the energy industry as a synonym for the million-Btu (MM Btu).*

DYNE (dyn). *A unit of force. One dyne equals the force necessary to give 1 gram mass an acceleration of 1 centimeter/(second)(second).* (The dyne is the unit of force in the CGS system.) *Expressed in SI units, the dyne equals 10^{-5} newton. This is quite a small force: it equals about $2.248\times10^{-}$ pound of force (lbf) in the traditional English system.* The word dyne comes from the Greek *dynamis*, power.

ELECTRIC HORSEPOWER. *A unit of power, equal to exactly 746 watts (550.221 foot pounds per second), used in the electric industry.*

ELECTRONVOLT (eV). 1. *A unit of energy. One electronvolt equals the energy acquired by an electron when it passes through a potential difference of 1 volt in a vacuum. The size of the electronvolt must be determined experimentally; the currently accepted value (1998) is $160.217\ 646\ 2\times10^{-21}$ joule, or $1.602\ 176\ 462\times10^{-12}$ erg. This unit is accepted for use with SI units.* 2. *A unit of mass used in particle physics. Mass and energy are related by Einstein's famous equation, $E=mc^2$. The constant c is the speed of light, 299.79×10^{6} m/sec. The energy of 1 electronvolt is therefore equivalent to a mass of about $1.782\ 662\times10^{-33}$ gram, or about $1.073\ 544\times10^{-9}$ atomic mass unit.*

ERG (erg). *A unit of energy. One erg equals 10^{-7} joule*. (Also, 1 erg equals the work done when a force of 1 dyne is applied through a distance of 1 centimeter. One foot-pound equals 13,560,000 ergs.)

EXAJOULE (EJ). *A unit of energy. One exajoule equals 947.817 (U.S.) trillion Btu, 277.7778 petawatt hours, or about 9480 megatherms.*

FARAD (F). *The capacitance of a capacitor in which a charge of 1 coulomb produces a potential difference of 1 volt between the terminals. This is a natural definition, but the unit it defines is very large. In practical circuits, capacitance is often measured in microfarads, nanofarads, or sometimes even in picofarads (10^{-12} farad, or trillionths of a farad).* The unit is named for the British physicist Michael Faraday (1791–1867), who was known for his work in electricity and electrochemistry. (The SI unit of electric capacitance.)

FATHOM (fth or fath). *A traditional unit of distance equal to 2 yards or 6 feet (1.83 meters).* Once also used for measuring distances on land, the fathom is now restricted to nautical uses, especially expressing the depth of water or the length of nautical rope or cable. The word comes from the Old English *fæthm*, meaning "outstretched arms", because a fathom is the distance between a man's outstretched fingertips.

FLUID DRAM or FLUIDDRAM (fl dr). *A unit of volume in the traditional apothecary system, equal to 1/8 fluid ounce. The U. S. fluid dram contains about 0.225 586 cubic inches or 3.696 691 milliliters. In the British imperial system, the fluid dram is about 0.216 734 cubic inches or 3.551 633 milliliters.*

FLUID OUNCE (fl oz). *A unit of liquid volume. In the U. S. customary system there are 16 fluid ounces in a pint, so each fluid ounce represents 1.804 687 cubic inches or 29.573 531 milliliters. In the British Imperial system there are 20 fluid ounces in an imperial pint, so each fluid ounce represents about 1.733 871 cubic inches or 28.413 063 milliliters.* (Called the fluid ounce to avoid confusion with the weight ounce.)

FOOTCANDLE (fc). *A unit of luminance or illumination. One footcandle equals 1 lumen per square foot*. (The name *lumen per square foot* is recommended for this unit. The SI unit, lux (lumen per square meter), is preferred.)

FOOTLAMBERT (fL). *A unit of luminance, the brightness of a surface. One lumen per square foot leaves a surface whose luminance is 1 footlambert in all directions within a hemisphere*. (If luminance is measured in English units, the candela per square inch is preferred. However, use of the SI unit, the candela per square meter, is generally accepted.)

FRANKLIN (Fr). *A CGS unit of electric charge equal to 3.3356×10^{-10} coulombs or 1 statcoulomb. An electrostatic charge of one franklin exerts a force of one dyne on an equal charge at a distance of one centimeter.*

FURLONG (fur). A traditional unit of distance. Long before the Norman Conquest in 1066, Saxon farmers in England were measuring distance in rods and furlongs and areas in acres. The word "furlong", from the Old English *fuhrlang*, means "the length of a furrow"; it represents the distance a team of oxen could plow without needing a rest. *A furlong equals 40 rods, which is exactly 10 chains, 220 yards, 660 feet, or 1/8 mile. One furlong is exactly 201.168 meters, so a 200-meter dash covers a distance very close to a furlong.*

GAL (Gal). *A unit of acceleration. One Gal equals 1 centimeter per second per second*.

GALLON (gal). Because the gallon, quart, and pint differ in the United States and the United Kingdom, the use of this unit and term is generally discouraged for scientific purposes. An imperial gallon equals 1.20095 U.S. gallons. One U.S. gallon equals 3.785×10^{-3} cubic meter.

GAUSS (G). *The CGS unit of magnetic flux density. A unit of magnetic flux density, or magnetic induction. The ratio of the flux in any cross section to the area of that cross section, the cross section being taken normal to the direction of flow. One gauss equals 1 maxwell per square centimeter. (In SI units, the tesla, is preferred. One gauss equals 10^{-4} tesla.)*

GIGABECQUEREL (GBq). *A unit of radioactivity equal to one billion atomic disintegrations per second or 27.027 millicuries.*

GIGAFLOPS (Gflops). A unit of computing power equal to one billion (10^9) floating point operations per second.

GIGAGRAM (Gg). *An SI unit of mass equal to 10^9 grams, one million kilograms, or 1 kilotonne (1000 metric tons). One gigagram equals about 2.2046 million pounds or 1102.3 U.S. (short) tons.*

GIGAHERTZ (GHz). *A unit of frequency equal to 10^9 per second, or 1 per nanosecond.*

GIGAJOULE (GJ). *A metric unit of energy. One gigajoule equals 947 817 Btu, 277.7778 kilowatt hours, or about 9.48 therms.*

GIGALITER (GL or Gl). A *metric unit of volume equal to 10^9 liters or one million cubic meters. This is equivalent to 810.713 acre feet or 35.315 million cubic feet.*

GIGAMETER (Gm). *A metric unit of distance equal to one million kilometers or about 621 371.2 miles. The distance from the earth to the sun is about 149.60 gigameters.*

GIGAPARSEC (Gpc). *Used in astronomy the gigaparsec is a non-metric unit of distance equal to one billion parsecs, 3.2616 billion light years, or 30.856 78 zettameters ($30.856\ 78\times10^{21}$ kilometers).*

GIGAPASCAL (GPa). *A metric unit of pressure. One gigapascal equals 10 kilobars or approximately 145 038 pounds (72.519 short tons) per square inch.*

GIGAWATT (GW). *A metric unit of power equal to one billion (10^9) watts or about 1.341 million horsepower.*

GIGAWATT HOUR (GW-h). *A metric unit of energy equal to one billion watt hours, 3.6 terajoules, or about 3.412 billion Btu.*

GILBERT (Gb). *A unit of magnetomotive force. One gilbert equals $0.4\ \pi$(ni), where (ni) is an ampere-turn*. (The gilbert is a unit of the CGS system. Use of the SI unit, the ampere (or ampere-turn), is preferred.)

GRAIN (gr). *A unit of mass. One grain equals 0.06480 gram*. (One ounce, avoidupois, equals 437.5 grains; 1 ounce, troy, equals 480 grains; 1 ounce, apothecaries', equals 480 grains. One pound, avoirdupois, equals 7,000 grains.)

GRAM (g). *A unit of mass. One gram equals 1/1,000th kilogram*. (See also **Kilogram** in this list.)

HECTARE (ha). The customary metric unit of land area, equal to 100 ares. *One hectare is a square hectometer, that is, the area of a square 100 meters on each side: exactly 10 000 square meters or approximately 107 639.1 square feet, 11 959.9 square yards, or 2.471 054 acres.*

HENRY (H). *A unit of inductance. The inductance of a circuit in which a current of 1 ampere induces a flux linkage of 1 weber.* (The SI unit of electric inductance.)

HERTZ (Hz). *A unit of frequency. One hertz equals a frequency of one cycle per second.* (The SI unit of frequency.) The hertz is used to measure the rates of events that happen periodically in a fixed and definite cycle; the *becquerel*, also equal to one "event" per second, is used to measure the rates of things which happen randomly or unpredictably. Multiples of the hertz are common: the frequencies of radio and television waves are measured in kilohertz (kHz), megahertz (MHz), or even gigahertz (GHz), and the frequencies of light waves in terahertz (THz). The unit is named for the German physicist Heinrich Rudolf Hertz (1857–1894), who proved in 1887 that energy is transmitted through a vacuum by electromagnetic waves.

HORSEPOWER (hp). The horsepower is considered an anachronism in science and technology. Use of the SI unit of power, the watt, is preferred. When used, 1 horsepower equals (1) 42.44 Btu/minute; (2) 33,000 foot-pounds/minute; (3) 550 foot-pounds/second or (4) 745.6999 watts.

HORSEPOWER HOUR (hp hr). *A unit of work or energy equal to the work done at the rate of 1 horsepower for 1 hour. The horsepower hour equals 1 980 000 foot pounds or approximately 2.685 megajoules, 2545 Btu, 641.1 (large) Calories, or 745.7 watt hours.*

HOUR (h or hr). *A unit of time. One hour equals 60 minutes, or 3,600 seconds or 1/24 day.*

HUBBLE. *A unit of distance used in astronomy. The Hubble is equal to 10^9 light years. This is 9.4605×10^{21} kilometers, 9.4605 yottameters, 5.8785 sextillion miles (U.S.), 63.240×10^{12} astronomical units, or 306.595 megaparsecs.*

INCH (in). *A unit of length. One inch equals 1/12 foot or exactly 2.540 centimeters.*

INCH OF MERCURY (inHg). *A unit of pressure. One inch of mercury equals 3,386.4 newtons per square miter.* (An inch of mercury also equals (1) 0.03342 atmosphere; (2) 1.133 feet of water; (3) 345.3 kilograms/square meter; (4) 70.73 pounds/square foot; or (5) 0.4912 pounds/square inch.

INCH OF WATER (in H_2O). *A unit of pressure. One inch of water equals 249.09 newtons per square meter.* (An inch of water also equals (1) 2.458×10^{-3} atmosphere; (2) 0.07355 inch of mercury; (3) 2.540×10^{-3} kilogram/square centimeter; (4) 0.5781 ounce/square inch; (5) 5.204 pounds/square foot; or (6) 0.03613 pound/square inch. The latter Figures hold for a temperature of 4° C.)

JOULE (J). *A unit of energy. The work done by 1 newton acting through a distance of 1 meter.* (The SI unit of energy. One joule equals 1 watt-second; equals 10^7 ergs; equals 10^7 dyne-centimeters.) The joule is named for the British physicist James Prescott Joule (1818–1889), who demonstrated the equivalence of mechanical and thermal energy in a famous experiment in 1843.

JOULE PER KELVIN (J/K). *A unit of heat capacity and entropy.*

KELVIN (K). *The basic unit of thermodynamic temperature. One kelvin is the fraction 1/273.16 of the thermodynamic temperature of the triple point of water. Since this temperature is also equal to 0.01° C, the temperature in kelvins is always equal to 273.15 plus the temperature in degrees Celsius. The kelvin equals exactly 1.8 degrees Fahrenheit.* (The term *degree Kelvin* was officially dropped in 1967. Thus, the symbol is K and not °K. Relationship of the Kelvin scale to the Celsius scale is given earlier in this list under DEGREE CELSIUS.)

The unit is named for the British mathematician and physicist William Thomson (1824–1907), later known as Lord Kelvin after he was named Baron Kelvin of Largs.

KILOGRAM (kg). *A unit of mass and is based upon a cylinder of platinum-iridium alloy kept by the International Bureau of Weights and Measures at Paris.* A duplicate in the custody of the National Bureau of Standards at Washington is the mass standard for the United States. The kilogram is the only base unit still defined by an artifact. (A kilogram equals (1) 1,000 grams; (2) 2.205 pounds; (3) 9.842×10^{-4} long tons; or (4) 1.102×10^{-3} short tons.

KILOHERTZ (kHz). *A common unit of frequency equal to 1000 per second or 1 per millisecond.*

KILOJOULE (kJ). A common metric unit of work or energy, comparable to the British thermal unit (Btu). *One kilojoule equals approximately 0.947 817 Btu. In other energy units, the kilojoule is also equivalent to 0.238 846 kilocalories, 0.277 778 watt hour, or 737.562 foot-pounds in the traditional English system.*

KILOMETER (km). *A common metric unit of length or distance. One kilometer equals exactly 1000 meters, about 0.621 371 19 mile, 1093.6133 yards, or 3280.8399 feet.*

KILOPARSEC (kpc). *A unit of distance used in astronomy. The kiloparsec equals 1000 parsecs, 3261.631 light years, $3.085\,678\times10^{16}$ kilometers, or about 19.18 quadrillion miles.*

KILOPASCAL (KpA). *A metric unit of pressure. One kilopascal equals 1000 pascals (Pa), 10 millibars(mb), or about 0.145 038 pounds per square inch (lbf/in^2 or psi), 20.8855 pounds per square foot, 7.502 millimeters of mercury (mm Hg), 0.2953 inches of mercury (in Hg), 4.015 inches of water column (in WC), or 0.3346 foot of head (ft hd).*

KNOT (kn). *A unit of speed. One knot equals 1 nautical mile per hour.* (A knot also equals 6,080.2 feet/hour; or 1.151 statute miles per hour (mph), exactly 1.852 kilometers per hour, or 0.5143 meters per second.)

LAMBERT (L, La or Lb). *A CGS unit of luminance. One lumen per square centimeter leaves a surface whose luminance is 1 lambert in all directions within a hemisphere. A geometric calculation shows that a surface area having an intensity of one candela per square meter emits a total light flux of pi lumens per square meter; as a result, one lambert equals 10^4/pi=3183.099 candelas per square meter and 1 millilambert equals 3.183 099 candelas per square meter.* (The candela per square meter is the preferred unit of luminance.)

LIGHT SECOND. *A unit of distance equal to the distance light travels in a vacuum in one second. In accordance with the official definition of the meter, this distance is exactly 299 792 458 meters (about 186 282.4 miles). A* light minute *is 60 light seconds (about 17 987 547 kilometers or 11 176 944 miles) and a* light day *is 1440 light minutes (about 25.902 billion kilometers or 16.095 billion miles).* See also Light-Year.

LITER OR LITRE (L or l). *A unit of volume. One liter equals 10^{-3} cubic meter.* (A liter also equals (1) 1,000 cubic centimeters; (2) 0.03531 cubic foot; (3) 61.02 cubic inches; (4) 1.308×10^{-3} cubic yard; (5) 0.2642 U.S. liquid gallon; (6) 1.057 U.S. liquid quarts; or (7) 0.22 Imperial gallon. Compared to the customary volume units, the liter is a little more than a U. S. liquid quart (1.056 688 qt or 33.814 fluid ounces) but a little less than a U. S. dry quart (0.908 08 qt) or a British imperial quart (0.879 89 qt or 35.195 fluid ounces). Both the lower case letter l and the upper case L are accepted as symbols for the liter, but the U.S. Department of Commerce specifies that L be used, at least by businesses, to avoid confusion with the numeral 1.

LUMEN (lm). *A unit of luminous flux. The intensity of a light source is measured in candelas. One lumen represents the total flux of light emitted, equal to the intensity in candelas multiplied by the solid angle in steradians (1/(4·pi) of a sphere) into which the light is emitted. Thus the total flux of a one-candela light, if the light is emitted uniformly in all directions, is 4·pi lumens.* (The SI unit for measuring the flux of light being produced by a light source or received by a surface.)

LUMEN PER SQUARE FOOT (lm/ft^2). *A unit of illuminance and also a unit of luminous excitation.* (Use of the SI unit, lumen per square meter, is preferred.)

LUMEN PER SQUARE METER (lm/m^2). *A unit of luminous excitation.* (The SI unit of luminous excitation.)

LUMEN PER WATT (lm/W). *A unit of luminous efficacy.* (The SI unit of luminous efficacy.)

LUMEN SECOND (lm· s). *A unit of quantity of light.* (The SI unit of quantity of light.)

LUX (lx). *A unit of illuminance. In considering the various light units, it's useful to think about light originating at a point and shining upon a surface. The intensity of the light source is measured in candelas; the total light flux in transit is measured in lumens (1 lumen=1 candela·steradian); and the amount of light received per unit of surface area is measured in lux (1 lux=1 lumen/square meter). One lux is equal to approximately 0.09290 foot candle.* (The SI unit for measuring the illumination (illuminance) of a surface.)

MACH (M or Ma). *A measure of relative velocity, used to express the speed of an aircraft relative to the speed of sound. The name of the unit is often placed before the measurement. Thus "Mach 1.0" is the speed of sound; "Mach 2.0" is twice the speed of sound, and so on.* (The actual speed of sound varies, depending on the density and temperature of the atmosphere. At 0° C and a pressure of 1 atmosphere the speed of sound is about 1088 ft/s, 331.6 m/s, or 741.8 mi/h). The mach speed is important to the control of an aircraft, especially at speeds close to or exceeding Mach 1.0.

MAXWELL (Mx). *A CGS unit of magnetic flux, equal to 10^{-8} weber. The flux through a square centimeter normal to a field at 1 centimeter from a unit magnetic pole.*

METER OR METRE (m). *A unit of length. Defined as 1,650,763.73 wavelengths in vacuum of the orange-red line of the spectrum of* 86Kr *(krypton).* (The SI unit of length. A meter also equals (1) 100 centimeters; (2) 3.281 feet; (3) 39.37 inches; (4) 0.001 kilometer; (5) 5.396×10^{-4} nautical mile; (6) 6.214×10^{-4} statute mile; or (7) 1.094 yards.

METRIC HORSEPOWER. *A unit of power. Defined as the power required to raise a mass of 75 kilograms at a velocity of 1 meter per second.* (Approximately 735.499 watts or 0.986 32 horsepower.)

MHO (mho). *A unit of conductance (and of admittance). The conductance of a conductor whose resistance is 1 ohm.* (The name *siemens* (S) also is used for this quantity.)

MICROMETER (μm). *A unit of length. One micrometer equals one-millionth of a meter.* (The term *micron* formerly used for this unit no longer is preferred.)

MICRON. See MICROMETER above.

MIL (mil). *A unit of distance. One mil equals one-thousandth of an inch.*

MILE, STATUTE (mi). *A unit of length. One mile equals 5,280 feet.* (One statute mile also equals (1) 1.609 kilometers; (2) 1,760 yards; (3) 6.336×10^{4} inches; or (4) 0.8684 nautical mile.)

MILE, NAUTICAL (nmi). *A unit of length. One nautical mile equals 1.1516 statute miles.* (One nautical mile also equals (1) 6,080.20 feet (1,853.24 meters); (2) 1.853 kilometers; or (3) 2,027 yards.)

MINUTE, TIME (min). *A unit of time. One minute equals 60 seconds.* (Time also may be designated by means of superscripts, as in $9^{h}\ 46^{m}\ 30^{s}$, where there otherwise will be no confusion with abbreviations.)

MOLE (mol). The SI base unit of the *amount* of substance (as distinct from its mass or weight. Moles measure the actual number of atoms or molecules in an object. An alternate name is **gram molecular weight**, because one mole of a chemical compound is the same number of grams as the molecular weight of a molecule of that compound measured in atomic mass units. The official definition, adopted as part of the SI system in 1971, is that one mole of a substance contains just as many elementary entities (atoms, molecules, ions, or other kinds of particles) as there are atoms in 12 grams of carbon-12 (carbon-12 is the most common atomic form of carbon, consisting of atoms having 6 protons and 6 neutrons). The actual number of "elementary entities" in a mole is called **Avogadro's number** after the Italian chemist and physicist Amedeo Avogadro (1776–1856). Careful measurement determines Avogadro's number to be approximately $602.214\ 199\times10^{21}$. In the American system of naming big numbers, that's 602 sextillion 214 quintillion 199 quadrillion, give or take about 50 quadrillion.

MOUSE UNIT (MU or U). An unofficial unit of toxicity used in pharmacology. A mouse unit is the dose of a toxin that kills 50% of mice (that is, it is the LD_{50} dose for mice).

NEPER (Np). A dimensionless unit for expressing the ratio of two voltages, two currents, or two power values in a logarithmic manner. The number of nepers is the natural (Napierian) logarithm of the square root of the ratio of the two values being compared. Thus, the neper uses the base of 2.71828 in contrast with the bel (or decibel) which uses the common-logarithm base of 10. One neper equals 8.686 decibels. The unit recognizes the Scottish mathematician John Napier (1550–1617), the inventor of the logarithm (Napier often spelled his name Jhone Neper, and he used the Latin form Ioanne Napero in his writings).

NEWTON (N). *A unit of force. One newton is the force that will impart an acceleration of 1 meter per second per second to a mass of 1 kilogram. The corresponding unit in the CGS system is the dyne; there are 10^{5} dynes in one newton. In traditional English terms, one newton is about 0.224 809 pounds of force (lbf) or 7.233 01 poundals. The newton is also equal to about 0.101 972 kilograms of force (kgf) or kiloponds (kp).* (The SI unit of force.) The newton is named for Isaac Newton (1642–1727), the British mathematician, physicist, and natural philosopher. He was the first person to understand clearly the relationship between force (F), mass (m), and acceleration (a) expressed by the formula $F=ma$.

NIT(nt). *A unit of luminance and is synonymous with candela per square meter, or 10^{-4} stib.* The nit is not approved as part of the SI, but it has been approved since 1947 by the International Commission on Illumination (CIE) and is in wide use.

NORMAL CUBIC METER (Nm^3). *A unit of mass for gases equal to the mass of 1 cubic meter (35.3147 ft^3) at a pressure of 1 atmosphere and at a standard temperature, often 0°C (32°F) or 20°C (68°F).* The symbol Nm^3, though common, is not permissible under the SI because that symbol means "newton cubic meter." An acceptable SI symbol would be "m^3 normal."

OERSTED (Oe). *A unit of magnetic field strength. The magnetic field produced at the center of a plane circular coil of 1 turn and of radius 1 centimeter, which carries a current of $(\frac{1}{2}\pi)$ abamperes.* (An abampere equals 10 amperes. The oersted is the CGS unit of magnetic field strength. Use of the SI unit, the ampere per meter, is preferred.)

OHM (Ω). *A unit of resistance (and of impedance). The resistance of a conductor such that a constant current of 1 ampere in it produces a voltage differences of 1 volt between its ends.* (The SI unit of electric resistance.) The unit honors the German physicist Georg Simon Ohm (1787–1854).

PARSEC (pc or psc). A non-metric unit of distance used in astronomy. As the Earth makes its orbit around the Sun, nearby stars appear to shift their positions in relation to the background of distant stars. This shift, called the *parallax* of the star, is very small, less than one arcsecond even for the nearest stars. *One parsec is the distance at which a star would appear to shift its position by one arcsecond during the time in which the Earth moves a distance of one astronomical unit (AU) in the direction perpendicular to the direction to the star. Using this unit makes it easy to compute distances: the distance to a star, in parsecs, is simply one divided by the parallax, in arcseconds. If the parallax is 0.01 arcsecond, the distance is 100 parsecs. One parsec divided by one astronomical unit (the length of the semi major axis of the Earth's elliptical orbit) is the trigonometric function of the parallax called the cotangent; from this relation we can compute that one parsec equals 206 264.8 AU. This is the same as 3.261 631 light years, 30.856 78 petameters ($30.856\ 78\times10^{12}$ kilometers), or about 19 173 510 000 000.*

PASCAL (Pa). *A unit of pressure or stress. One pascal equals 1 newton per square meter or one "kilogram per meter per second per second."*

PECK (pk). *A traditional unit of volume. A peck is 2 gallons, 8 quarts, or 1/4 bushel. In the U. S. customary system, a peck holds 537.605 cubic inches or approximately 8.8098 liters. In the British imperial system, a peck is a little larger, holding 554.84 cubic inches or approximately 9.0923 liters.*

PHON (phon). *A unit of loudness level. The pressure level in decibels of a pure* 1,000 Hz*tone.* In the U.S., sound loudness is frequently measured in sones rather than phons: a sound of loudness s sones has loudness $10\log_2 s+40$ phons. In English the unit is pronounced "fon" rather than "phone."

PHOT (ph). *A unit of illuminance. One phot equals 1 lumen per square centimeter or 10,000 lux.* (The phot is the CGS unit of illuminance or Illumination. Use of the SI unit, the lux, is preferred.)

PINT (pt). A traditional unit of volume equal to 1/2 quart. Because the gallon, quart, and pint differ in the United States and the United Kingdom, the use of this unit and term is generally discouraged for scientific purposes. One U.S. pint equals: (1) 473.2 cubic centimeters; (2) 0.01671 cubic foot; (3) 28.87 cubic inches; (4) 4.732×10^{-4} cubic meter; (5) 6.189×10^{-4} cubic yard; (6) 0.125 U.S. gallon; (7) 0.4732 liter; or (8) 0.5 liquid U.S. quart (16 fluid ounces, or approximately 473.176 milliliters).

POISE (P, Ps, or Po). A unit of dynamic viscosity. The unit is expressed in dyne second per square centimeter. The centipoise (cP) is more commonly used. The formal definition of viscosity arises from the concept put forward by Newton that under conditions of parallel flow, the shearing stress is proportional to the velocity gradient. If the force acting on each of two planes of area A parallel to each other, moving parallel to each other with a relative velocity V, and separated by a perpendicular distance X, be denoted by F, the shearing stress is F/A and the velocity gradient, which will be linear for a true liquid, is V/X. Thus, $F/A=\eta\ V/X$, where the constant η is the viscosity coefficient or dynamic viscosity of the liquid. The poise is the CGS unit of dynamic viscosity.

The unit is named for the French physician Jean Louis Marie Poiseuille (1799–1869). The *SI* recognizes no named unit for dynamic viscosity; in SI units, one poise equals 0.1 pascal second (Pa·s). The poise is also equivalent to 14.5038×10^{-6} reyn. **P** is the proper symbol for the unit, but Ps and Po are also used.

POUNDAL (pdl or pl). *An English unit of force. One poundal equals the force required to give a standard 1-pound body an acceleration of 1 foot per second per second.* Since the acceleration of gravity averages about 32.174 ft/sec^2 at the Earth's surface, one poundal is about 1/32.174=0.031 081 pound of force. One poundal is also equal to approximately 0.138 255 newton, or 13 825.5 dynes. The newton, the SI unit, is now the preferred unit of force in engineering and technical work. The poundal was invented in the 1870s by the British mathematician James Thomson, who also named the radian.

QUART (qt). *A unit of volume, so-called because it equals exactly 1/4 (1 quarter) of a gallon.* Because the gallon, quart, and pint differ in the United States and the United Kingdom, the use of this unit and term is generally discouraged for scientific purposes. One U.S. quart (liquid volume) equals: (1) 946.4 cubic centimeters; (2) 0.03342 cubic foot; (3) 57.75 cubic inches; (4) 32 fluid ounces; (5) 9.464×10^{-4} cubic meter; (6) 1.238×10^{-3} cubic yard; (7) 0.25 U.S. gallon; or (8) 0.9463 liter. One U.S. quart (dry volume) equals: 67.201 cubic inches, or approximately 1.101 221 liters.

RAD (rd). *A unit of absorbed dose in the field of radiation dosimetry. One rad is equal to a dose of 0.01 joule of energy per kilogram of mass (J/kg), or 100 ergs of energy per gram of mass.*

RADIAN (rad). *A unit of plane angle measure widely used in mathematics and science. One radian equals the angle subtended at the center by a circular arc which is equal in length to the radius of the circle.* (The SI unit of plane angle.)

REAM (rm). *A unit of quantity used for counting sheets of paper.* Traditionally a ream equals 500 sheets of paper.

REM (rem). *A unit of dose equivalent in the field of radiation dosimetry. One rem equals the amount of ionizing radiation of any type which produces the same damage to humans as 1 roentgen of approximately 200 kilovolts x-radiation.* (The unit is abbreviation of Roentgen Equivalent Man.) The unit was introduced in 1944 by the physicist H.M. Parker of the Manhattan Project.

REVOLUTION PER MINUTE (r/min). Although use of rpm as an abbreviation is common, it should not be used as a symbol.

ROD (rd). *A traditional unit of distance equal to 5.5 yards (16 feet 6 inches or exactly 5.0292 meters).* The rod and the furlong were the basic distance units used by the Anglo-Saxon residents of England before the Norman conquest of 1066.

ROENTGEN (R). A unit of exposure in the field of radiation dosimetry. That quantity of x–or gamma-radiation such that the associated corpuscular emission per 0.001293 gram of dry air (equals 1 cubic centimeter at 0° C and 769 millimeters of mercury pressure) produces in air ions carrying 1 esu of quantity of electricity of either sign. (The emu (electrostatic unit) is a unit in the CGS system in which the statcoulomb is the charge that repels an exactly similar charge in a vacuum with a force of 1 dyne. One statcoulomb equals 3.3356×10^{-10} coulomb.) The unit is named for one of the early investigators of radioactivity, the German physicist Wilhelm Konrad Roentgen (1845–1923).

SECOND (s). *A unit of time. The duration of 9,192,631,770 periods of the radiation corresponding to the transition between the two hyperfine levels of the ground state of the ^{133}Cs (cesium) atom.* (The SI unit of time.) See also **Second**; and **International System Of Units (SI)**.

SIEMENS (S). A unit of electric conductance. The most important property of a conductor is the amount of current it will carry when a voltage is applied. Current flow is opposed by resistance in all circuits, and by also by reactance and impedance in alternating current circuits. Conductance, susceptance, and admittance are the inverses of resistance, reactance, and impedance, respectively. To measure these properties, the siemens is the reciprocal of the ohm. In other words, the conductance, susceptance, or admittance, in siemens, is simply 1 divided by the resistance, reactance or impedance, respectively, in ohms. It is named after the German inventor and industrialist Ernst Werner von Siemens, and is equivalent to the now-obsolete mho. In English, it is *siemens* in both singular and plural. The 14th General Conference on Weights and Measures approved the addition of the siemens as an SI derived unit in 1971. (The SI unit of electric conductance, susceptance, and admittance.) See **Ohm**.

SLUG (slug). *A unit of mass. One slug is the mass accelerated at 1 foot per second per second by a force of 1 pound. One slug equals 32. 174 04 pounds (14.593 90 kilograms.*)

STERADIAN (sr). *A unit of solid angle. One steradian equals the solid angle subtended at the center by* $\frac{1}{4}\pi$ *of the surface area of a sphere of unit radius.*

STILB (sb). *A unit of luminance. One stilb equals 1 candela per square centimeter or 10^4 nits (candelas per square meter).*

STOKES (St). A unit of kinematic viscosity. The centistokes (cSt) is more commonly used. Kinematic viscosity is the dynamic viscosity divided by the density. See **POISE** given previously in this list. Being a CGS unit, the stokes is therefore defined to be 1 cm^2/s, equivalent to 10^{-4} m^2/s or 0.001 076 391 ft^2/s. The SI has no named unit of kinematic viscosity, requiring the use instead of m^2/s. The unit, called the stokes in Britain and the stoke in the U.S., is named for a British mathematician and physicist, Sir George Gabriel Stokes (1819–1903), who described the basic principles of fluid mechanics in 1845.

TABLESPOON or TABLESPOONFUL (T, tbs, or tbsp). *A unit of volume. In the U.S., the tablespoon is equal to 1/2 fluid ounce; this is about 14.8 milliliters (3 teaspoons equals 1/16 cup). In Canada, the traditional tablespoon is 1/2 Imperial fluid ounce (14.2 milliliters). In Britain, traditional tablespoons varied somewhat in size, and various older references give sizes in the range from 1/2 to 5/8 Imperial fluid ounce (14.2–17.6 milliliters).*

TEASPOON or TEASPOONFUL (t, or tsp). *A unit of volume. The U.S. teaspoon is equal to 1/3 tablespoon or 1/48 cup; this is equivalent to 1/6 fluid ounce, about 0.30 cubic inches, or approximately 4.9 milliliters. In Britain, a traditional* **teaspoonful** *in the kitchen was equal to 1/8 Imperial fluid ounce or approximately 3.55 milliliters.*

TESLA (T). *A unit of magnetic flux density (magnetic induction). The magnetic flux density of a uniform field that produces a torque of 1 newton-meter on a plane current loop carrying 1 ampere and having a projected area of 1 square meter on the plane perpendicular to the field.* $T = N/A \cdot m$. (The SI unit of magnetic flux density.) The tesla, defined in 1958, honors the Serbian-American electrical engineer Nikola Tesla (1856–1943), whose work in electromagnetic induction led to the first practical generators and motors using alternating current.

THERM (thm). *A unit of heat. One therm equals 100,000 British thermal units (Btu).* Because there have been several definitions of the Btu, there are two official definitions of the therm. In the U.S., the legal definition (made in 1968) is that the therm equals 105.4804 megajoules. The European Union's definition, made in 1979 using the more current IT Btu, is 105.5060 megajoules. Either way the therm is equal to about 25 200 (large) calories or about 29.3 kilowatt hours of electrical energy. One therm can also be provided by about 96.7 cubic feet of natural gas.

TON (ton). A unit of weight. If not otherwise specified, a *short ton* equal to 2,000 pounds (907.185 kilograms) is assumed. A *long ton* equals 2,240 pounds (1,016.05 kilograms). To distinguish between the two units, the British ton is called the **long ton** and the American and Canadian one is the **short ton**. A metric ton equals 1,000 kilograms (2,205 pounds), also called *tonne* (t).

VAR (var). *A unit of the reactive electric power delivered by an alternating current (AC) circuit. The reactive power at the port of entry of a single-phase two-wire circuit when the product of (a) the rms (root mean square) value in amperes of the sinusoidal current, (b) the rms value in volts of the voltage, and (c) the sine of the angular phase difference by which the voltage leads the current is equal to 1.* (The SI unit of reactive power.)

VOLT (V). *A unit of voltage. The voltage between 2 points of a conducting wire carrying a constant current of 1 ampere, when the power dissipated between these points is 1 watt.* (The SI unit of voltage.) The name of the unit honors the Italian scientist Count Alessandro Volta (1745–1827), the inventor of the first battery.

VOLTAMPERE (VA). *A unit of apparent power. The apparent power at the port of entry of a single-phase two-wire circuit when the product of (a) the rms (root mean square) value in amperes of the current and (b) the rms value in volts of the voltage is equal to 1.*

(The SI unit of apparent power.)

WATT (W). *A unit of power. The watt equals 1 joule per second.* (The SI unit of power. One watt equals: (1) 3.4192 Btu/hour; (2) 0.05688 Btu/minute; (3) 10^7 ergs/second; (4) 44.27 foot-pounds/minute; (5) 0.7378 foot-pounds/second; (6) 1.341×10^{-3} horsepower; (7) 1.360×10^{-3} metric horsepower; (8) 0.01433 kilogram-calories/minute; or (9) 0.001 kilowatt. The name of the unit honors James Watt (1736–1819), the British engineer who built the first practical steam engines.

TABLE 4. (*Continued*)

WATT PER METER KELVIN (W/m·K). The SI unit of thermal conductivity.

WATT PER STERADIAN (W/sr). The SI unit of radiant intensity.

WATT PER STERADIAN SQUARE METER (W/Sr·m^2). The SI unit of radiance.

WATTHOUR (Wh). *A unit of energy. One watthour equals 3,600 joules*. (One watthour equals: (1) 3.413 Btu; (2) 3.60×10^{10} ergs; (3) 2,656 footpounds; (4) 859.85 gram-calories; (5) 1.341×10^{-3} horsepower-hour; (6) 0.8598 kilogram-calorie; (7) 367.2 kilogram-meters; or (8) 0.001 kilowatt-hour.

WEBER (Wb). *A unit of magnetic flux. The magnetic flux passing through an area of 1 square meter placed normal to a uniform magnetic field of magnetic flux density equal to 1 tesla*. Wb =T·m^2.

(The SI unit of magnetic flux.) If the flux linked by a circuit changes at a uniform rate of 1 weber per second, a voltage of 1 volt is induced in the circuit. Wb=V·s.

*Although, officially, A (without small circle over it) may be used as an abbreviation or symbol for angstrom, to avoid possible confusion with the use of A for ampere, the Å symbol is used throughout this text.

TABLE 5. COMMON EQUIVALENTS AND CONVERSIONS

Approximate Common Equivalents		Conversions Accurate to Parts Per Million	
1 inch	25 millimeters	inches × 25.4*	millimeters
1 foot	0.3 meter	feet×0.3048*	meters
1 yard	0.9 meter	yards×0.9144*	meters
1 mile	1.6 kilometers	miles×1.60934	kilometers
1 square inch	6.5 square centimeters	square inches×6.4516*	square centimeters
1 square foot	0.09 square meter	square feet×0.0929030	square meters
1 square yard	0.8 square meter	square yards×0.836127	square meters
1 acre	0.4 hectare	acres×0.404686	hectares
1 cubic inch	16 cubic centimeters	cubic inches×16.3871	cubic centimeters
1 cubic foot	0.03 cubic meter	cubic feet×0.0283168	cubic meters
1 cubic yard	0.8 cubic meter	cubic yards×0.764555	cubic meters
1 quart (liquid)	0.9463 liter	quarts (liquid)×0.946353	liters
1 gallon	0.004 cubic meter	gallons×0.00378541	cubic meters
1 ounce (avoirdupois)	28 grams	ounces (avoirdupois)×28.3495	grams
1 pound (avoirdupois)	0.45 kilogram	pounds (avoirdupois)×0.453592	kilograms
1 horsepower	0.75 kilowatt	horsepower×0.745700	kilowatts
1 millimeter	0.04 inch	millimeters×0.0393701	inches
1 meter	3.3 feet	meters×3.28084	feet
1 meter	1.1 yards	meters×1.09361	yards
1 kilometer	0.6 mile	kilometers×0.621371	miles
1 square centimeter	0.16 square inch	square centimeters×0.155000	square inches
1 square meter	11 square feet	square meters×10.7639	square feet
1 square meter	1.2 square yards	square meters×1.19599	square yards
1 hectare	2.5 acres	hectares×2.47105	acres
1 cubic centimeter	0.06 cubic inch	cubic centimeters×0.0610237	cubic inches
1 cubic meter	35 cubic feet	cubic meters×35.3147	cubic feet
1 gram	0.035 ounce (avoirdupois)	grams×0.0352740	ounces (avoirdupois)
1 kilogram	2.2 pounds (avoirdupois)	kilograms×2.20462	pounds (avoirdupois)
1 kilowatt	1.3 horsepower	kilowatts×1.34102	horsepower

UNIVALVES. See **Mollusks**.

UNIVERSAL TIME COORDINATED (UTC). UTC stands for what used to be called Greenwich Mean Time (GMT) and Zulu Time (Z). This is the time at the Prime Meridian (0° Longitude) given in hours and minutes on a 24 hour clock. For example, 1350 UTC is 13 hours and 50 minutes after midnight or 1:50 PM at the Prime Meridian.

The Greenwich Royal Observatory at Greenwich, England (at 0° Longitude) was where naval chronometers (clocks) were set, a critical instrument for calculating longitude. This is why GMT became the standard for world time. Meteorologists have used UTC or GMT times for over a century to ensure that observations taken around the globe are taken simultaneously.

On most satellite pictures and radar images the time will be given. If it's not in local time then it will usually be given as UTC, GMT, or Z time. See Figs. 1 and 2.

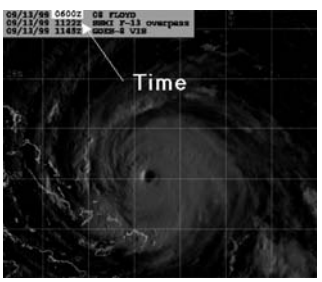

Fig. 1. Hurricane Floyd Z time.

To convert this to ones' local time it is necessary to subtract the appropriate number of hours for the Western Hemisphere or add the correct number of hours for the Eastern Hemisphere (Table 1). And do not forget the extra hour adjustment for Daylight Savings Time or Winter Time over Standard Time for one's zone.

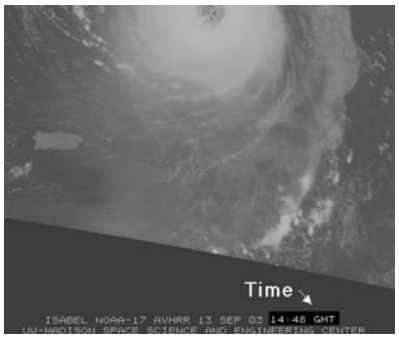

Fig. 2. Hurricane Isabel GMT (Greenwich Mean Time).

TABLE 1. TIME CONVERSION FACTORS

Local Time Zone	Time Adjustment (hours)
Atlantic Daylight Time (ADT)	−3
Atlantic Standard Time (AST) Eastern Daylight Time (EDT)	−4
Eastern Standard Time (EST) Central Daylight Time (CDT)	−5
Central Standard Time (CST) Mountain Daylight Time (MDT)	−6

Western European Time (WET) Greenwich Mean Time (**GMT**)	0

UNIVERSAL TIME (CT). See **Time**.

UNIVERSAL TIME (UT). The basis for civil timekeeping. It is formally defined by a mathematical formula which relates UT to Greenwich mean sidereal time. Depending on the context, universal time and UT are commonly used to mean 1) UT0, which is dependent on the observer's location; 2) UT1, which removes the effect of the motion of the geographic pole; or 3) coordinated universal time (UTC). Since 1 January 1972, weather services have used UTC as the standard of time. See also **Time**; and **Universal Time Coordinated (UTC)**.

UNIVERSE (The). Approximately 15 billion years ago in cosmic history, the first galaxies took shape from vast clouds of early chemical elements.

In the furnace of stars, life-sustaining chemicals such as carbon and oxygen came into being. Then, in awe-inspiring blasts from dying stars, life's chemicals blew out into space, only to condense anew into stars like our sun and planets like Earth.

Through the mixing of these vital chemicals and energy, the living Universe blossomed with the earliest self-replicating organisms and the profusion of life on our planet.

Timeline of the Universe

The 15-billion-year-long history of the Universe shown in Fig. 1 illustrates the major chain of events that eventually led to life on Earth. The sequence starts at upper right with the Big Bang and proceeds counter-clockwise following the arrows to the Chemistry of Life.

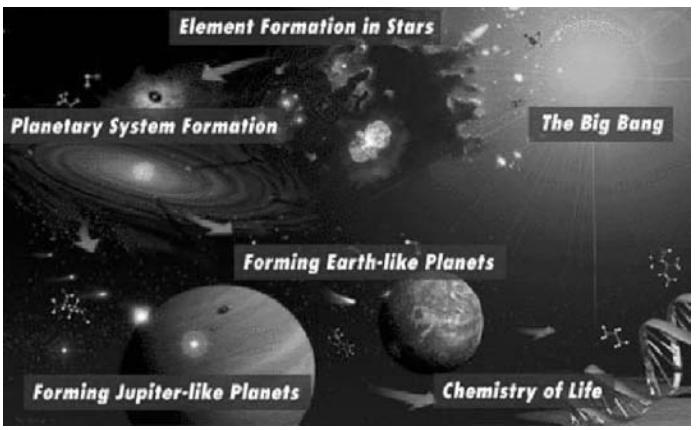

Fig. 1. Timeline of the Universe. (*NASA/Jet Propulsion Laboratory, Pasadena, CA.)*

The Big Bang

Scientists believe that the universe was created about 15 billion years ago in a single violent event known as the Big Bang. All the space, time, energy, and matter that constitute today's universe originated in the Big Bang. The early universe was extremely small, dense, and hot. For the first fraction of a second, only energy existed. See also **Cosmology**.

As the universe expanded and cooled, the four fundamental forces (gravity, electromagnetism, and the strong and weak nuclear forces) became distinct. Quarks, then atomic particles and their antimatter partners, appeared. As matter and antimatter met, they annihilated each other, leaving behind energy and a slight excess of ordinary matter — almost exclusively the lightest elements, hydrogen and helium. The faint residual heat from the Big Bang can be observed coming from everywhere in the sky.

Galaxies. The young universe did not have a perfectly even distribution of energy and particles. These irregularities allowed forces to start to collect and concentrate matter. Accumulations started to develop ever more complicated structures. Concentrations of matter formed into clouds, then condensed into stars and the collections of stars we call galaxies. The way in which galaxies spin indicates that their visible portions of stars and diffuse gas and dust clouds known as nebulae constitute only one tenth of the total mass. The so-called "missing mass" could hold the key to the ultimate fate of the universe — that is whether it expands forever or is pulled back together by the combined gravitational attraction of all of its mass.

From the standpoint of the development of life, what matters is that each galaxy is a stellar factory, producing stars out of giant gas clouds; each star is a chemical factory, transmuting simple elements into heavier, more complex ones; and life is a collection of some of these complex molecules. See Fig. 2. Visible matter comes in a wonderful variety of galaxy forms, characterized by their distributions of stars and glowing or dark nebulae. See also **Galaxy**; and **Nebula**.

Giant Molecular Clouds. The largest inhabitants of galaxies are giant clouds of molecules that contain the raw material for stars and planets. A cloud with a diameter of 300 light years (1 light year is equal to about 10 trillion kilometers) contains enough mass to manufacture 10,000 to a million stars, each with the mass of our Sun. However, only about 10 percent of the cloud will be in clumps dense enough for stars to form — enough to produce a few hundred to a few thousand new stars. Giant molecular clouds last for 10 to 100 million years before they dissipate.

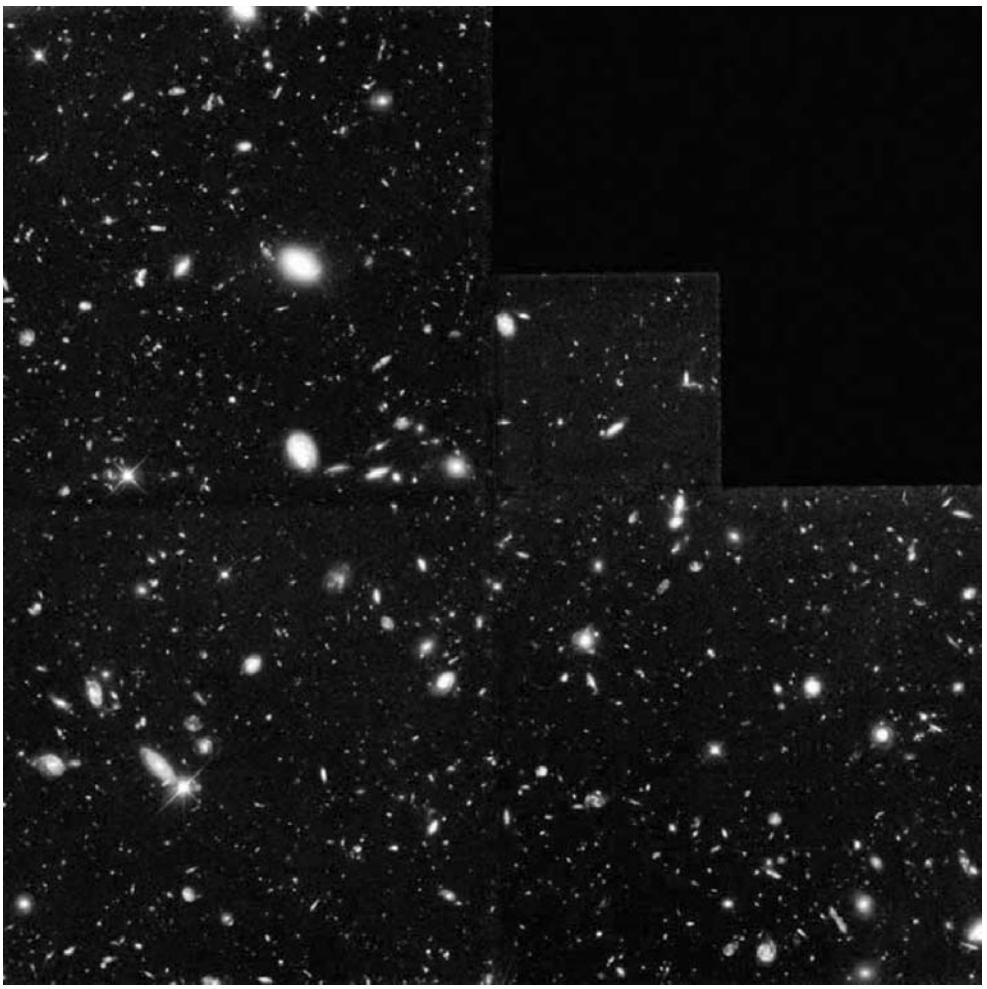

Fig. 2. Distant Galaxies and the Hubble Deep Field. The Hubble Deep Field is our deepest and most detailed look at the horizon of the visible universe. This dark patch of sky was selected by astronomers to be as empty as possible of foreground stars and known clusters of galaxies. This image was constructed from 342 separate Wide-Field Planetary Camera-2 (WFPC2) exposures taken in ultraviolet, blue, red, and infrared light during ten consecutive days of observing in December 1995 by the Hubble Space Telescope (HST). The Hubble Deep Field is located near the handle of the Big Dipper, and its size in the sky would appear to the naked eye about equal to the size of a grain of sand held at arm's length.

The Hubble Deep Field shows over 3000 galaxies at various distances and stages of evolution. There are only four obvious stars visible in the image (they appear as point-like objects with diffraction spikes, can you find them?). The small number of stars is a consequence both of the tiny field of view and of the fact that we are looking up out of the plane of the Milky Way Galaxy. Many different types of galaxies are visible, including spirals like our own, almost featureless ellipticals, and many disturbed-looking "oddballs." Some of these oddball galaxies may be in the midst of titanic collisions with other galaxies, while others are still in the star-forming exuberance of youth.

Astronomers are using the largest telescopes in the world to determine which of the galaxies in the image are relatively nearby and faint, and which are truly at the edge of the visible universe. The light from these farthest galaxies took many billions of years to cross the vast expanse of the universe, and so we are seeing them as they appeared very shortly after they and the universe were born. The Hubble Deep Field therefore promises to become the Rosetta Stone of cosmology, allowing astronomers to answer fundamental questions about the age, size, and composition of the universe. Whatever the answers, the Hubble Deep Field will rank among the greatest scientific treasures of the twentieth century. (*Robert Williams (Space Telescope Science Institute), the Hubble Deep Field Team, and NASA*.)

Element Formation in Stars

Clouds and Star Birth. Gravity acts on individual particles to form collections that attract still more particles. Under the right conditions, gravity can overcome the disruptive forces of heat and turbulence to create spheres of gas that are hot enough and dense enough at their centers so that hydrogen can fuse into helium — creating a star. See Fig. 3. But this new star will probably not yet be apparent in visible light. The young star is surrounded by a dense, opaque shroud of dust. As the star heats the dust, the star becomes detectable by infrared telescopes as a "hot spot" within a large, dense molecular cloud. Winds from the star will eventually blow away residual gas and dust and the star will become visible in optical telescopes.

Mature Stars and Nucleosynthesis. Young stars grow and shrink as they try to strike an evolving balance between gravity, which tries to compress the star, and the pressure from the fusion reactions that try to make the star expand. **Mature stars** have achieved that delicate balance and spend almost their entire lives that way.

A star's size, color, brightness, and life span are the consequence of the total amount of its mass. Stars with only small amounts of material (a few tenths the mass of our Sun) become cool "red dwarfs" that live for many billions of years. Stars with the mass of our Sun last for about 10 billion years. Giant stars, with a few tens of the mass of our Sun, consume their fuel furiously and burn, white-hot, for only a few million years.

Over its entire lifetime, a star's hydrogen is being fused into helium. Late in the star's life, its helium mass becomes great enough to reach the necessary pressure and temperature, and the helium begins to fuse into still heavier elements. Shells of fusion, each requiring higher and higher pressures and temperatures, form from the ashes of the previous reaction and create new elements in the process known as **nucleosynthesis**. The additional heat produced in the core causes the star to swell. See also **Star**.

Star Death and the Distribution of Elements for New Star Systems. Eventually, all stars run out of fuel in their cores. They lose their equilibrium as the force of gravity comes to dominate. Different-mass stars end their lives differently. Low-mass stars die quietly as their nuclear fires

Fig. 3. Star Birth in the Eagle Nebula. These magnificent, pillar-like structures are vast columns of gas and dust in the Eagle Nebula, within which new stars have recently formed. The pillars protrude from the interior wall of a dark molecular cloud like stalagmites from the floor of a cavern. The tallest of the pillars (at left) is about one light year in length from base to tip. The Eagle Nebula is a star-forming region 7000 light years away in the constellation Serpens.

The pillars are in some ways akin to buttes in the desert, where basalt and other dense rock have protected a region from erosion while the surrounding landscape has been worn away. In this celestial setting, especially dense clouds of dust and gas have survived longer than their surroundings as they are flooded by intense ultraviolet light from nearby hot, massive, newborn stars in an erosive process called photoevaporation. The ultraviolet light is also responsible for illuminating the convoluted surfaces of the pillars and the ghostly streamers of gas boiling away from their surfaces.

As the pillars are slowly eroded by the ultraviolet light, small globules of even denser gas and dust buried within the pillars are uncovered. These globules have been named evaporating gaseous globules (EGGs). The term describes their nature, for forming inside some of the EGGs are embryonic stars, which abruptly stop growing when the EGGs are uncovered and separated from the larger reservoir of gas and dust from which they were drawing mass. Eventually, the new-born stars emerge as the EGGs themselves succumb to photoevaporation.

This image has been constructed from three separate WFPC2 exposures taken in the light of emissions from different atomic constituents: red shows emission from singly ionized sulfur atoms, green is emission from atomic hydrogen, and blue shows emission from doubly ionized oxygen atoms. (*J. Hester and P. Scowen (Arizona State University), and NASA*.)

dwindle. The core in a Sun-like star collapses rapidly into an Earth-size white dwarf. The star's outer layers, containing atoms formed in the fusion process, are left as expanding bubbles or jets of material that expand out into the universe. A massive star's core collapses almost instantaneously. It rebounds outward and strikes other material falling inward. This collision occurs with so much energy that it creates all of the naturally occurring elements and blows the star apart. This explosion, a **supernova**, is the source of all the heavy elements that are found in nebulae, stars, planets, and interstellar space. See also **Supernova 1987A and 1993J**.

Deep in cold, interstellar space, elements such as carbon, oxygen, and nitrogen can combine with primordial hydrogen to form complex molecules, particularly in dense condensations of gas called molecular clouds, where collisions between gas atoms and dust grains are possible. A large number of complex molecules, particularly those involving carbon atoms, have been detected in interstellar space.

Planetary System Formation

Photoplanetary Disks. Forming planetary systems may appear as dark or luminous disks silhouetted against a glowing nebula. Others, deeply embedded in their natal clouds, can be seen only in infrared light. Still others show knots of material with long, comet-like streamers formed as an interstellar wind blows the area clear.

These protoplanetary regions are up to 20 times the diameters of our solar system. All the material in a protoplanetary disk spins in the same direction around the star. The disk includes the complex molecules found in the original nebula, plus others that may form as the density and temperature change in the dense regions of the nebula surrounding the star.

Planetesimals Form and Photoplanets Condense. Within the spinning protoplanetary disk, gravity allows clumps to form and grow — creating objects called planetesimals. Heavy metals and silicates can survive the winds and high temperatures found close to the star, but lighter, volatile materials such as water and hydrogen gas survive only in the outer parts of the disks.

Clumps of solid material begin to solidify as they accumulate enough mass; growing larger as the result of collisions. Eventually, a few large objects — protoplanets — will begin to dominate the nebula, accreting more and more of the nebular material as the amount of free dust and gas is steadily reduced. See Fig. 4.

Forming Jupiter- and Earth-like Planets

Very subtle differences in the way mass is distributed in the protoplanetary disk will determine where planets will form and how big they will be.

The rocky and metallic planetesimals in the inner solar system form into Earth-like planets with molten interiors. As these Earth-like planets radiate the heat of compression into space, they form hard crusts. Over long periods of time, they may become solid all the way through. Bombardment by rocky and icy planetesimals disrupts the surface but also delivers elements and molecules, including, most critically from the standpoint of the evolution of life, water.

Predominantly icy objects in the outer solar system form Jupiter-like planets. With or without a rock and metal core, these planets are mostly liquid surrounded by thick gaseous layers; the composition of a Jupiter-like planet is similar to that of its star. These planets, too, are subject to frequent impact by icy and rocky objects.

Chemistry of Life

Found in interstellar space, and therefore in planet-forming nebulae, are complex carbon molecules and amino acids — the building blocks of life. The universe appears to be very well populated with the raw materials to manufacture the deoxyribonucleic (DNA) molecule, the blueprint of all life

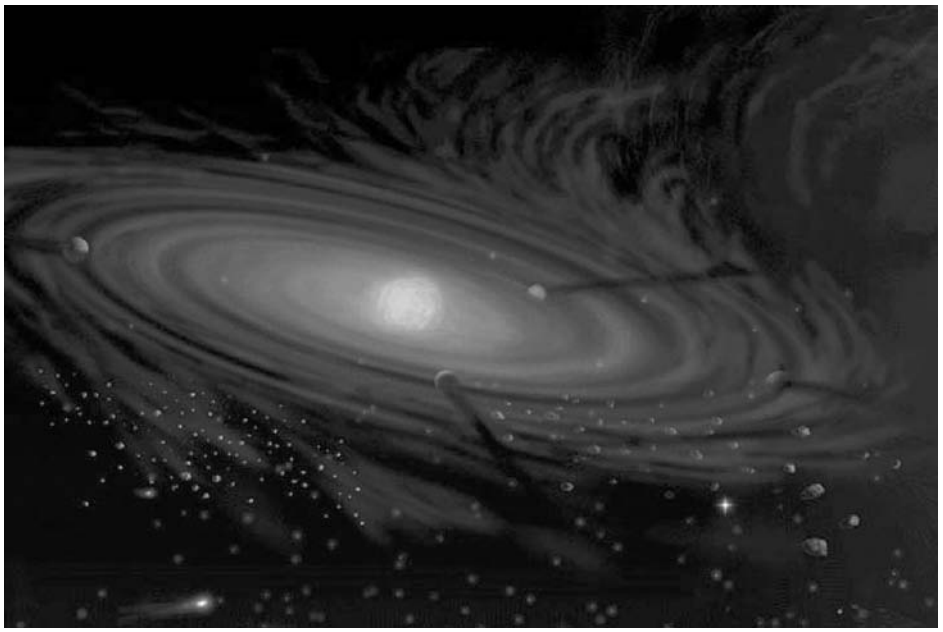

Fig. 4. Artist's conception of the formation of planetesimals within a photoplanetary disk. (*Pat Rawlilngs, for the Jet Propulsion Laboratory.*)

on Earth. However, the method for ensuring that all of the right components find each other in the right quantities and under the right circumstances has yet to be identified. The fact that it happened once, and with such prolific consequences, suggests that in the chain of events described here, the opportunity exists for repeated occurrences of life elsewhere in the universe.

UNSYMMETRICAL BENDING. The condition that exists at any cross section of a flexural member, (see also **Flexure**) when the plane of the loads contains the shear center, but does not coincide with either of the two principal planes of bending, is known as unsymmetrical bending. Under these conditions the flexure formula is not applicable because the neutral axis is not perpendicular to the plane of the loads although it does pass through the center of gravity of the cross section.

The flexural stress due to unsymmetrical bending is found from the formula

$$s = \frac{M \cos\theta y}{I_x} + \frac{M \sin\theta x}{I_y}$$

where s = Flexural unit stress at a point.
M = Bending moment.
x, y = Coordinates of the point taken with respect to the principal axes.
I_x, I_y = Moments of inertia referred to the principal axes.
θ = Angle which the plane of the loads, and hence the plane of the bending moment, makes with the y-axis.

It should be noted that this formula, which is applicable if the stress does not exceed the proportional limit, may be obtained by resolving the bending moment into components parallel to the two axes. The flexure formula is then applied to each of the principal axes and the results combined by the theory of superposition. The simplest way to determine the sign of the resultant stress (+ for tension and − for compression) is to note the sign for bending about each axis and use this sign when combining the results in the formula.

UPLIFT (Hydraulic). If water from a reservoir should work its way between the base of a dam and its foundation, it would exert a pressure upwards against the base of the dam. It would, in the extreme case, equal the full hydrostatic head corresponding to the height of the water surface above the base of the dam. This water pressure is known as uplift, and could possibly overturn a gravity type dam if it were not prevented, or allowed for in the design. Sometimes $\frac{2}{3}$ of the static head is assumed to be acting as uplift. Uplift might be considered to be maximum at the upstream edge of the base, decreasing from that to zero or to a pressure corresponding to the pool elevation at the downstream edge. Where measures are taken to prevent uplift, the foundation must be very thoroughly grouted, cutoff walls must be let into the foundation near the upstream edge of the base, and drains provided to relieve any pressure which might be built up by a slow seepage.

UPPER AIR OBSERVATIONS. To some extent, the practical application of weather satellites has altered the former full dependence upon rockets, balloons, and high-flying aircraft for observations of the meteorological conditions existing in the upper air. However, rockets and balloons still play an important role. Balloons are released at regular intervals by a number of weather stations, many of which are equipped with radiosonde instrumentation. See also **Radiosonde**; and **Weather Technology**.

Meteorological rockets are designed primarily for routine upper-air observation (as opposed to research) in the portion of the atmosphere that is inaccessible to balloons, from about 20 to 60 miles (32 to 96 kilometers) altitude. Upper-air measurements by sounding rocket are made, in the main, by the use of three techniques: (1) Rocket grenades are ejected and exploded at ascending altitudes. Atmospheric temperature and wind characteristics at the successive altitudes are determined from the time and distance data gathered by means of microphones, optical instruments, and

radar equipment on the ground. (2) Tracer elements, such as sodium, are ejected into the air at high altitudes to form luminous clouds or trails, from which observations are made of wind direction and velocity, and wind shear effects. (3) A pitot-static tube, a modification of the pitot tube, is carried at the tip of a sounding rocket. Reactions of various sensitive parts of the tube to atmospheric pressures, ionization, and radiation are telemetered to the ground, and these data are used to calculate atmospheric pressure and density at various altitudes.

UPSIDE-DOWN CATFISH. See **Catfishes**.

UPSILON PARTICLE. As of 1977, when the upsilon particle was discovered at the Fermi National Accelerator Laboratory, the particle was the heaviest to be identified. Discovery of upsilon prompted physicists to introduce a massive new quark, raising the number of quarks from four to five (but probably six). See also **Quarks**. The upsilon has a mass three times greater than any subatomic entity previously detected. It was discovered in energetic collisions between protons and copper nuclei. With a mass at its lower energy state equivalent to 9.0 GeV and masses in excited states equivalent to 10 and 10.4 GeV, the upsilon particle has been interpreted by scientists as consisting of a massive new quark (fifth) bound to its antiquark. The experiment was later reinforced by research at the Deutsches Elektronen-Synchrotron (DESY), located near Hamburg. At Fermilab, the excited upsilon particle appeared as a resonance in the yield of muons generated in collisions between protons and nuclei. A discussion of the upsilon experiment is described by a principal scientist of the project, L.M. Lederman (*Sci. Amer.*, **239**(4), 72–80, 1978). See also **Particles (Subatomic)**.

UPSLOPE FOG. See **Fog and Fog Clearing**.

UPWELLING. An oceanographic phenomenon that involves wind-driven motion of dense, cooler, and usually nutrient-rich water towards the ocean surface, replacing the warmer, usually nutrient-deplete surface water. There are at least five types of upwelling: coastal upwelling, large-scale wind-driven upwelling in the ocean interior, upwelling associated with eddies, topographically-associated upwelling, and broad-diffusive upwelling in the ocean interior.

Coastal upwelling is the best known type of upwelling, and the most closely related to human activities as it supports some of the most productive fisheries in the world, like small pelagics (sardines, anchovies, etc.). Deep waters are rich in nutrients which include nitrate and phosphate, themselves the result of decomposition of sinking organic matter (dead/detrital plankton) from surface waters. When brought to the surface, these nutrients are utilized by phytoplankton, along with dissolved CO_2 (carbon dioxide) and light energy from the sun, to produce organic compounds, through the process of photosynthesis. Upwelling regions therefore result in very high levels of primary production (the amount of carbon fixed by phytoplankton) in comparison to other areas of the ocean. High primary production propagates up the food chain because phytoplankton are at the base of the oceanic food chain. The most important coastal upwelling regions are found in the eastern boundary currents of the subtropical gyres, that is, in the Peru/Chile, California, Benguela, and Canary Currents. The Somali, East Arabian, and South Java Currents develop upwelling on a seasonal basis. See also **Ocean Currents**.

The key piece of physics that gives rise to coastal upwelling is the Coriolis effect, by which wind-driven currents tend to be driven to the right of the winds in the Northern Hemisphere and to the left of the winds in the Southern Hemisphere. For example, in the northern Hemisphere, when winds blow either equatorward along an eastern ocean boundary or poleward along a western ocean boundary, surface waters are driven away from the coasts. Because the surface currents of the Ekman spiral are deflected offshore in these situations, the surface water is drawn away from the coast, causing the colder water from deeper layers to upwell. The associated lowering of the sea surface temperature results in atmospheric heat loss and modifies the local climate.

A related phenomenon is found at the equator (equatorial upwelling). Easterly (westward) winds blowing along the equator in both the Pacific and Atlantic Basins drive water to the right (northwards) in the Northern Hemisphere and to the left (southwards) in the Southern Hemisphere. This again results in a divergence, with denser, nutrient-rich water being upwelled from below, and results in the remarkable fact that the equatorial region in the Pacific can be detected from space as a broad line of high phytoplankton concentration.

Large-scale upwelling is also found in the Southern Ocean. Here, strong westerly (eastward) winds blow around Antarctica,driving a significant flow of water northwards. Since there are no continents in a band of open latitudes between South America and the tip of the Antarctic Peninsula, some of this water is drawn up from great depths. In many numerical models and observational syntheses, the Southern Ocean upwelling represents the primary means by which deep dense water is brought to the surface. Shallower, wind-driven upwelling is also found in the North Atlantic and North Pacific, associated with the counter-clockwise subtropical gyre circulations.

URACIL. See **Cell (Biology)**; and **Nucleic Acids and Nucleoproteins**.

URALITE. A metamorphic mineral. It is well established that pyroxene rocks may be metamorphosed into hornblende rocks. If the hornblende thus produced is fibrous and retains the original form of the pyroxene, it is called uralite, and the process by which the change is brought about chemical process which in many cases is accompanied by the generation chemical process which in many cases is accompanied by the generation of new minerals such as calcite, epidote, and magnetite. Uralite was first observed in rocks from the Ural Mountains, hence its name. See also **Hornblende**.

URANINITE. A mineral approximating the composition UO_2, but containing besides the higher oxide of uranium, UO_3, and oxides of lead, thorium, and rare earths. The uraninite usually occurs as cubic or cubo-octahedral crystals of specific gravity 7.5–10; when in masses of pitchy luster it is called pitchblende, specific gravity 6.5–9. All uraninites and pitchblende contain a minute amount of radium. It was in pitchblende obtained from the Joachimsthal in Czechoslovakia that Mme Curie discovered radium. Other localities for uraninite are in Saxony, Rumania, Norway, Cornwall, East Africa, and in the United States in the pegmatites of Connecticut Grafton Center, New Hampshire, North Carolina, and South Dakota, and in Gilpin County, Colorado. An important occurrence of pitchblende is at Great Bear Lake, Northwest Territories, Canada, where it has been found in large quantities associated with silver.

URANIUM. [CAS: 7440-61-1]. Chemical element symbol, U, at. no. 92, at. wt. 238.03, periodic table group (Actinides), mp 1,131 to 1,133 °C (2,068 to 2,071 °F), bp, 3,927 °C (7,101 °F) density 18.9 g/cm^3 (20 °C). Uranium metal is found in three allotropic forms: (1) *alpha phase*, stable below 668 °C (1,234 °F), orthorhombic; (2) *beta phase*, existing between 668 and 774 °C (1,234 and 1,425 °F), tetragonal; and (3) *gamma phase*, above 774 °C (1,425 °F), body-centered cubic crystal structure. The gamma phase behaves most nearly that of a true metal. The alpha phase has several nonmetallic features in its crystallography. The beta phase is brittle. See also **Chemical Elements**.

Prior to the production of artificially-created elements, uranium was the highest in terms of atomic number and atomic weight. It was difficult to locate uranium in the periodic table of the elements, although chemically uranium resembles the elements of group 6b, namely, chromium, molybdenum, and tungsten. Subsequent to the production of the transuranium elements (atomic numbers 93 through 103), these elements, along with

actinium (89) [CAS: 7440-34-8], thorium (90) [CAS: 7440-29-1], protactinium (91) [CAS: 7440-13-3], and uranium (92) have been placed into the Actinide group of transition elements. They are similar in their mutual relations to the rare-earth group lanthanum (57) [CAS: 7439-91-0] to lutetium (71) 9CAS: 7439-94-3]. See also **Periodic Table of the Elements**.

Earthly abundance of uranium will be described shortly. In terms of presence in seawater, no significant concentrations have been reported. In terms of cosmic abundance, uranium also is very scarce. The study by Harold C. Urey (1952), in which silicon was given a base figure of 10,000, the concentration of uranium was represented by a figure of 0.0002.

Uranium is a white metal, ductile, malleable, and capable of taking a high polish, but tarnishes readily on exposure to the atmosphere. Finely divided uranium burns upon exposure to air, and the compact metal burns when heated in air at 170 °C (338 °F). Uranium metal slowly decomposes water at ordinary temperatures and rapidly at 100 °C (212 °F); is soluble in HCl and in HNO_3; and is unattacked by alkalis. Chemically related to chromium [CAS: 7440-47-3], molybdenum [CAS: 7439-98-7], and tungsten [CAS: 7440-33-7]; and, like thorium, is radioactive. In the radioactive decomposition radium is formed.

Uranium was discovered in a pitchblende [CAS: 1317-75-5] specimen in 1789 by Martin HHeinrich Klaproth who named the element *uranit* after the planet Uranus, which had been discovered eight years earlier by William Herschel. For 50 years the material discovered by Klaproth was thought to be metallic uranium. Péligot showed that the uranit discovered by Klaproth was really uranium dioxide [CAS: 1344-57-6], UO_2, and obtained the true elemental uranium as a black powder in 1841 by reduction of UCl_4 [CAS: 10026-10-5] with potassium [CAS: 7440-09-7].

In 1896, Becquerel discovered that uranium was radioactive (3). Becquerel was studying the fluorescence behavior of potassium uranyl sulfate, and observed that a photographic plate had been darkened by exposure to the uranyl salt. Further investigation showed that all uranium minerals and metallic uranium behaved in this same manner, suggesting that this new radioactivity was a property of uranium itself. In 1934, Fermi bombarded uranium with neutrons to produce new radioactive elements.

Prior to 1939, uranium played no significant role in technical processes, and was only used as a pigment in glass and ceramics. In 1939, Hahn and Strassman reported their discovery of nuclear fission which announced the dawn of the nuclear age. Following this report, uranium gained importance as fuel for nuclear reactors and as starting material for the synthesis of plutonium. There are 19 isotopes of uranium with masses 218, 222, 225–240, and 242 and radioactive half-lives ranging from 1 μs (^{222}U) to, the latter for the main naturally occurring (99.27%) uranium isotope, ^{238}U.

Natural uranium is a mixture of three α-emitting isotopes: ^{238}U (99.274%, half-life of 4.47×10^9 yr, 4.15 MeV α), ^{235}U (0.7202%, half-life of 7.08×10^8 yr, 4.29 MeV α), and ^{234}U (0.0057%, half-life of 2.45×10^5 yr, 4.78 MeV α). Uranium is the progenitor of two naturally occurring decay series, ^{238}U ($4n+2$), shown in Figure 1 and ^{235}U ($4n+3$) which terminates at stable ^{207}Pb. The man-made Np series, which ends in ^{209}Bi, includes ^{233}U. Two of the isotopes of the ^{238}U ($4n+2$) chain, ^{226}Ra and ^{222}Rn, have significant historical and radiological implications. Natural uranium is not highly radioactive in a relative sense; for example, 2800 kg of natural uranium have a radioactivity equivalent to that of approximately one g of radium-226.

Uranium isotopes and their radioactive decay products, from thorium to lead, are used extensively in determining the geochronology and geochemistry of a wide variety of minerals, rocks, and geologic formations. In the uranium decay series (^{238}U parent) eight α-particles are emitted in the decay from ^{238}U to ^{206}Pb. A mineral can thus be dated once the concentration ratios of ^{238}U and He are known. Another common method of dating U-minerals is based on considering the distribution of lead isotopes. Lead has four stable isotopes of which three are end products of radioactive decay series. The fourth isotope, ^{204}Pb, is found in lead minerals in about 1.4% isotopic abundance and has no radiogenic origin.

The U/Pb decay schemes have been used to date the oldest known terrestrial rocks. The types of samples studied using these methods are extensive, including but not limited to archaeological deposits, carbonates and other sediments, pebble conglomerates, zircons, volcanic and pyroclastic rocks, granites, basalts, and uranium ores. For example, uranium-bearing quartz conglomerates have been used to study uranium ore mineralization. The Greenbushes pegmatite is a giant Archean pegmatite dike with substantial Li–Sn–Ta mineralization, including half the world's Ta resource, and was dated utilizing imprecise whole-rock Pb–Pb and precise U–Pb zircon techniques. Uranium oxide ages have been used to study ore formations and uranium mineralization.

Ratios of ^{234}U and ^{238}U to ^{230}Th and ^{226}Ra daughters, combined with differences in chemical reactivity have been used to investigate the formation and weathering of limestone in karst soils of the Jura Mountains, and of the mountains in the central part of Switzerland. Uranium contained within calcite is released during weathering, and migrates as stable uranyl(VI) carbonato complexes through the soil. In contrast, the uranium decay products, Th and Ra, hydrolyze and are strongly sorbed to soil particles and/or form insoluble compounds that become more and more enriched in the soil as a function of time. It is interesting to note that the ratios of ^{234}U and ^{238}U provide information on weathering, because ^{234}U, as the product of a lattice damaging α-decay of ^{238}U, is preferentially leached.

Uranium (^{233}U) is a fissionable isotope of uranium produced artificially by bombarding thorium-232 with neutrons. Used as an atomic fuel in molten salt reactor and is a possible fuel in breeder reactors. Half-life 1.62×10^5 years.

In addition, uranium and lead transport mechanisms in radioactive minerals have been studied in order to evaluate the suitability of mineral phases as hosts for radioactive wastes. Zircon is one of the most commonly used geochronometers, as well as a proposed nuclear waste matrix material, and there are many mechanisms by which uranium and lead can migrate through its structure

Electronic configuration is $1s^2 2s^2 2p^6 3s^2 3p^6 3d^{10} 4s^2 4p^6 4d^{10} 4f^{14} 5s^2 5p^6 5d^{10} 5f^3 6s^2 6p^6 6d^1 7s^2$. Ionic radii U^{4+} 0.89 Å; U^{3+} 1.04 Å (Zachariasen). Metallic radius 1.4318 Å (805 °C). Oxidation potential $U + 2H_2O \rightarrow UO_2^{2+} + 4H^+ + 6e^-$, 0.82 V.

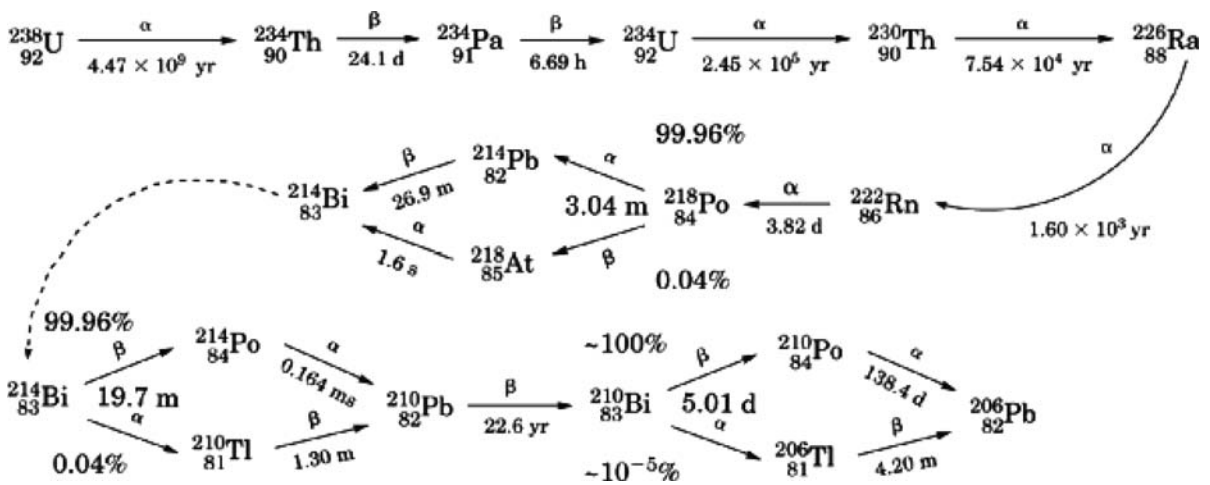

Fig. 1. Uranium-238 decay scheme.

Occurrence in Nature

Uranium is widely distributed in nature. It is found in significant concentrations in rocks, oceans, lunar rocks, and meteorites. Estimates of the concentrations of uranium in various geological matrices are given in Table 1. It can be seen in Table 1 that uranium is present at about 2 ppm in the earth's crust, and is thus more abundant than many other common elements, such as Cd, Ag, Hg, etc. In general, igneous rocks with a high silicate content, such as granite, contain an above average uranium concentration; whereas basic rocks, such as basalts contain a below average uranium content. Sedimentary rocks also generally contain below average uranium concentrations. Despite this low uranium content, sedimentary rocks like sandstones and conglomerates contain approximately 90% of the world's uranium resources.

TABLE 1. OCCURRENCE OF URANIUM IN NATURE

Location	U concentration, ppm
Igneous rocks	
Basalts	0.6
Granites (normal)	4.8
Ultrabasic rocks	0.03
Sandstones, shales, limestones	1.2–1.3
Earth's crust	2.1
Oceanic	0.64
Continental	2.8
Earth's mantle	~0.01
Seawater	0.002–0.003
Meteorites	0.05
Chondrites	0.011
Uraniferous materials	
High grade veins	$(3-8.5)\times10^5$
Vein ores	$(2-10)\times10^3$
Sandstone ores	$(0.5-4)\times10^3$
Gold ores (South Africa)	150–600
Uraniferous phosphates	50–300
Uraniferous granites	15–100
Chattanooga shale (Tenn., U.S.)	60

Uranium resources can be assigned on the basis of their geological setting to fifteen main categories of uranium ore deposit types arranged according to their approximate economic significance: (1) unconformity-related deposits; (2) sandstone deposits; (3) quartz pebble conglomerate deposits; (4) vein deposits; (5) breccia complex deposits; (6) intrusive deposits; (7) phosphorite deposits; (8) collapse breccia pipe deposits; (9) volcanic deposits; (10) surficial deposits; (11) metasomatite deposits; (12) metamorphite deposits; (13) lignite; (14) black shale deposits; and (15) other deposits.

Unconformity-related deposits are found near principal unconformities. Examples include the ore bodies at Cluff Lake, Key Lake, and Rabbit Lake in northern Saskatchewan, Canada, and in the Alligator Rivers area in northern Australia. Sandstone deposits are contained in rocks that were deposited under fluvial or marginal marine conditions. The host rocks nearly always contain pyrite and organic plant matter. The sediments are commonly associated with tuffs. Unoxidized deposits of this type consist of pitchblende and coffinite in arkasoic and quartzitic sandstones. Upon weathering, secondary minerals such as carnotite, tuyamunite, and uranophane are formed. More information on these and other uranium deposit types is available.

Approximately 155 minerals are known that contain uranium as an important, or major constituent, and another 60 that contain minor amounts of uranium, or contain uranium as an impurity. Uranium minerals can be divided into two mineral classes, primary and secondary. Primary uranium minerals are those that formed during the last stages of magma crystallization, and are rich in silicates such as quartz and feldspar. Primary uranium minerals include uraninite [CAS: 1317-99-3], pitchblende [CAS: 1317-75-5], and a large number of complex multiple oxides such as uranium-containing lanthanide niobates, tantalates, and titanates. Uraninite and pitchblende are very important uranium minerals with a composition that varies from UO_2 to $UO_{2.67}$ and are found in veins, pegmatites, and unweathered portions of conglomerate and sandstone ores which contain the bulk of the world's economic uranium deposits. Secondary uranium minerals are produced by hydration, metathesis, oxidation or possibly transport and redeposition. Primary minerals are generally black and contain uranium in an average oxidation state less than VI, while secondary minerals are generally yellow, green, or orange, and contain uranium in the hexavalent state. Uraninite can be considered both a primary and secondary mineral, and there are a wide variety of theories regarding the mechanism of formation of uraninite veins.

The Oklo Phenomenon. Naturally occurring uranium consists mainly of ^{238}U and fissionable ^{235}U. The isotopic ratio can be calculated from the relative decay rates of the two isotopes. Because ^{235}U decays faster than ^{238}U, the isotopic ratio decreases with time. In 1997, the isotopic abundance of ^{235}U in natural uranium is $0.7202 \pm 0.006\%$. In 1972, uranium samples from the Oklo open-pit uranium mine in southeastern Gabon Republic were found to be depleted in ^{235}U, relative to the expected natural isotopic composition. The levels of ^{235}U depletion were inhomogeneous throughout the ore body, with the lowest isotopic ratio 0.296%. After much study, it was determined that the uranium ore deposit at Oklo was the site of at least six natural nuclear reactors. Geochemical reactions (weathering) and geological changes created different regions enriched and depleted in uranium, and at that time in geologic history the ^{235}U enrichment was estimated to be approximately 3%, the same as used in commercial nuclear reactors. Under these conditions, a critical mass could be attained and a nuclear fission reaction initiated with groundwater or water in the clays as a neutron moderator. The chain reaction is thought to have cycled. As the reaction heated up, water would be driven away thereby slowing the reaction. As the reaction cooled, water could return, thereby slowing the neutrons and starting the chain reaction all over again. The identification of fission products in the proper ratios, and differing from that expected for natural occurrence, gave unequivocal evidence that a nuclear chain reaction had taken place. In addition to the purely scientific interest, the Oklo phenomenon has also led to a better understanding of environmental migration of radioactive materials. As such, the information attained at Oklo is of great importance in understanding the aqueous transport and redistribution of uranium as it pertains to the safe disposal of radioactive waste.

Uranium Reserves. During the past few decades, the construction of new nuclear power reactors in the United States has been limited, although this does not hold for France and some other countries. As with any nonrenewable fuel, there is concern over some ultimate date in the future when the supply may approach exhaustion. As of the early 1990s, with a new period of calm prevailing pertaining to the need for construction of nuclear weaponry, forecasts of useable uranium reserves made in earlier years no longer hold, and revised forecasts are lacking. In terms of current usage of uranium, there are several avenues available for conserving the fuel.

1. *Improvement of uranium efficiency in thermal reactors* which consume more fissionable material than they breed. If it is assumed that on average a typical light-water reactor (LWR) is operated at 75% total capacity (load factor = 0.75), it will consume about 6000 tons of U_3O_8 per gigawatt of electrical output GWe over an expected 30-year reactor life. During this period, the reactor will produce about 5 tons of fissile plutonium, which is discharged in the spent fuel. In the past, minimal consumption of uranium has not been a major design goal. Improvements in reactors (not requiring major alterations) could effect savings of from 10 to 15% in uranium consumption even without considering fuel recycling. For example, simply enriching the level of U-235 from 3 to 4.2% would allow the fuel to remain in the reactor for 5 years instead of the usual 3 years. As pointed out by Hafenmeister (California Polytechnic University), the longer residence time and the higher enrichment would allow a greater fraction of the U-235 to be used, increasing the in situ generation and burning of plutonium, while at the same time reducing the discharge of plutonium by 30% (from 5 to 3.5 tons over lifetime of the reactor). If the burn-up of fuel is increased from the traditional 30,000 to 50,000 megawatt-days per ton, the level of U-235 in the discharged fuel is reduced from 0.85% to 0.71%, and refueling can be considered either on a 12- or an 18-month cycle.

2. *Design changes in new reactors can conserve uranium*. Traditional LWRs use control poisons such as boric acid in the reactor coolant as a means to reduce reactivity. This practice results in a waste of from 5 to 10% of available neutrons. Newer designs which would allow faster and more frequent refueling could reduce the need for such poisons and consequent loss of neutrons. Such changes could result in a saving of some 25% of the fuel required.
3. *Reprocessing of spent fuel and blanket materials*, with the recovery of purified uranium and plutonium, could effect another fuel savings of nearly 20%. Such reprocessing not only would conserve the U_3O_8 supply, but would also alleviate a severe nuclear waste problem. As described in the entry on **Nuclear Power Technology**, the spent-fuel storage facilities at existing nuclear power facilities already have reached or are rapidly approaching their full capacity, and new storage systems must be developed. Processes for spent-fuel recovery are described in the next section of this article. The principal deterrent to reprocessing is concern with "nuclear proliferation." In the most straightforward reprocessing scheme, plutonium is recovered along with uranium. Plutonium is the primary ingredient of nuclear weapons. Contemporary nuclear power plants operating in a number of countries do not yield plutonium in a form useful for weapons production, whereas a fuel reprocessing scheme would.
4. *Extending uranium supplies by using thorium in LWRs*. Instead of using boron as a poison in the coolant, 40% heavy water (D_2O) could be used along with thorium. Hafemeister observes that the heavier D_2O in this "spectral shift control reactor" would result in breeding and then burning more plutonium from the fertile U-238. It is estimated that the savings would be about 12% of the U_3O_8 when compared to the LWR on a conventional uranium cycle; and about 20% of the U-233 required for a LWR on a thorium cycle. The Canada Deuterium Uranium (CANDU) power reactors are described under "Heavy Water Reactor" in the entry on **Nuclear Power Technology**. This means of uranium conservation, of course, would require large capital expenditures.
5. *Fast breeder reactors*. These reactors (FBRs) produce more fissionable material during operation than is originally furnished. A number of nations are interested in the FBR as a means of extending their available uranium. Plutonium is more valuable in an FBR because it raises breeding ratios by 10 to 20% when compared with U-235. But, as pointed out in the entry on **Nuclear Power Technology**, the FBR essentially remains in the design and development stage. In terms of nuclear proliferation, uranium has an advantage over plutonium because isotopic enrichment is necessary to obtain weapons-usable material from a fuel containing both U-233 and U-238, whereas only chemical separations are required to purify plutonium from a fuel containing plutonium and uranium.

Uranium Spent-Fuel Reprocessing

In the PUREX process, the spent fuel and blanket materials are dissolved in nitric acid to form nitrates of plutonium and uranium. These are separated chemically from the other fission products, including the highly radioactive actinides, and then the two nitrates are separated into two streams of partially purified plutonium and uranium. Additional processing will yield whatever purity of the two elements is desired. The process yields purified plutonium, purified uranium, and high-level wastes. See also "Radioactive Wastes" in the entry on **Nuclear Power Technology**. Because of the yield of purified plutonium, the PUREX process is most undesirable from a nuclear weapons proliferation standpoint.

In a modified PUREX process (sometimes called coprocessing), the plutonium and uranium are not handled separately as their nitrates, but rather they are processed together, yielding plutonium diluted with uranium. The diluted product is useful for nuclear reactors, but not directly usable for nuclear weapons.

In the CIVEX fuel reprocessing system, most of the uranium is separated and purified from the spent nuclear reactor fuel, while some of the fission fragments, some of the uranium, and all of the plutonium are handled together. The system thus yields a fuel containing some of all three materials. The fission products render the fuel unsafe for any but sophisticated handling for a period of at least one year. The plutonium does not exist in high concentrations. Hafemeister (1979) observes that the costs of remote fabrication for CIVEX make it potentially attractive only for nations with large breeder reactor programs. In addition, the fission products in CIVEX fuels would, to some extent, act as poisons in thermal reactors, reducing the flow of neutrons.

Uranium Exploration and Mining

The exploration and mining of radioactive ores in the United States began around the turn of the 20th century. Sources for radium (contained in uranium ore) were sought for use as luminous paint for watch dials and other instruments, as well as for health-related applications (some of which in retrospect were incredibly unhealthy). Because of the need for the element during World War II, the Manhattan Project contracted with numerous vanadium mining companies in the American Southwest, and also purchased uranium ore from the Belgian Congo, through the Union Miniére du Haut Katanga, and in Canada from the Eldorado Mining and Refining Limited company, which had large stocks of uranium as waste from its radium refining activities. American uranium ores mined in Colorado were primarily mixes of vanadium and uranium, but because of wartime secrecy the Manhattan Project would only publicly admit to purchasing the vanadium, and did not pay the uranium miners for the uranium ore (in a much later lawsuit, many miners were able to reclaim lost profits from the U.S. government). American uranium ores did not have nearly as high uranium concentrations as the ore from the Belgian Congo, but they were pursued vigorously to ensure nuclear self-sufficiency. Similar efforts were undertaken in the Soviet Union, which did not have native stocks of uranium when it started developing its own weapons program.

Australia has the world's largest uranium reserves –28 per cent of the planet's known supply. Almost all the uranium is exported, but under strict International Atomic Energy Agency safeguards to satisfy the Australian people and government that none of the uranium is used in nuclear weapons. Australian uranium is used strictly for electricity production.

The Olympic Dam operation run by BHP Billiton in South Australia is combined with mining of copper, gold, and silver, and has reserves of global significance. There are three uranium mines in Australia, but more have been proposed. The most controversial was Jabiluka, to be built inside the World Heritage listed Kakadu National Park.

In spite of Australia's huge reserves, Canada remains the largest exporter of uranium ore with mines located in Athabasca basin in northern Saskatchewan. Cameco, the world's largest, low-cost uranium producer accounting for 18% of the world's uranium production, operates 3 mines in the area.

Processing of Uranium Ores

The extraction of uranium from ores varies widely, and depends on the nature of the ore involved. The ore may vary from hard, igneous rock to soft, weakly cemented sedimentary rock. The principal gangue mineral may be quartz, which is chemically inactive, or an acid-consuming mineral, such as calcite. Some ores are highly refractory and require intensive processing, whereas others break down between the mine and the mill. In order to recover the uranium from ores, a series of steps is often required including crushing and concentrating by conventional physical means; roasting and leaching the ore with acid in the presence of an oxidant to ensure conversion to $UO2+_2$; recovery of the uranium from the leach solution, and refining to a high purity product.

Preconcentration of uranium ores by methods based on gravity, magnetic, or electrical properties, or by flotation have not been generally successful because of the softness of the raw materials and the absence of differing physical properties among the constituents. Thus, treatment has involved the whole ore wherein an extractant has been used. The uranium is recovered from solution after appropriate solid-liquid separations. Either an acid or alkaline extractant can be used. The extraction is enhanced by use of fine grinding of the ore, by increasing the concentration of extractant, and by using higher temperatures and oxidizing agents. The uranium can be separated from the inert material by solid-liquid separation, filtration, or countercurrent washing. The uranium is recovered from solution by treatment with ion-exchange resin or solvent extraction. Alkaline leaching predominates over the acid process. The process is illustrated and briefly described in the Fig. 2. The uranium concentrate produced requires

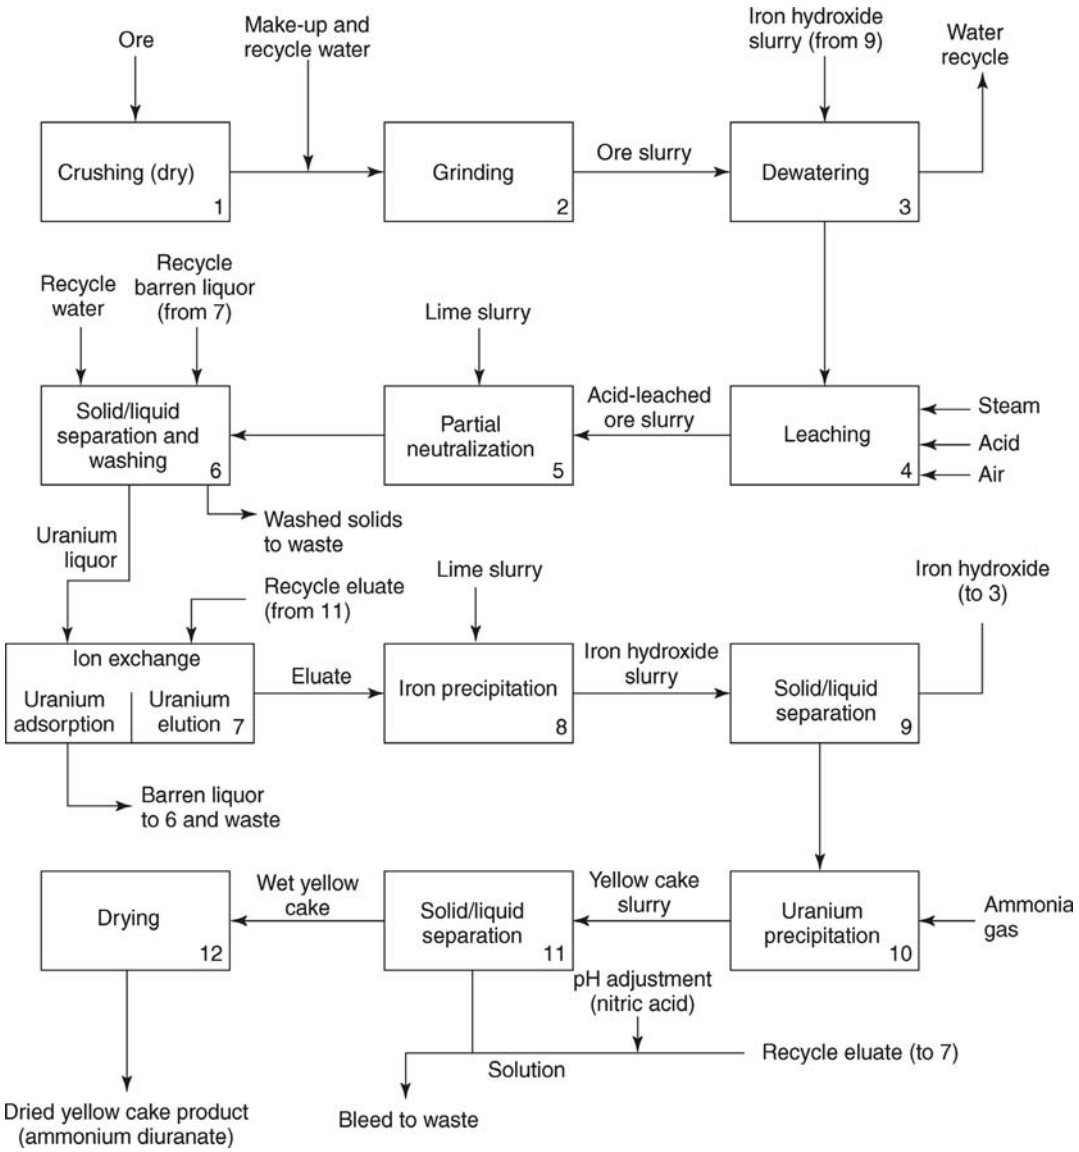

Fig. 2. Schematic flowsheet of uranium processing (acid leach and ion exchange) operation. Numbers refer to the numbers that appear in the boxes on the flowsheet. Operations (3), (6), (9), and (11) may be done by thickening or filtration. Most often, thickeners are used, followed by filters. The pH of the leach slurry (4) is elevated to reduce its corrosive effect and to improve the ion-exchange operation on the uranium liquor subsequently separated. In the ion exchange operation (7), resin contained in closed columns is alternately loaded with uranium and then eluted. The resin adsorbs the complex anions, such as $UO_2(SO_4)_3^{4-}$, in which the uranium is present in the leach solution. Ammonium nitrate is used for elution, obtained by recycling the uranium filtrate liquor after pH adjustment. Iron adsorbed with the uranium is eluted with it. Iron separation operation (8) is needed inasmuch as the iron hydroxide slurry is heavily contaminated with calcium sulfate and coprecipitated uranium salts. Therefore, the slurry is recycled to the watering stage (3). Washed solids from (6), the waste barren liquor from (7), and the uranium filtrate from (11) are combined. The pH is elevated to 7.5 by adding lime slurry before the mixture is pumped to the tailings disposal area. (Rio Algom Mines Limited, Toronto.)

additional refining before fabrication into a fuel for nuclear reactors. Generally, this is accomplished by dissolving the product in HNO_3, filtering, and treating the uranyl nitrate solution by solvent extraction methods.

Uranium Compounds

Oxides. Oxides of uranium are some of the most prevalent and technologically important binary uranium compounds known. Numerous oxide phases have been observed and characterized, including uranium oxide [CAS: 12035-97-1], UO, UO_2 [CAS: 1344-57-6]; U_4O_9 [CAS: 12037-15-9]; U_3O_7 [CAS:1203-04-6]; U_3O_8 [CAS: 1344-59-8]; UO_3 [CAS: 1344-58-7]; hydrated species such as $UO_3{\cdot}xH_2O$ and the peroxo complex, $UO_4{\cdot}xH_2O$; and anionic uranates including $[U_2O_7]^{2-}$ [CAS: 85096-44-2] and $[U_4O_{13}]^{2-}$ [CAS: 128085-85-8]. Of these oxide phases, UO_2, U_3O_8, and UO_3 are extremely important both industrially and in the nuclear energy cycle.

Uranium dioxide [CAS: 1344-57-6], UO_2, is found in nature as the mineral pitchblende and as a component in uraninite. The crystalline solid melts at 2878 °C and is paramagnetic with a room temperature magnetic moment of 3.2 μ_B. The density has been found to range from 10.79 to 10.95 g/cm^3, lower values are observed for hyperstoichiometric complexes, UO_{2+x}. Industrially, UO_2 is prepared by the decomposition of ammonium uranyl carbonate on the scale of 10 kg/d, using a fluidized-bed furnace. In addition to the industrial process, pure UO_2 has been synthesized by (1) oxidation of uranium metal, (2) reduction of higher valent oxides, (3) thermal decomposition of uranyl uranates, (4) oxidation or reduction of uranium halides, (5) decarboxylation of uranium compounds of carbonic acids, (6) hydrometallurgical preparation, and (7) electrolysis of uranium halides. Single crystals of UO_2 have been grown by a variety of techniques, including vapor or electrolytic deposition from salt melts or vapor deposition on ionic substrates. The nature of the bonding in UO_2 is best described as ionic. The x-ray analysis of the stoichiometric complex

reveals a face-centered cubic CaF_2 type structure, with the uranium atoms occupying the face-centered sites. Hyper- and hypostoichiometric, UO_{2+x} and UO_{2-x}, respectively, are also known and have been analyzed by x-ray crystallography. In the case of the UO_{2+x}, extra oxygen atoms occupy central lattice holes in the normal UO_2 structure. For the hypostoichiometric complex, the structure indicates the presence of layers of UO_2 and UO.

The main technological uses for UO_2 are found in the nuclear fuel cycle as the principal component for light and heavy water reactor fuels. Uranium dioxide is also a starting material for the synthesis of UF_4 [CAS: 10049-14-6], UF_6 [CAS: 7783-81-5] (both critical for the production of pure uranium metal and isotopic enrichment), UCl_4 [CAS: 10026-10-5], and $UO_2(NO_3)_2{\cdot}6H_2O$ [CAS: 10102-06-4]. In order to be useful as a nuclear fuel, the material must have certain physical and chemical properties in the reactor temperature range, ie, small coefficients of linear and volume expansion, reasonable heat conductivity, and chemical stability. Uranium dioxide has been found to exhibit a majority of these desirable properties with an average thermal coefficient of expansion of 10.8×10^{-6} (20–946 °C (68–1,735 °F), specific heat from 0.237 to 0.338 J/gK (300–1,773 °C (572–3,223 °F), and a thermal conductivity of 8.281 to 2.353 W/mK (300–1773 °C) at 0 atomic % burnup UO_2. The sintered complex has also been found to be chemically stable toward air and H_2O up to 300 °C (572 °F).

Triuranium octaoxide [CAS: 1344-59-8], U_3O_8, is a greenish black material which is also a constituent of pitchblende. This complex has been identified with a number of different oxygen deficiencies, depending mostly on the temperature and partial pressure of O_2 used in the preparation. From 900 to 1,500 °C (1,652 to 2,732 °F), the oxide decomposes prior to melting or subliming to form gaseous UO_3. The preparation of U_3O_8 has been accomplished by a variety of means, including thermal decomposition of $(NH_4)_2U_4O_{13}$ [CAS: 129002-73-9], $UO_4{\cdot}xH_2O$ [CAS: 12036-71-4], and $UO_2(NO_3)_2{\cdot}6H_2O$ [CAS: 10102-06-4] at 600 °C (1,112 °F), the oxidation of UO_2 under streaming O_2 at 600 °C, and the reduction of UO_3 at high temperatures (600–800 °C (1,112–1,472 °F) under streaming oxygen. Industrially, U_3O_8 has been shown to be active in the decomposition of organics, including benzene and butanes and as supports for methane steam reforming catalysts. In the nuclear fuel industry, U_3O_8 is an oxidation product of UO_2 (SIMFUEL), and thus, a large component of spent fuel rods.

Uranium trioxide [CAS: 1344-58-7], UO_3, is a versatile solid that also has important applications in the nuclear fuel cycle. The trioxide has been isolated in six well-defined stoichiometric modifications as well as a hypostoichiometric modification, $UO_{2.9}$. Similar to U_3O_8, the trioxide decomposes into lower oxides prior to melting or subliming. Even though UO_3 is formally U(VI), a small temperature-dependent paramagnetism exists with molar magnetic susceptibility values ranging from 128 to 157×10^{-6} cm^3/mol. A general trend has been observed for the densities of uranium oxides; an inverse proportionality between the O/U ratio and the density of the material. The trioxide does not deviate from this trend with density values ranging from 6.99 to 8.54 g/cm^3, depending on the modification. The preparation of UO_3 has been accomplished by a variety of means. Industrially, the complex is prepared by three main routes, thermal decomposition of UO_4xH_2O [CAS: 12036-71-4], $(NH_4)_2U_4O_{13}$ [CAS: 128085-85-8], or $UO_2(NO_3)_26H_2O$ [CAS: 10102-06-4] under O_2. For the latter complex, the techniques utilized to accomplish the decomposition include batch decomposition, continuous stirred-bed, fluidized bed, and spray decomposition. The trioxide can also be synthesized by the oxidation of lower oxides, UI_3 [CAS: 13775-18-3] (low temperature), UI_4 [CAS: 13470-22-9] (low temperature), UC [CAS: 12070-09-6], or UN [CAS: 25658-43-9] with O_2, and by the calcination of $(NH_4)_4UO_2(CO_3)_3$ [CAS: 17872-00-3].

The most important role of UO_3 is in the production of UF_4 [CAS: 10049-14-6] and UF_6 [CAS: 7783-81-5], which are used in the isotopic enrichment of uranium for use in nuclear fuels. The trioxide also plays a part in the production of UO_2 for fuel pellets. In addition to these important synthetic applications, microspheres of UO_3 can themselves be used as nuclear fuel. Fabrication of UO_3 microspheres has been accomplished using sol-gel or internal gelation processes. Finally, UO_3 is also a support for destructive oxidation catalysts of organics.

Nitrides. Uranium nitrides are well known and are used in the nuclear fuel cycle. There are three nitrides of exact stoichiometry, uranium nitride [CAS: 25658-43-9], UN; U_2N_3 [CAS: 12033-85-1]; and U_4N_7 [CAS: 12266-20-5]. In addition to these, nonstoichiometric complexes, U_2N_3+, where the N/U ratio ranges from 1.64 to 1.84, have been identified. The brown mononitride, which is the only nitride complex stable above 1,300 °C (2,372 °F), melts at 2,600 °C (4,712 °F). Uranium mononitride is the densest of the nitrides with a density of 14.31 g/cm^3. The magnetic properties of the nitrides are extremely dependent on the phase and stoichiometry of the complex. Classically, the different nitrides have been prepared from direct interaction of the elements under the appropriate conditions. A number of alternatives to this preparation have been investigated, including uranium metal under static NH_3 at 300–350 °C (572–662–F) to yield U_2N_3, uranium metal or uranium carbides with NH_3 or N_2 at 600–900 °C (1,112–1,652 °F) to produce U_2N_{3+x}, uranium carbide fuels reacted with N_2/H_2 to form UN, and a self-propagating metathetical reaction, thermolysis at 500 °C (932 °F) of UCl_4 [CAS: 10026-10-5] with Li_3N, yielding UN and U_2N_3.

Carbides. Uranium carbides, UC [CAS: 12070-09-6], U_2C_3 [CAS: 12076-62-9], and UC_2 [CAS: 12071-33-9] are all dark gray solids with a metallic luster. In addition to these binary materials, numerous mixed uranium–plutonium and uranium–transition-metal carbides have been prepared and are mainly utilized in nuclear fuel. The melting points of UC and U_2C_3 are 2,400 °C (4,352 °F) and 2,417 °C (4,480 °F), respectively, and the dicarbide melts at 2,475 °C (4,487 °F) and boils at 4370 °C (760 mm Hg). The monocarbide is the most dense of the carbide series with a room temperature density of 13.60 g/cm^3, whereas U_2C_3 and UC_2 have densities of 12.85 g/cm^3 and 11.69 g/cm^3, respectively. The magnetic properties of the carbides are extremely composition dependent. All three materials are paramagnetic at room temperature, with U_2C_3 becoming antiferromagnetic at low temperatures. The typical techniques involved in the synthesis of the carbides include the reaction of carbon or hydrocarbons with uranium metal or UH_3 [CAS: 13598-56-6] at elevated temperature, precipitation from metal melts, and reduction of uranium halides.

As previously stated, uranium carbides are used as nuclear fuel. Two of the typical reactors fueled by uranium and mixed metal carbides are thermionic, which are continually being developed for space power and propulsion systems, and high temperature gas-cooled reactors. In order to be used as nuclear fuel, carbide microspheres are required. These microspheres have been fabricated by a carbothermic reduction of UO_3 and elemental carbon to form UC. In addition to these uses, the carbides are also precursors for uranium nitride based fuels.

Oxo Ion Salts. Salts of oxo anions, such as nitrate, sulfate, perchlorate, iodate, hydroxide, carbonate, phosphate, oxalate, etc, are important for the separation and reprocessing of uranium, hydroxide, carbonate, and phosphate ions are important for the chemical behavior of uranium in the environment.

Nitrate complexes are very weak, and the determination of the formation constants for aqueous nitrate solution species is extremely difficult. There appears to be reliable thermodynamic data only for the formation of $UO_2(NO_3)^+$. Although determination of the formation constants is complicated, there is little doubt that under high nitric acid conditions, $UO_2(NO_3)_2$, and perhaps $UO_2(NO_3)_3^-$ are formed, at least to some extent. Solid uranyl nitrate [CAS: 10102-06-4], $UO_2(NO_3)_2{\cdot}xH_2O$, is obtained as the orthorhombic hexahydrate from dilute nitric acid solutions, and as the trihydrate from concentrated acid. The melting point of the hexahydrate is at 118 °C (244 °F). Uranyl nitrate plays an important role in the reprocessing of uranium in spent fuel and in uranium extraction from aqueous solutions.

The aqueous uranyl sulfate system has been extensively studied and complexes of formula $UO_2(SO_4)_n^{2n-2}$, where $n = 0$, 1, and 2, are likely to be formed in solution. Quantitative data only exists for the formation of complexes with $n = 0$ and 1. $UO_2(SO_4)_2{\cdot}xH_2O$ (x =1, 2, 2.5, 3, or 4) can be precipitated from aqueous solutions as the trihydrate. The monohydrate and the anhydrous salt can be obtained by dehydration of the trihydrate. The fluorosulfate, $UO_2(SO_3F)_2$ [CAS: 75357-79-8], is obtained by treating $UO_2(MeCO_2)_2$ [CAS: 541-09-3] with HSO_3F. A large number of ternary U(VI) sulfates of the general formula $(M)_k(UO_2)_m(SO_4)_n{\cdot}xH_2O$, where M=monovalent cation, ie, NH_4 or alkali metals, $M(UO_2)_m(SO_4)_n{\cdot}xH_2O$, where M=bivalent cation, such as alkaline-earth or transition metals (Mn, Cd, Hg), have been reported. A layered structure is observed for $(NH_4)_2UO_2(SO_4)_22H_2O$ [CAS: 12357-71-0] with local pentagonal

biypyramidal coordination around the U atom, and bridging sulfate groups joining the uranyl polyhedra. In $K_4UO_2(SO_4)_3$ [CAS: 69567-87-9] each uranium in the pentagonal bipyramid is coordinated to five oxygen atoms from four sulfate groups in the equatorial plane.

The U(IV) sulfate system has also been studied in strong acid solutions, and quantitative data are only available for $U(SO_4)^{2+}$ and $U(SO_4)_2$. Solids of composition $U(SO_4)_2 8H_2O$ [CAS:14355-39-6] and $U(SO_4)_2 4H_2O$ can be precipitated from weak and concentrated sulfuric acid solution, respectively. In neutral solution the basic salt, $UOSO_4 2H_2O$ [CAS: 18902-45-9], is formed. The octahydrate looses four hydration waters at 70 °C (158 °F), the remaining four molecules of water can be removed at temperatures over 400 °C (752 °F). In $U(SO_4)_2 4H_2O$ the uranium atoms are surrounded by a square antiprism of O atoms, with each U bonded to four molecules of water and linked by bridging sulfate groups to other uranium atoms. Several U(IV) fluorosulfates have been obtained involving mono- and bidentate SO_3F^- groups as reported for $U(SO_3F)_4$.

Crystals of uranyl perchlorate, $UO_2(ClO_4)_2 xH_2O$ [CAS: 13093-00-0], have been obtained with six and seven hydration water molecules. The uranyl ion is coordinated with five water molecules in the equatorial plane with a U–O(aquo) distance of 245 nm (2.45 Å). The perchlorate anion does not complex the uranyl center. The unit cells contain two $[ClO_4]^-$ and one or two molecules of hydration water held together by hydrogen bonding.

Isotope Enrichment

Uranium-235 Enrichment. The enrichment of uranium is expressed as the weight percent of ^{235}U in uranium. For natural uranium the enrichment level is 0.72%. Many applications of uranium require enrichment levels above 0.72%, such as nuclear reactor fuel. Normally for lightwater nuclear reactors (LWR), the 0.72% natural abundance of ^{235}U is enriched to 2–5%. There are special cases such as materials-testing reactors, high flux isotope reactors, compact naval reactors, or nuclear weapons where ^{235}U enrichment of 96–97% is used.

Uranium isotope enrichment can be achieved in a number of ways. At the time of writing, the methods that have been, or are currently in use include gaseous diffusion, gaseous centrifugation, electromagnetic separation, chemical exchange, laser photoionization and photodissociation, separation nozzle, and cyclotronic resonance isotope separation. Most of these processes are of historical significance, and have been described. The gaseous diffusion and centrifugation processes (GDP and GDC) are the only methods employed on an industrial scale in the United States and Europe. Vigorous research programs are under way in the United States, France, and Japan, for a new industrial technique known as atomic-vapor laser isotope separation (AVLIS, or SILVA in France). The AVLIS process is expected to have a lower cost per separative work unit (SWU) than the diffusion process for uranium enrichment.

The gaseous diffusion method of isotope separation is based upon the difference in the rate of diffusion of gases that differ in density. Since the rate of diffusion of a gas is inversely proportionate to the square root of its density, the lighter of two gases will diffuse more rapidly than the heavier. Therefore, the result of a partial diffusion process will be an enrichment of the partial product in the lighter component.

To separate isotopes by this process, they must be in the gaseous form. Therefore, the separation of isotopes of uranium required the conversion of the metallic uranium into a gaseous compound, for which purpose the hexafluoride, UF_6, was chosen. Since the atomic weight of fluorine is 19, the molecular weight of the hexafluoride of ^{235}U is $235+(6 \times 19) = 349$, and the molecular weight of the hexafluoride of ^{238}U is $238+(6 \times 19) = 352$. Since the rate of diffusion of a gas is inversely proportional to the square root of its density (mass per unit volume), the maximum separation factor for one diffusion process of the uranium isotopes is $\sqrt{352/349} = 1.0043$. Since only part of the gas can be allowed to diffuse, the actual separation factor is even less than this theoretical maximum.

From this small figure, it is apparent that many diffusion stages are necessary in the separation of ^{235}U from ^{238}U. The number originally calculated for the Oak Ridge plant was about 4,000. Other reasons are the small apertures demanded by diffusion processes (in this case less than 00001 centimeter in diameter), which reduce the rate of gas flow and demand a great barrier area for appreciable production.

The centrifugal method of isotope separation consists essentially of the passage of the mixture through a rapidly rotating force field, such as that of a rotating cylinder. If a current of mixed gases is passed into such a cylinder, moving parallel to the axis of rotation, the lighter gas will tend to concentrate near the axis, and the heavier gas, near the periphery. This is the principle of the cream separator; its successful application to separation of isotopes in the gaseous phase requires apparatus operating at very high speeds of rotation.

The electromagnetic method of isotope separation is based upon the principle of the mass spectrograph. As in that apparatus, a stream of charged particles is passed through a system of electric and magnetic fields. If the particles are ions of two or more isotopes of the same element, all bearing the same charge, the deflections produced by the fields will vary with the masses of the particles, and will thus provide a means for their separation. This method is especially effective for the separation of particles of a number of masses, and has been widely used for that purpose in research studies and in production-separation operations. The method is also used extensively in a number of research laboratories, particularly those of northern Europe, for the isotopic separation of individual radioactive nuclides that are to be used as sources in instruments, such as beta- and gamma-ray spectrometers, in which measurements are made of the characteristics of ionizing radiations.

The thermal diffusion method of isotope separation has broad application to liquid-phase as well as gaseous-phase separations. The apparatus widely used for this purpose consists of a vertical tube provided with an electrically heated central wire. The gaseous or liquid mixture containing the isotopes to be separated is placed in the tube, and heated by means of the wire. In such an apparatus two effects act to separate the isotopes. Thermal diffusion tends to concentrate the heavier isotopes in the cooler outer portions of the system, while the portions near the hot wire are enriched in the lighter isotopes. At the same time, thermal convection causes the hotter fluid near the hot wire to rise, while the cooler fluid in the outer portions of the system tends to fall. The overall result of these two effects causes the heavier isotopes to collect at the bottom of the tube and the lighter at the top, whereby both fractions may be withdrawn.

The electrolytic method of isotope separation is of importance not only because of its present day uses, but also because of its historical interest. It was by this method that G.N. Lewis and his co-workers at the University of California obtained practically pure deuterium. Since deuterium oxide had been shown to be present in ordinary water, the conclusion was drawn that water (or rather the dilute aqueous solution) from electrolytic cells used for the production of hydrogen and oxygen by continuous electrolysis of water, should be richer in the heavier isotope (deuterium having a mass number of 2, as against 1 for protium). Starting with such residual water from an electrolytic cell, it was found that by repeated electrolysis a small residue consisting almost entirely of deuterium oxide (D_2O) was obtained. This process is still used for the separation of pure hydrogen isotopes, as well as for other purposes.

The distillation method of isotope separation has also been the basis of important research contributions. In the work on the hydrogen isotopes, it preceded the electrolytic separation methods discussed above. Following the suggestion by Birge and Menzel, of the possible presence of deuterium in ordinary hydrogen to the extent of 1 part in about 4,500, Urey, Brickwedde and Murphy, in 1931, began their search for this isotope. By evaporating about 4,000 milliliters of liquid hydrogen to a volume of about 1 milliliter, Brickwedde obtained a residue that gave conclusive spectroscopic evidence of the presence of deuterium. The distillation method of separation has been responsible for many other research contributions. Among them may be mentioned separation of the isotopes of oxygen, of mercury, zinc, potassium and chlorine.

The chemical exchange methods of isotope separation are of value, not only for that purpose, but also because they provide a direct means for the study of chemical reactions. A well-known example of an isotopic chemical exchange is the heavy water equilibrium:

$$H_2 + D_2O \rightleftharpoons D_2 + H_2O$$

In this equation, the formula H_2 is used for the hydrogen isotope of mass number 1, which constitutes all but a small fraction of ordinary hydrogen; H_2O is the corresponding "light water"; D_2 is hydrogen of mass number 2 (deuterium) and D_2O is the corresponding heavy water. The double arrows indicate an equilibrium reaction, whereby under suitable conditions ordinary hydrogen reacts with heavy water to produce hydrogen

of mass number 2 and light water. If one were to start either with the two reactants on the left of the arrows, or with the two on the right, the system at equilibrium would have all four present. However, in this system at equilibrium the reverse reaction predominates, so that the ratio of ^2H to ^1H (that is, the ratio of D_2O to H_2O) in the liquid phase is about three times as great as in the gas. Because of this differential reactivity, this method is useful in the separation of the two hydrogen isotopes.

Another equilibrium system is useful in the separation of ^{14}N and ^{15}N. It is represented by the equation:

$$^{15}NH_3 + {}^{14}NH_4NO_3 \rightleftharpoons {}^{14}NH_3 + {}^{15}NH_4NO_3$$

This exchange reaction is conducted by the countercurrent flow of ammonia gas and ammonium nitrate solution (in water). The forward reaction is favored, resulting in the concentration of the ^{15}N in the ammonium nitrate in solution. The multistate conduct of this reaction that is necessary for effective operation is accomplished by arranging later stages in which the enriched ammonium nitrate solution is divided into two parts. One part is treated with caustic soda to displace the enriched NH_3 which is then used in a second stage of the process with the other part of the NH_4NO_3 solution. Three or more stages may thus be used, until the desired concentration of ^{15}N has been effected.

Another method of isotope separation is by ion mobility, a process based on the difference in mobility of the ions in an electrolytic solution, under the influence of an electric field.

The laser process for enrichment of uranium dates back to the early 1970s. In addition to early and continuing development of this process at the Lawrence Livermore National Laboratory, pioneering efforts were made by Exxon Nuclear Corporation and Avco Corporation in early 1971. These efforts concentrated on an atomic vapor laser isotope separation approach. The process now in a reasonably late stage of development at the Lawrence laboratory is known by the acronum AVLIS (for atomic vapor laser isotope separation). The process differs radically from all other uranium enrichment approaches. The AVLIS processes uses a bank of very finely tuned lasers to create an electrical charge on uranium-235 atoms while leaving nonfissle uranium-238 atoms unchanged. Fundamentally, the process involves the firing of light from high-powered copper-vapor lasers into a stream of uranium atoms. Through tuning of the lasers, electrons will be stripped from some of the atoms, thus leaving positively charged uranium-235 ions. These are drawn to negatively charged plates. The uncharged uranium-238 atoms pass through the process unaffected. Advantages claimed for the process include a smaller capital investment to build and less costly to operate and maintain. Also, the construction of laser plants can be smaller and modular as compared with the former huge diffusion, centrifuge, and magnetic plants.

Uses

The predominant civilian use of uranium is as a fuel for nuclear electricity generation. The thermal energy released by the fission of 1 g of ^{235}U is equivalent to that released by burning 2200 L of crude oil, or 2.7 tonnes of coal. The energy is also extracted from uranium without the environmental consequences associated with fossil fuels.

Nuclear power technology evolved in the late 1950s, and throughout the 1960s, as a parallel initiative on the part of many countries. The most influential country in this global development effort was the United States, which evolved the *light-water reactor* concepts known as the *pressurized-water reactor* (PWR) and the *boiling light-water reactor* (BWR), from successful naval propulsion designs. See also **Nuclear Power Technology**.

The priorities associated with naval applications were (1) high power density, (2) batch fueling, and (3) inherent response to steam demand ("load following"); these are also distinguishing characteristics of the light-water power reactors that followed. The uranium fuel for these designs, which describe most of the world's roughly 400 nuclear power plants, is artificially enriched in the fissionable isotope, ^{235}U (from 0.72% to 2–4%).

The only other civilian reactor design from the early development period which remains competitive in the open market today is the Canadian CANDU reactor. The CANDU approach is based on a natural uranium fuel cycle, with "heavy water" (deuterium oxide) as moderator. CANDU reactors account for less than 10% of worldwide installed plant, but in the 1990s were leaders in a very tight marketplace. Other power reactor designs, based on graphite moderators. gaseous coolants, and other variations, are not considered commercially viable today.

Another uranium isotope of interest to the nuclear power industry is ^{233}U, which is also fissionable. ^{233}U is created by neutron absorption in thorium, and since thorium is theoretically more abundant than uranium in the earth's crust, this option would become attractive for future nuclear power fuel cycles if the cost of uranium supply were to rise significantly. For example, mixed thorium-uranium fuel cycles have been developed for the CANDU reactor, but no incentive for implementation exists at this time. However, India has progressed to the point of pilot implementation of thorium fuel cycles in its heavy-water power reactors; the incentive in that country is the lack of indigenous uranium coupled with an abundance of indigenous thorium.

Uranium also has nonnuclear applications that are related to its high density (more that twice that of steel). In the form of *depleted uranium*, typically about 0.2% ^{235}U, it is also quite economical since this material is found in the wastestream of the uranium enrichment process. Depleted uranium and uranium alloys such as $UT_{0.75}$ are very useful as armor-piercing projectiles, and are also of potential value in flywheels and radiologic shielding. A corrosion-resistant material can be obtained by alloying uranium with 2–8 wt% molybdenum and, therefore, can be used in medical radiation equipment shielding and in aircraft trimming weights.

Health and Safety Factors

Exposure and Health Effects. Uranium is a general cellular poison, which can potentially affect any organ or tissue. Uranium and its compounds can be damaging due to chemical toxicity and by the injury caused by ionizing radiation. The chemical toxicity of uranium compounds depends on their solubility in biological media. Highly soluble and therefore highly transportable and toxic compounds include fluorides, chlorides, nitrates, and carbonates of uranium(VI); moderately transportable compounds include corresponding uranium(IV) compounds; slightly transportable compounds include oxides, hydrides, and carbides.

Uranium can enter the human body orally, by inhalation, and through the skin and mucous membranes. Uranium compounds, both soluble and insoluble, are absorbed most readily from the lungs. In the blood of exposed animals, uranium occurs in two forms in equilibrium with each other: as a nondiffusible complex with plasma proteins and as a diffusible bicarbonate complex.

Occupational Protection and Radiation Consideration. The main adverse factor during the mining and processing of uranium and uranium-containing minerals is airborne dust. Personal protection should be used. Finely divided uranium metal, some alloys, and uranium hydride are pyrophoric, therefore such materials should be handled in an inert atmosphere glovebox.

The toxicity of uranium caused by its radiation depends on the isotopes present. Natural uranium does not constitute an external radiation hazard since it emits mainly low energy α-radiation. It does, however present an internal radiation hazard if it enters the body by inhalation or ingestion. The concentration of 1 mg U/g biological tissue corresponds to an absorbed dose of 0.006 Sv per year. Large quantities of fissile isotopes, ^{233}U and ^{235}U, should be handled and stored appropriately to avoid a criticality hazard. Clear and relatively simple precautions, such as dividing quantities so that the minimum critical mass is avoided, following administrative controls, using neutron poisons, and avoiding critical configurations (or shapes), must be followed to prevent an extremely treacherous explosion.

URANUS. Seventh planet outward from the Sun, Uranus is estimated to have a diameter of about 4 times that of the Earth. To the naked eye, Uranus is barely visible as a sixth-magnitude star, but in a telescope of moderate aperture, the body appears as a disk with a bluish-green color. The latter is now known to be caused by methane in the outer layer of the planet. Methane absorbs in the red. Uranus, like Neptune, is intermediate between the terrestrial planets (Mercury, Venus, Earth, and Mars), which are made up mostly of metals and their oxides, and the Jovian planets that consist mostly of water, ammonia, and methane ices. See Fig. 1.

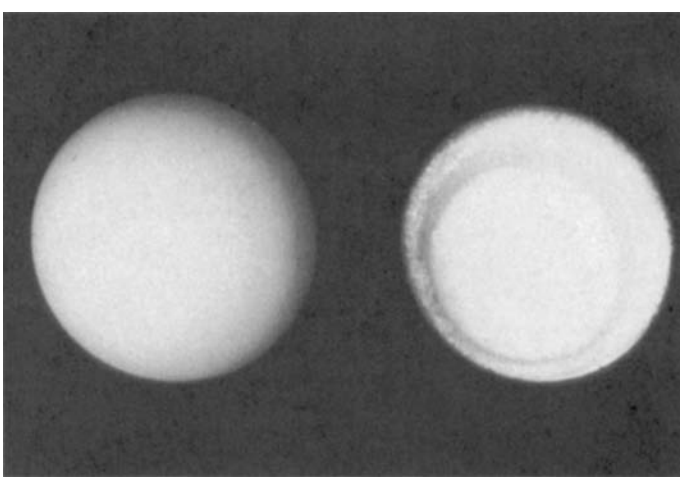

Fig. 1. Views of Uranus made from *Voyager* 2 on January 17, 1986, when the spacecraft was about 9.2 million kilometers (5.7 million miles) from the planet. (*Left*) Black-and-white rendition of the original grennish-blue image of Uranus. (*Right*) Black-and-white replica of the false-color image, indicating features of the planet not obtainable without use of color filters. (*Jet Propulsion Laboratory, Pasadena, California*.)

The most distinctive feature of Uranus is its unusual rotational position, tipped over on its axis. Some scientists suggest that early in the history of the planet, a collision with another, smaller body may have tilted the planet from a vertical or near-vertical axis to its present orientation. In the 84-year long orbit of Uranus, one pole is in sunlight for 42 years while the other is in darkness. For many years, the length of a Uranian day had been estimated between 16 and 24 hours. Data from *Voyager 2* (1986) confirmed a rotational period of 17.24 hours. However, features at different latitudes were found to circle at different rates, with periods ranging from 14 to 18 hours. The 17.24-hour period was determined by observing individual convective plumes of methane ice, using periodic radio emissions.

Uranus has 15 confirmed satellites, five of which are considered major. Ten additional satellites were discovered by *Voyager 2*, one during its approach to the planet in 1985, and the other nine moons found during the encounter. The orbital planes of these satellites, excepting Miranda, lie close to the plane of the planet's equator and hence are nearly perpendicular to the plane of the ecliptic. Further data on the satellites are given in this article.

Uranus in Perspective

Uranus was found accidentally by Herschel, in 1781, while sweeping the sky with a 7-inch reflecting telescope of his own manufacture. His discovery stirred up a tremendous amount of popular interest in astronomy, and history relates that during the weeks following the discovery, the streets in front of Herschel's house were crowded with people eager to get a view of the telescope and a glimpse of the discoverer. Herschel named the planet Georgium Sidus (star of the Georges) in honor of the then reigning king of England, George III, but the name was never adopted on the continent. Many Europeans called the planet Herschel, in honor of the discoverer, but the name Uranus, proposed by Bode, is the one that has survived.

Early ground observations showed that the planet is very much flattened at the poles, which provides evidence of a relatively high rotational speed. In 1912, Lowell and Slipher, using the Doppler principle, indicated a period of rotation of about 19.75 hours (now considered an inaccurate figure). Several years ago, Dunham concluded the presence of large amounts of methane in the planet's atmosphere. On March 10, 1977, Uranus occulted a 9th-magnitude star and scientists at four observatories (Kuiper Airborne Observatory, Perth Observatory, South African Astronomical Observatory, and Kalvalur, India observes) photoelectrically recorded the star as it disappeared behind the planet and reappeared again. They also detected a series of fluctuations in the star's light. At first believed to be caused by moonlets, the final conclusion drawn was that the fluctuations were caused by the presence of rings. At a somewhat later date, additional rings were found, bringing the total to nine. The latter number was confirmed by *Voyager 2* data. The finding of these rings erased Saturn's former distinction as being the only ringed planet in the solar system. Later, Neptune was also found to have rings.

During the late 1700s, when Herschel first noted a definite polar flattening of Uranus, he also suggested that there may be two rings at right angles to each other, and, in fact, after numerous observations, appeared somewhat convinced that a ring about the planet was the cause of a bulge at the equator. Herschel's ring observations were not taken seriously in the scientific community, which attributed the suspicion to inadequate instrumentation — that is, until the 1977 observations.

Voyager 2 Encounter with Uranus. On January 24, 1986, *Voyager 2*, which previously had visited Jupiter on March 5, 1979 and was in the vicinity of Saturn on August 25, 1981, encountered Uranus. It should be pointed out that *Voyager 2* later continued on to Neptune. The path of *Voyager 2* is sketched in the article on Neptune (Fig. 1). Details of *Voyager 2's* flight path past Uranus are given in Fig. 2. The Uranus encounter is quite remarkable, considering that the spacecraft was launched in 1977. Interesting statistics pertaining to the Uranian encounter include:

- One-way light time, Earth to Uranus, is 2 hours, 44 minutes, 50 seconds.
- Distance of *Voyager 2* from Earth at time of encounter, 2,965,400,000 km (1,842,610,000 mi).
- Closest distance of *Voyager 2* to Uranus cloudtops, 81,500 km (50,600 mi)
  - — to center of planet, 107,000 km (64,500 mi).
  - — to satellite Miranda, 29,000 km (18,000 mi).
  - — to satellite Ariel, 127,000 km (79,000 mi).
  - — to satellite Umbriel, 325,000 km (202,000 mi).
  - — to satellite Titania, 365,200 km (227,000 mi).
  - — to satellite Oberon, 470,600 km (300,000 mi).
- Velocity of *Voyager 2*, Geocentric: 36 km/second (80,200 mph)
  Heliocentric: 22 km/second (49,000 mph)

The increasing distance between the spacecraft and tracking stations on Earth, as compared with earlier planetary encounters, required innovative telecommunications techniques. For example, at Jupiter, data rates of 115,200 bits/second were possible; at Saturn, the rate dropped to 44,800

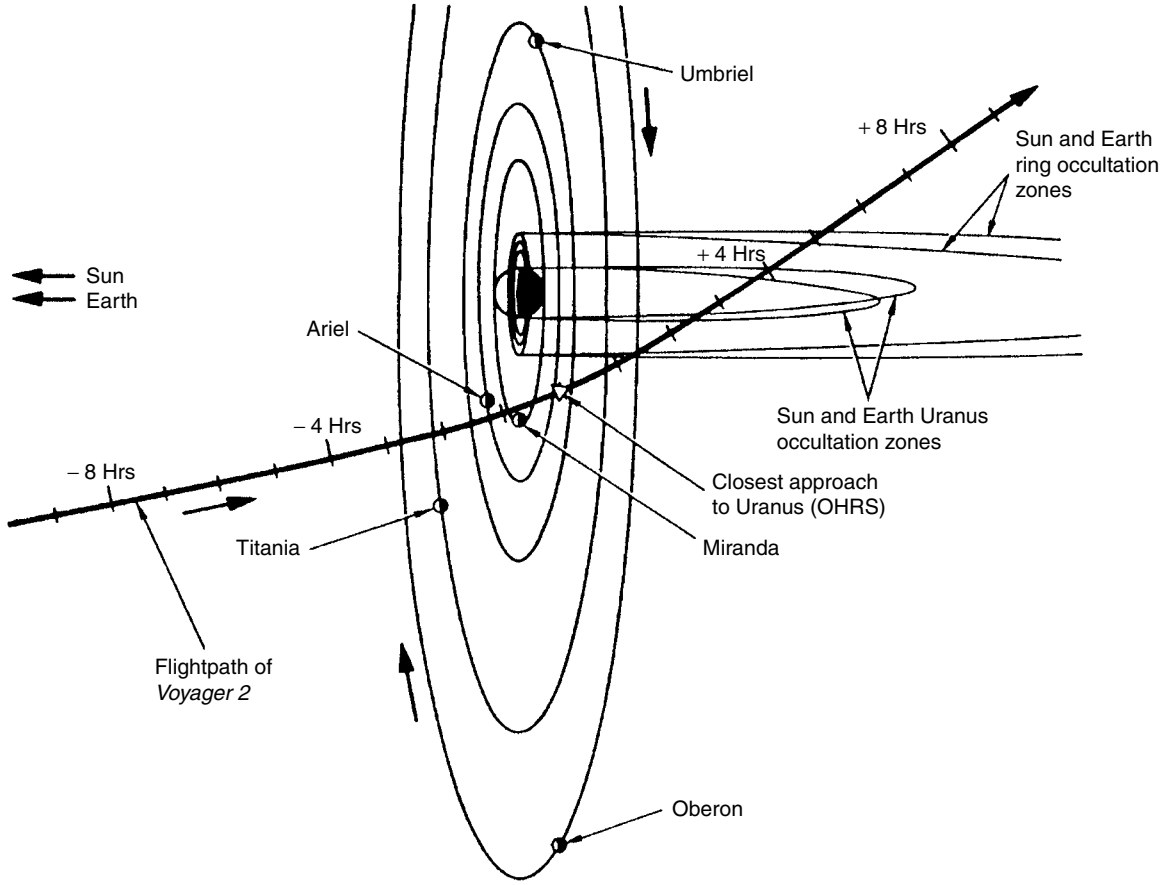

Fig. 2. The flight path of *Voyager 2* past Uranus (January 24, 1986). This view is vertical to plane of flight path. (*Jet Propulsion Laboratory, Pasadena, California.*)

bits/second. At Uranus, the spacecraft signal was considerably weaker, but the same signal, received at two or more antennas (different groupings of 34- and 64-meter antennas) at each of three deep space network complexes were combined in a technique known as *arraying*. This technique reinforced the strength of the signal received by electronically combining the same telemetry recorded at multiple stations. Thus, arraying made possible a data rate of 21,600 bits per second at Uranus. Without arraying, fewer than half the observations planned could have been performed and satisfactory data returned to Earth.

Image-motion compensation was required in connection with *Voyager 2*'s camera equipment. The high velocity of the spacecraft as well as the light levels in the Uranian system required this special instrumentation to prevent image smear and assure good image resolution. Much engineering of this type was performed on the spacecraft by ground-based personnel. It should be pointed out that with Uranus being twice as far from the sun as Saturn (the previous *Voyager 2* encounter), the light levels at Uranus were four times lower and the targets were inherently darker. It has been estimated that the sunlight received on the illuminated portions of Uranus do not exceed the light received by Earth during a total eclipse of the sun.

Voyager 2 investigations and instrumentation systems used to observe the Uranian system included: Imaging system; photopolarimetry; infrared interferometer spectroscopy; ultraviolet spectroscopy; radio science, magnetometry; plasma; low-energy charged particles; cosmic ray, planetary radio astronomy; and plasma waves.

Considerable information on the *Voyager 2* spacecraft is given in separate article on *Voyager* **Missions to Jupiter and Saturn**.

The Uranian Atmosphere

Several months after *Voyager 2*'s encounter with the Uranian system, scientists prepared preliminary summaries of the data received. The process of refining these data will continue for several years. Reporting on the planet's atmosphere, E.C. Stone (California Institute of Technology) and E.D. Miner (Jet Propulsion Laboratory) provided the following highlights:

Uranus apparently does not have a large internal heat source. Although the sun directly heats the polar regions, the atmosphere of Uranus resembles those of Jupiter and Saturn. See also **Jupiter**; and **Saturn**.

At a pressure of 600 mbar, temperatures at the planet's poles and the equator are close to the same. This indicates some means of dynamical redistribution of the solar energy received in the polar regions. (Slightly colder bands were found at about 25 °S and 40 °N, a condition contrasting with the findings for Jupiter and Saturn.)

At higher altitudes (pressure of 100 mbar), the temperature drops to a minimum of 52 ± 2 K. The temperature reaches a maximum in the extreme upper atmosphere, 750 K.

At an altitude of 2000 to 3500 km (1250 to 2185 mi) beyond the 100 mbar region, a multilayer ionosphere exists. It is estimated that this layer may extend to an altitude of 10,000 km (6,240 mi). A hydrogen corona extends from the planet outward beyond the rings. The corona has an estimated density of 100 cm^{-3} at the epsilon ring.

Helium presence in the atmosphere (range of 0.15 ± 0.05 mole fraction) is somewhat greater than that at Jupiter and Saturn, but consistent with solar helium abundance. The upper atmosphere also contains a trace of methane. (Methane absorbs in the red, thus giving the planet its blue-green color.)

Radio occultation information indicated a cloud deck of methane ice at pressures of 900 to 2300 mbar. These measurements indicated a methane mole fraction of about 2% deeper in the atmosphere. Although this value is some twenty times that of solar carbon abundance, it was not surprising because of the ice-rich material from which Uranus is presumed to have formed.

At about 50 °S, methane clouds are noted as band with a 700-km (440-mi) latitudinal scale. These clouds suggest discrete sources and little latitudinal diffusion. Convective plumes of methane ice having prograde velocity of from 40 to 160 m sec^{-1} relative to the interior of the planet were noted. These winds flow in a direction opposite to that of the thermal winds that may be expected from the observed latitudinal temperature gradient. Thus, the initial conclusion is that other dynamical processes must be present.

At higher altitudes, intense ultraviolet light was found emitting almost uniformly from the sunlit hemisphere, this emission resulting from *electroglow*.[1]

Auroral emissions were noted on the dark side of Uranus. These emissions are produced by the excitation of H_2 by approximately 10-keV electrons and form an auroral region 15° to 20° in diameter about the magnetic pole.

As noted by Ingersoll, in a three-layer model of Uranus, melted ices form a liquid "ocean" between a rocky core and a gaseous hydrogen-helium atmosphere. *Voyager 2* data, however, suggest a two-layer model in which the gases and ices are mixed in a dense atmosphere. Near the visible surface layers of the atmosphere of Uranus, ammonia, ammonium hydrosulfide (NH_4HS) and water are believed by some researchers to condense to form icy clouds. The condensation sequence would be determined by the condensation temperatures of the constituent materials. Uranus is sufficiently cold to permit methane to condense above the other clouds. Thus the diagram of Fig. 3 is suggested.

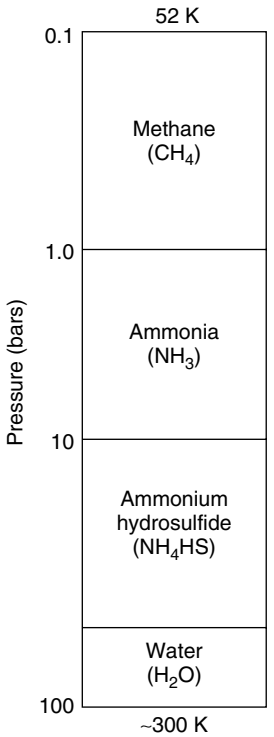

Fig. 3. Estimated variation of the atmosphere of Uranus versus pressure (bars). (*After Ingersoll.*)

The Uranian Ring System

The existence of rings around Uranus was not confirmed until 1977. The rings are dark, narrow, and dissimilar to the broad, bright rings of Saturn. Uranian rings, in some cases, are noncircular and vary in width. There are vast reaches of space between the rings. The rings of Uranus were discovered during a stellar occultation, in which the brightness of a star was being monitored as Uranus passed between the star and the Earth. The star involved in the 1977 observation was SAO 15867. The observers noted that as Uranus passed in front of the star, the starlight was blocked sharply during several short intervals as the planet passed through the path. The occultations (as observed by several researchers) on the one side of Uranus were matched by those on the other side of the planet. Thus, it was logical to conclude that a number of rings around the planet were the cause. Such observations continued. They involved well over 200 stellar occultations by Uranus and the presence of nine narrow rings was well established. In order of increasing distance from Uranus, the rings are identified as 6, 5, 4, alpha, beta, eta, gamma, delta, and epsilon. In addition to some noncircular paths taken by the rings, not all of the rings lie in the plane of the planet's equator. Widths vary from only 2 km (11/4 mi) to almost 100 km (621/2 mi). The largest and outermost ring is epsilon. Its width ranges from 20 to 96 km (121/2 to 60 mi). As noted by Cuzzi and Esposito, the variations in the width of epsilon are not random. The width increases in proportion to the distance of the ring material from Uranus; i.e., at its closest point to the planet, the epsilon ring is narrowest and nearly opaque; at its farthest point from the planet, it is 5 times wider and 5 times more transparent. Similar behavior is exhibited by the alpha and beta rings.

[1] Electroglow is a phenomenon first noted on Jupiter and Saturn. The emission consists of both molecular and atomic hydrogen emissions.

Two new rings were discovered by *Voyager 2*, identified as 1986UIR and 1986U2R. From ground-based occultation data, there may be other minor or partial rings (arcs), but these were not confirmed by *Voyager 2*.

From *Voyager* data analyses thus far (early 1988), the physical data pertaining to the Uranian rings are summarized in Table 1. See also Fig. 4.

Prior to the **Voyager 2** encounter, it was expected that as many as 18 small satellites (moons or shepherds) confining the narrow rings between them might be confirmed. However, only two such shepherd satellites (1986U7 and 1986U8) were found on either side of the epsilon ring. It is believed that shepherd satellites for the other Uranian rings may be too small (less than 14 km; 10 mi in diameter) and dark for observation by the *Voyager 2* instrumentation.

Voyager 2 data revealed quantities of microscopic dust widely spread throughout the rings. Cuzzi and Esposito observe that such dust is of special interest because tiny particles in and around planetary rings are rapidly removed as a result of erosion by micrometeroids and radiation-belt electrons. The existence of the dust implies that a local, long-lived source consisting of more massive particles must exist. However, relatively little

TABLE 1. RING SYSTEM OF URANUS

Feature	Distance from Uranus Center (10^2 KM)	Eccentricity (10^{-3})	Inclination (10^{-3} Degrees)	Width (km)†	Mean Visual Optical Depth†	Maximum Radio Optical Depth†
1986U2R	37–39.5	0?	0?	~2500	0.001–0.0001	
6 ring	41.85*	1.0*	63*	1–3	0.2–0.3	0.8–1.1
5 ring	42.24*	1.9*	52	2–3	0.5–0.6	1.2–2.3
4 ring	42.58*	1.1*	32*	2–3	0.3	1.2–1.5
Alpha	44.73*	0.8*	14*	7–12	0.3–0.4	1.0–2.5
Beta	45.67*	0.4*	5*	7–12	0.2	0.5–1.0
Eta	47.18*	(0)*	(2)*	0–2	0.1–0.4	0.7–1.1
Gamma	47.63*	(0)*	(11)*	1–4	1.3–2.3	3.8–6.9
Delta	48.31*	(0)*	4*	3–9	0.3–0.4	1.2–4
1986U1R	50.04	0?	0?	1–2	0.1	
Epsilon	51.16*	7.9*	(1)*	22–93	0.5–2.1	2.5–8

†Ring widths and optical depths vary greatly with ring longitude.
